peritoneum—*pericolitis*—give rise to a variety of symptoms. Most frequently the patient complains of discomfort in the lower part of the abdomen and, after a time, of attacks of colic, which gradually increase in severity and in frequency. The discomfort is generally most marked in the left iliac fossa. At the same time the constipation, from which the patient has generally suffered for many years, becomes more severe. Aperients aggravate the pain, which is relieved to some extent by the passage of flatus or fæces. Mucus may be present in the stools, and pus cells can occasionally be discovered on microscopical examination, but both obvious and occult blood are generally absent.

The temperature is sometimes slightly raised, and in acute exacerbations it may be very high and accompanied by severe constitutional symptoms with polymorphonuclear leucocytosis.

The bladder is often irritable, the patient having to pass urine with abnormal frequency; this is due to adhesions between the colon and the bladder. At a later stage cystitis occurs, and in very rare cases gas and fæces are finally passed *per urethram* owing to the development of a vesico-colic fistula, diverticulitis being a more common cause of this condition than cancer of the colon.

Tenderness is always most marked in the left iliac fossa and occasionally also immediately above the pubes. The rigidity of the abdominal wall over the tender area may make it difficult to palpate the colon, but in most cases it is possible to feel the irregularly thickened and extremely tender iliac colon. Digital examination of the rectum generally reveals nothing abnormal; the sigmoidoscope cannot often be passed beyond the pelvic-rectal flexure or an inch or two farther, the bowel at this point appearing to be abnormally fixed and its lumen narrowed. Very rarely the minute mouths of diverticula can be seen at the lower end of the affected portion of the pelvic colon.

An opaque meal shows that there is generally little or no delay in the passage through the bowel till the iliac colon is reached. The presence of diverticula can often be recognised when the opaque meal reaches the affected part, as some of it enters and remains in them after the rest has been evacuated. In all cases a barium enema should also be given, as whenever diverticula are present their number and localisation can be more accurately determined in this way than by any other method. They may be discovered directly the enema is given, but more often only after it has been evacuated, a double row of small rounded shadows representing the diverticula being then seen in the position of the iliac and pelvic colon. They often remain visible for several days.

Diagnosis.—Discomfort and colicky pain in the lower part of the abdomen in middle-aged and elderly patients, especially if associated with increasing constipation, should raise the suspicion of diverticulitis as well as of a growth of the colon. If the pain is most marked in the left iliac fossa, if it is associated with bladder irritability, and if leucocytosis and pyrexia are present, the former is the more probable diagnosis. A tender tumour in the left iliac fossa, associated with muscular rigidity, is much more frequently due to diverticulitis than to cancer. An X-ray examination after an opaque meal and an opaque enema generally settles the diagnosis. It is necessary to add that cancer occasionally develops in a colon affected with diverticulosis

or diverticulitis. The only sign which might suggest such a possibility would be the appearance of red blood and obvious pus in the stools in a patient in whom an X-ray examination has shown diverticula to be present.

Treatment.—The accidental discovery of diverticulosis in the course of a routine X-ray examination indicates the necessity for permanently keeping the stools soft by means of large doses of paraffin and the avoidance of pips and skins of fruit and of pickles, salads, and cooked green vegetables except as purées. No other aperient should be used. In very mild cases of diverticulitis the same treatment is effective. In more severe cases with pyrexia and abdominal rigidity the patient should be kept in bed till all signs of active inflammation have disappeared. The diet already mentioned should be given together with an ounce of paraffin three times a day. Belladonna may be required to control the secondary spasm. Six ounces of paraffin should be injected into the rectum every evening and retained during the night. If the bowels do not act satisfactorily in the morning, water should be injected into the rectum very slowly and under very low pressure, in quantity insufficient to cause pain. By this means the accumulation of faeces generally present is gradually evacuated, and the pain and inflammation subside. Contrary to what was formerly thought, very few cases require operation. Only if the condition is complicated by the development of an abscess, signs of spreading peritonitis, definite obstruction, or increasing cystitis suggesting that a vesico-colic fistula is about to form is an immediate operation indicated. In addition to this, if the treatment described does not lead to the subsidence of inflammation and obstructive symptoms, an operation is required. It is sometimes possible to excise or short-circuit the whole of the affected portion of the bowel, but more often a colostomy has to be performed.

INTUSSUSCEPTION

ACUTE INTUSSUSCEPTION : see Acute Intestinal Obstruction (p. 602)

CHRONIC INTUSSUSCEPTION

Ætiology.—Chronic intussusception is a rare disease occurring only in adults. Twenty per cent. are secondary to innocent tumours, most of which project as polypi into the lumen of the bowel, 15 per cent. are secondary to malignant tumours, and 6 per cent. to dysenteric, tuberculous and other ulcers. A case of mine was associated with chronic uræmia in a man suffering from nephritis due to lead poisoning.

Symptoms.—A chronic intussusception may last for a month, a year or longer before it terminates in an attack of acute obstruction or of general peritonitis from perforation. It may finally reach the anus, from which it may project for some inches without preventing the passage of faeces. The onset is generally insidious; occasionally it is acute, but the severity of the symptoms generally diminishes and the subsequent progress of the case is chronic. Only about one-half of the cases are accompanied by constipation, diarrhoea being present in the majority of the others. The most

prominent symptom is colic, occurring in attacks which steadily increase in frequency and severity, and which may be brought on by taking food or by aperients; constipation is present during the attack, and blood and mucus may be passed at frequent intervals in entero-colic and colic, but not in enteric, intussusceptions. A palpable tumour is present in half the cases; it becomes harder and longer during an attack of colic, and appears to recede in the intervals. Severe attacks are accompanied by vomiting, especially in the enteric form. Visible peristalsis and dilatation often occur in the intestines above the intussusception. An opaque enema, given for suspected chronic obstruction, may reveal the presence of an intussusception by the typical appearance it produces.

Treatment.—The treatment is always surgical.

ACHALASIA OF THE PELVI-RECTAL AND ANAL SPHINCTERS (HIRSCHSPRUNG'S DISEASE IN CHILDREN AND MEGACOLON IN ADULTS)

Ætiology and Pathology.—Hirschsprung's disease is a rare condition occurring in young children, in which the colon becomes greatly dilated and hypertrophied although no organic obstruction is present. The disease is better named after the Danish physician who in 1886 first satisfactorily described it, or, in view of its pathogenesis, achalasia of the pelvi-rectal and anal sphincters, than by the alternative designation of "congenital idiopathic dilatation of the colon."

Megacolon is a similar condition occurring in adults; it is either the sequel of Hirschsprung's disease which has remained latent, or it may develop only in later life.

Both Hirschsprung's disease and megacolon in adults occur about eight times more frequently in males than in females.

In children the lower limit of the dilatation is situated with equal frequency at the junction of the pelvic colon with the rectum—the pelvi-rectal sphincter—and at the anal sphincter, but in adults it is always at the latter. From these points upwards there is a rapid enlargement, the maximum diameter being generally 3 or 4 inches higher. In about half of the cases, the enlargement is confined to the pelvic colon or rectum and pelvic colon, which may be so dilated that it reaches the left dome of the diaphragm or even finds its way above the liver under the right dome. In other cases, varying lengths of intestine are dilated, but the dilatation is always greatest in the pelvic colon, and diminishes as it is traced towards the cæcum, the small intestine being always spared. The muscular coat of the dilated intestine is greatly hypertrophied. The mucous membrane is thickened from chronic inflammation and is often ulcerated. The hypertrophy can only be a result of the increased work which the intestine has to do in order to overcome some obstruction, and peristalsis occurring in the hypertrophied colon could not fail to evacuate it, if there were no obstruction to the passage of its contents into the undilated rectum in the pelvi-rectal cases or through the anal canal in the anal cases. The obstruction in the two varieties is probably due to absence of the relaxation of the circular muscle fibres respectively at the pelvi-rectal sphincter and anal sphincter,

which should occur during defæcation; it is analogous to achalasia of the cardia, which is the cause of so-called idiopathic dilatation and hypertrophy of the œsophagus. It probably depends, like the latter, upon organic changes in Auerbach's plexus in the region of the sphincter; these are probably secondary to inflammation of the mucous membrane, which disappears completely but leaves behind permanent degeneration of the nerve tissue. Such degenerative changes have been observed in a case of Hirschsprung's disease by Munro Cameron. In the pelvi-rectal variety the primary cause of obstruction must be aggravated at an early stage by obstruction of a different sort: the pelvic colon, when once dilated, produces a kink by overhanging the undilated rectum below.

Symptoms.—In Hirschsprung's disease there is almost always a history of constipation dating either from birth or from the first few months of life. At an early stage the bowels cease to act spontaneously, and drugs gradually lose their effect, until an evacuation can only be procured by means of enemata. The stools are generally soft or even semi-fluid, but in early cases scybala may be passed. Soon after the onset of the constipation, the abdomen, which is generally normal at birth, begins to increase in size owing to distension of the colon with gas and fæces, the size varying from time to time according to the frequency with which the bowels are opened. By examining the patient with the X-rays after a barium meal it is possible to recognise where the stasis begins, and if a barium enema is also given the exact extent of the dilatation can be discovered. In pelvi-rectal achalasia the rectum is empty but sometimes ballooned. In anal achalasia it is greatly dilated and filled with fæces, which are generally quite soft.

Sooner or later, an attack of complete obstruction may occur, no fæces being passed for even two or three months, though momentary relief sometimes follows the evacuation of small quantities of gas. The abdomen becomes enormously distended and tense; it is often painful, and the pressure on the diaphragm may cause severe dyspnœa, cyanosis and palpitation. The outline of the distended colon is seen, and peristalsis is generally visible. Albuminuria and œdema of the legs, penis and scrotum are sometimes observed. Vomiting may now occur, and the patient becomes exceedingly emaciated; death finally results from exhaustion, from general peritonitis secondary to perforation of a stercoral ulcer, or from some intercurrent disease, especially of the lungs. An attack of complete obstruction is sometimes relieved by enemata or by the passage of a rectal tube beyond the pelvi-rectal flexure; this permits the escape of gas and fæces under high pressure, but similar attacks are very apt to recur.

Death may occur in the first year of life, but more frequently between the ages of 3 and 8. In a few cases adult life is reached. When a megacolon is discovered in adults it is generally impossible to decide whether it dates from early childhood or whether it is a result of anal achalasia developing at a later date. It may give rise to no symptoms beyond more or less severe constipation. The abdomen is often not obviously distended, though the diaphragm is pushed up by the dilated bowel. Acute attacks of violent pain due to temporary obstruction may occur, but they generally end spontaneously after a few hours. An opaque meal shows the large intestine as far as the descending or iliac colon; it is then lost in the enormous pelvic colon. In order to define the position of the latter an opaque enema of six

or eight pints is required. A large gas-containing loop is often visible under the right dome of the diaphragm. The sigmoidoscope can be passed its full length without meeting the slightest resistance, and the walls of the enormous cavity formed by the pelvic colon can then be seen.

Treatment.—(a) *Anal achalasia*.—All cases of anal achalasia can be kept in a satisfactory state of health by non-surgical means. If the constipation is severe, a rectal tube should be inserted into the dilated rectum every day and the colon washed out. It may be necessary as a preliminary measure to empty the bowel digitally under an anæsthetic. Obviously neither a short-circuit operation nor colectomy could help, as the obstruction is at the anus. Even the results of colostomy are very unsatisfactory. On the other hand, daily lavage, if carried out with sufficient thoroughness, gives excellent results, and it is often possible after a time to wash the bowel out once a week or even less frequently instead of every day.

(b) *Pelvi-rectal achalasia*.—An attempt should be made to pass a rubber tube beyond the kink at the pelvi-rectal flexure, so that flatus can escape and the dilated bowel can be washed out. It is occasionally possible to do this by simply putting the patient into the knee-elbow position. As a rule, however, it is necessary to manipulate a sigmoidoscope beyond the kink into the pelvic colon, the patient being in the knee-elbow position; a tube is then passed through the sigmoidoscope, which is withdrawn, leaving the tube in position. In some cases recovery has followed dilating the pelvi-rectal sphincter with a distensible rubber bag. Very rarely operative treatment is required. It may be possible to make an anastomosis between the undistended rectum and the lower end of the dilated part of the colon. More frequently, however, the whole of the dilated colon has to be excised, but colectomy has a very high mortality in these cases.

ARTHUR F. HURST.

ACUTE INTESTINAL OBSTRUCTION

Acute intestinal obstruction is a condition in which the passage of the contents along the intestinal canal is more or less suddenly obstructed either completely or in greater part. Only mechanical causes of intestinal obstruction will be dealt with in this place, conditions of paralysis or spasm causing obstruction being considered elsewhere.

Ætiology.—The causes of acute intestinal obstruction are numerous, and may best be considered under (1) causes within the lumen of the bowel, (2) causes in the wall of the bowel, and (3) causes outside the bowel, while there are two additional conditions—intussusception and volvulus—which do not come under any of these categories.

1. Causes within the lumen of the bowel giving rise to acute obstruction are gall-stones, fæcal accumulations, and, very rarely, true foreign bodies.

Large gall-stones enter the intestine through a fistula between the gall-bladder and duodenum or, more rarely, some other part of the intestinal canal. Gall-stones are generally passed spontaneously; when this does not occur the site of impaction is nearly always the lower part of the ileum near the ileo-cæcal sphincter.

Fæcal accumulation is a common cause of an acute termination to a case

of chronic obstruction, but even without any previous narrowing it may cause obstruction. In such case the faecal mass may be enormous in size and of a stony hardness; it leads more frequently to the pseudo-diarrhoea of partial obstruction than to complete obstruction.

2. Causes in the wall of the bowel give rise in most cases to chronic rather than acute obstruction; the commonest of such narrowings are those due to cancer. These conditions are discussed elsewhere, and it is only their liability to an acute termination which needs consideration here. Such a final catastrophe may result from the impaction of faeces, a distended coil of bowel may become twisted, or acute paralysis of the intestinal wall with or without peritonitis may develop. Congenital stricture is a rare cause of acute intestinal obstruction in early infancy; apart from stricture of the rectum, the commonest site is in the duodenum, just above the entrance of the bile-duct and in connection with Meckel's diverticulum.

3. The most common cause outside the intestine is strangulation of a portion of intestine by congenital or adventitious bands, diverticula or peritoneal adhesions. Such bands may result from old tuberculous or inflammatory disease, or may be a sequel to a laparotomy, if blood is left in the peritoneum or the peritoneum is much damaged. They may be produced by the adherence of normal structures, such as the omentum, Fallopian tube or appendix to other abdominal organs, or may result from the presence of a persistent Meckel's diverticulum. The latter may remain attached to the umbilicus, or its free end may become adherent. Such bands may obstruct by bridging across a portion of bowel, or a knuckle of bowel may become twisted round or under them, or, if the band is not long, mere kinking at its point of attachment may be sufficient to obstruct the lumen. Internal hernias may give rise to strangulation and intestinal obstruction; their commonest sites are congenital or acquired slits or tears in the mesentery or omentum, one or other of the normal peritoneal fossae, or, more rarely, the foramen of Winslow or congenital or acquired apertures in the diaphragm. The peritoneal fossae into which such internal hernias may pass are situated in the neighbourhood of the duodeno-jejunal flexure, in the peri-caecal region, and in the root of the pelvic mesocolon.

4. *Intussusception*.—By intussusception is meant the passage of one segment of intestine into another immediately below. When this occurs a tumour is formed consisting of three layers, the outermost or intussusciens being the portion of bowel into which invagination is occurring, and the inner two constituting the intussusceptum, which therefore consists of an entering layer and a returning layer. Between these latter is the strangled mesentery, interference with the vessels of which speedily occurs and induces changes in the intussusceptum. The apex is the distal part of the intussusception, and the neck the narrow part where the returning layer turns to become the sheath or intussusciens.

The chief cause of intussusception is undue enlargement of the intestinal lymphatic tissue producing irregular muscular action, aided no doubt by an unusually long mesentery, and by an atonic condition of the ileo-caecal sphincter. All these three factors, particularly the first, are most common in early childhood, and intussusception is consequently rare at other ages; 70 per cent. of cases occur in infants under a year old. In adults an intestinal polypus or carcinoma is often the starting-point of the invagination, which

generally differs from that occurring in infants by being chronic instead of acute.

Various forms of intussusception occur, of which the ileo-cæcal variety, with the ileo-cæcal valve as its apex, constitutes about 70 per cent. Enteric, colic, ileo-colic and multiple intussusceptions are less frequent. An intussusception always increases at the expense of the ensheathing layer, its apex remaining constant.

5. *Volvulus* is a condition in which a coil of intestine becomes twisted on itself around its mesenteric axis, leading to interference with its circulation and with the passage of its contents. It occurs most frequently in the pelvic colon and the ileum, but may affect the cæcum or any part of the intestine with a mesentery. It usually occurs late in life, is commonest in males, and depends partly upon an abnormally shaped mesentery and partly upon loading of the loop from chronic constipation. The dilated coils above a chronic obstruction are especially liable to become twisted and so bring about an acute termination to the case.

Pathology.—In acute intestinal obstructions the conditions found fall mainly into two groups depending on (1) the occurrence of obstruction of intestine with a previously normal lumen, and (2) acute obstruction terminating a case of gradually increasing chronic obstruction.

1. In most cases in this group a portion of intestine is strangulated in addition to the obstruction to the lumen of the bowel, and consequently the condition of the intestine must be considered in three regions—namely, above the obstruction, below it, and in the strangulated coil itself. An exception occurs in the acute obstruction produced by an impacted foreign body, where, of course, there is no strangulation.

(a) The intestine above an acute obstruction is usually greatly distended, its walls are at first pale and thin, and later oedematous and purple in colour, and the extent of these changes rapidly increases upwards as the obstruction persists. The distended coils are full of fluid (partly the normal dammed-back secretion, partly an exudation of serum), and as the case progresses bacteria escape through the distended and paralytic coils, and lead to peritonitis. These changes are far more marked in small intestine obstruction than when the colon is affected.

(b) Below the obstruction the coils are, as a rule, empty, contracted and pale.

(c) As a result of circulatory interference, the strangulated coil itself becomes distended with effused blood and gas, the latter mainly CO_2 , which cannot be absorbed. It is purple in colour, tense, oedematous and paralysed, and it exudes bloodstained fluid both into its lumen and into the surrounding peritoneum. If the strangulation is sufficiently severe to obstruct arteries as well as veins the coil becomes gangrenous in less than an hour. Such a coil is grey and loses its peritoneal sheen; it is flaccid and exudes free gas and stinking fluid into the peritoneum. This condition is, of course, irrecoverable, but in less complete strangulation the intestinal wall quickly returns to normal when the strangulation is released. A strangulated coil soon loses power to prevent the passage of bacteria, and if left alone its vessels inevitably become thrombosed, and its walls become gangrenous and ultimately perforate. The contents of an obstructed loop are profoundly toxic, the toxicity being greater the higher in the course of the alimentary canal the obstruction is situated.

2. When acute supervenes on chronic obstruction, the bowel has already had time to accommodate itself in some degree to the presence of narrowing of its lumen. The final blockage of the passage is most frequently due to impaction of faeces in the narrowed part, or kinking, adhesion, volvulus or acute paralysis of the intestine above it. In such cases the already existing hypertrophy above the obstruction gives place to rapidly increasing distension, and as a result the intestinal circulation is interfered with, and gas, being no longer efficiently absorbed, collects within the bowel. The enteritis and ulceration usually present in some degree above a chronic obstruction rapidly increase, and perforation and consequent peritonitis speedily follow.

Symptoms.—The symptoms of acute intestinal obstruction vary to a certain extent with the particular cause of the condition, but some of them are present in all cases. Of the general symptoms, pain, vomiting, constipation and collapse are the most important.

Pain is an early symptom and is very severe, in many cases a patient in perfect health being suddenly seized with an acute abdominal pain which doubles him up and never remits. At first the pain is stabbing in nature, but later he complains of exacerbations which are colicky in character, and which occasionally serve to localise the obstruction. If the case is allowed to progress until peritonitis supervenes, the continuous pain and tenderness associated with that condition are present in addition.

Vomiting, preceded by nausea and severe retching, usually comes on about an hour after the pain, but it may be delayed for 8 or 10 hours. Once it has begun it continues with increasing frequency, and from the second to the fourth day it becomes faecal in character. The higher the site of the obstruction is situated in the bowel, the greater the vomiting and the sooner it becomes faecal. Faecal vomiting is not due to antiperistalsis, but is caused by the stagnant and excessive secretions of the portions of bowel above the obstruction, gradually extending upward until they overflow into the stomach and cause vomiting. The faecal character is accounted for by the remarkable speed with which *Bacillus coli* and other organisms multiply in the stagnant contents.

Collapse is early and severe. The patient is prostrated, anxious, and restless, the pulse is rapid, small and thready, the temperature subnormal, and the extremities cold and clammy. The collapse is partly reflex from stimulation of the vagal and splanchnic nerve endings in the abdomen, and is partly due to loss of fluid from sweating and excessive intestinal secretion. A very important part is also played by the toxic intestinal contents; the higher in the bowel the obstruction is situated the greater is the toxicity of the stagnating contents.

Constipation is as a rule absolute, although the bowel below the obstruction may empty itself shortly after the onset of the pain and vomiting. Neither faeces nor flatus are passed, and enemata after washing away any faecal material present in the bowel below are either retained or return slowly without force.

In addition to these cardinal symptoms the patient presents certain other important signs. The tongue is dry and the teeth are covered with sordes. The abdomen at first is not tender to touch, and sometimes pressure may relieve the pain. It is often not distended, though in some conditions,

such as *volvulus*, the distension may be extreme. If acute obstruction supervenes on chronic obstruction visible peristalsis may be present, and the coils can be felt to harden under the hand. Occasionally a tumour is felt in the abdomen, especially in intussusception, where a sausage-shaped mass can frequently be felt. On auscultation intestinal sounds are present in increased intensity. If the case goes on until peritonitis supervenes the symptoms of that condition develop and consequently the abdominal picture changes. In acute intestinal obstruction the urine is scanty and highly coloured, and when the obstruction is low in the bowel it contains a great excess of indican. The viscosity of the blood is increased from loss of fluid; this probably accounts for the frequent cramp-like pains in the limbs.

Diagnosis.—The diagnosis of acute intestinal obstruction is usually easy, but the further differentiation of the site and nature of the obstruction, though sometimes fairly simple, is often impossible before operation. The history is of importance in deciding whether the acute symptoms have supervened on those of chronic obstruction, in which case similar but less severe attacks which were relieved by enemata or purgatives may have occurred. A previous history pointing to gall-bladder trouble, particularly if the onset of obstruction is somewhat less acute than usual, suggests gall-stone impaction.

Inquiry should be made for evidence of abdominal attacks suggesting appendicitis, salpingitis, or other conditions, which might produce bands.

The presence in an infant of a sausage-shaped tumour, which can be felt to harden and is situated usually in the upper abdomen, with tenesmus and the passage of blood and slime, acute attacks of colic causing the child to scream and to draw up its legs, with occasional vomiting, forms a characteristic picture of intussusception, and enables a confident diagnosis to be made in many cases. In doubtful cases, examination under anaesthesia may be required, and rectal examination may enable the intussusception to be felt.

In *volvulus* the onset is acute, but collapse may be absent. Vomiting is not frequent at first, but the characteristic feature is the rapid onset and extreme degree of distension. This distension may at first be localised and indicate the seat of the *volvulus*, but it soon involves the whole abdomen and may cause severe cardiac and respiratory embarrassment.

Distension implies interference with the blood supply and consequent deficient absorption of gas from the bowel; it is thus a valuable indication as to whether strangulation has taken place as well as intestinal obstruction.

The conditions from which acute intestinal obstruction has to be differentiated are numerous. The most important is *hernia*, and a careful examination of the hernial apertures should always be made. In some cases of small femoral hernias in fat persons it is very easy to overlook the condition, and in the rare obturator hernia diagnosis is frequently only possible on opening the abdomen. Faecal impaction is another important condition to be considered, particularly in view of the grave results of laparotomy mistakenly undertaken for its relief. The history of chronic constipation and the presence of hard or putty-like masses in the rectum or pelvic colon should prevent errors.

Peritonitis is often a source of difficulty. The extreme tenderness and rigidity, the absence of faecal vomiting, the partial nature of the constipation at first, as well as the temperature, history, and silence of the abdomen on

auscultation are distinguishing features. Difficulty may arise from conditions causing acute stimulation of the sympathetic nerve, such as torsion of the testicle, ovary, or omentum, or the passage of a renal or biliary calculus. Careful inquiry of the history, the characteristic distribution of pain in the colics, examination of the scrotum and vagina and of the urine will usually lead to a correct diagnosis. Further, in these conditions enemata generally result in passing of flatus, and the course of the disease does not follow the usual sequence of cases of acute intestinal obstruction. In acute pancreatitis the pain is localised in the epigastrium, while the constipation is usually not absolute.

Lead colic can be distinguished by the blue line on the gums, the history, the blood picture, the absence of fæculent vomiting, and the result of enemata; while a routine neurological examination will distinguish tabetic crises.

Rare conditions which may lead to mistakes are embolus or thrombosis of the superior mesenteric vessels. In embolus some cardiac lesion is usually present, and in thrombosis there may be evidence of cirrhosis, gall-bladder disease or thrombosis of other veins, while hæmatemesis and melæna are common in both conditions.

Prognosis.—Spontaneous cure is remotely possible in all cases of intestinal obstruction, but in the majority of cases, if operation is not undertaken, death occurs at varying intervals, the average being after 6 days. Once the obstruction has been relieved by operation recurrence is uncommon, excepting perhaps in cases due to adhesions following operation. Even when operation is undertaken acute intestinal obstruction has a grave outlook, depending partly on the length of time elapsing before operation and partly on the nature of the lesion present. Volvulus is the most fatal form of obstruction, closely followed by gall-stone impaction. Other conditions materially affecting the prognosis are the age and general condition of the patient, and the presence of toxæmia, septicæmia, peritonitis, or complicating conditions elsewhere.

Treatment.—Excluding cases of fæcal impaction the treatment of all cases of acute intestinal obstruction is immediate operation. The object of the surgeon is to locate the seat of the obstruction, and to relieve it as quickly as possible with the minimum of handling and exposure of the abdominal contents. When the abdomen is opened a collapsed portion of gut is sought, as it helps to localise the seat of obstruction. When found, the obstruction must be relieved in the simplest possible manner, by reducing a hernia, dividing a band, reduction of an intussusception by manipulation, removing a gall-stone, etc. If, however, the obstruction cannot be relieved, or if the bowel is too severely damaged to return to the abdomen, it is wise simply to establish drainage above the obstruction and to wait till the acute period is passed before undertaking further measures. In cases with much distension, where the obstruction is obviously in the colon, and where an exploration would entail considerable handling, the proper treatment is undoubtedly to perform a blind cæcostomy and to delay further procedures until the distension has been relieved. Apart from operation, saline solution should be given intravenously, or subcutaneously to combat the fluid loss, and opium may be given to relieve pain once the diagnosis is established and operation agreed to.

APPENDICITIS

Ætiology.—The two sexes are affected equally. No age is exempt, but whereas acute appendicitis is more common in children, chronic appendicitis is more common in adults.

The appendix may become infected either by organisms spreading from the lumen of the cæcum or conveyed by the blood. In the former case, the original infection may presumably come from infected food, but septic foci in connection with the teeth, tonsils and naso-pharynx are undoubtedly of more importance. The latter are also the chief sources of hæmatogenous infection.

The commonest organism is the *Bacillus coli communis*; next in order of frequency come streptococci and staphylococci. The proteus, tubercle and actinomycosis organisms are rare. Congenital or acquired abnormalities are present in a considerable proportion of cases. In the former the appendix is not fully descended, is of the infantile variety, or is twisted on itself. In the latter, there are adhesions or kinks caused by previous inflammation either of the appendix itself or of neighbouring organs; and in many cases the bands resulting from chronic intestinal stasis lead to kinking of the appendix. Obstruction to its lumen from any of these causes produces stagnation of its contents, and provides the necessary conditions for bacterial invasion. Foreign bodies are another cause, but they occur less frequently than might be expected. Intestinal worms, pins, and fruit pips and stones have all been met with, but by far the commonest foreign body is the so-called "appendicular concretion," formed of inspissated faecal material moulded into shape by the appendix itself.

ACUTE APPENDICITIS

Pathology.—In catarrhal appendicitis the mucosa only is affected, but in the commoner diffuse type all the coats are involved, the organ being hyperæmic, rigid, tense, and swollen, and the mucous membrane being frequently ulcerated. Later the lumen of the appendix becomes filled with pus, and if there is obstruction, empyema of the organ results. Later still, local or general gangrene occurs, the most frequent sites being the tip or the base. Perforation is very liable to take place at any of these stages, leading either to a localised appendicular abscess or to generalised peritonitis. The chief factor in determining which of these two complications will occur is the virulence of the organism, since it requires time for the reaction of the peritoneum to come into play sufficiently to localise the results of perforation to the immediate neighbourhood. In milder cases the inflammation tends to resolve, and the appendix may return to an apparently normal condition, but if the attack has been at all acute, either adhesions or narrowing of the lumen generally remain, leaving it far more liable to further attacks of inflammation. If perforation and abscess formation occur and operation is not undertaken, spreading peritonitis results. Suppurative pylephlebitis may result from spread of infection along the mesenteric veins either with or without perforation of the appendix.

Symptoms.—In nearly all cases the following symptoms are present,

though they may vary in degree—(1) sudden abdominal pain, (2) pyrexia, (3) increased pulse rate, (4) gastro-intestinal symptoms, (5) local signs.

1. *Sudden abdominal pain*.—The onset is usually sudden, the patient being seized with severe abdominal pain, often severe enough to produce collapse and vomiting, and often referred at first to the region of the umbilicus, particularly in children. Later the pain becomes more or less localised to the right iliac fossa, and may be of considerable intensity. In very severe cases, especially in children, and where early gangrene occurs, the pain may be comparatively slight after the initial onset, and in other cases the affection may progress to abscess formation with relatively little pain. Such cases, are, however, the exception, and the pain is usually a prominent symptom.

2. *Pyrexia* is almost always present at some time during the attack, though its height is no measure of the severity of the lesion in the appendix. There is sometimes a rigor at the onset, and the temperature in an average case varies from 100° to 102° , rarely higher. A rise only to 99° or 100° is not uncommon, but is important, as very few cases occur in which there has not been some pyrexia at some period of the attack. When a localised abscess has formed, and in very severe cases with perforation and generalised peritonitis, the temperature may be normal or subnormal throughout.

3. The *pulse rate* is usually increased and tends to continue to increase as the disease progresses.

4. *Gastro-intestinal disturbances* are almost invariably present. The tongue is furred and rapidly becomes dry. Vomiting is frequent. There is usually vomiting at the onset of the attack, and though this persists in the severe cases with peritonitis, it may pass off, but nausea usually continues. Constipation is the rule, and in the majority of cases is absolute. Diarrhoea is, however, by no means uncommon, indicating usually a pelvic position of the appendix, in which the inflammation spreads to and irritates the rectum. If the process is allowed to progress, complete constipation resulting from peritonitis and consequent paralysis of intestinal movements ensues. Even before this stage has been reached, auscultation over the region of the cæcum often reveals a complete absence of the usual intestinal sounds, which may be of considerable help in diagnosis.

5. *Local signs*.—There is usually no distension of the abdomen at the onset of the attack, but on inspection it will be seen that the lower abdomen moves less freely than the upper on respiration, and the right side less than the left. There is frequently hyperæsthesia of the skin in the right iliac fossa, and occasionally some oedema can be discovered by loosely picking up the skin and subcutaneous tissues between the fingers and comparing with the other side. There is great rigidity of the right rectus muscle, and this is probably the most important single sign; the rigidity is often too great to allow of any proper deep palpation. In addition to the rigidity there is great tenderness and pain on palpation, which has its maximum at MacBurney's point, situated at the junction of the outer and middle thirds of a line drawn from the anterior superior iliac spine to the umbilicus. In children the maximum pain and tenderness are often in the region of the umbilicus. In some cases an ill-defined mass can be felt in the right iliac fossa, and the longer the history, the more likely is such a mass to be present. It is constituted mainly of adherent coils of intestine and omentum surround-

ing the inflamed or perforated appendix. Rectal examination is often of value, and in many cases a tender mass can be felt on the right side of the rectum, when none can be made out from above. Considerable irritability of the bladder may be present, especially with a pelvic appendix, and the urine, which is scanty, frequently contains albumin.

A blood count is occasionally of value for purposes of differential diagnosis, and usually shows a leucocytosis of from 15,000 to 20,000.

In many of the worst cases, some or all of these signs and symptoms may be absent, but with a careful examination and a clear history it is usually possible to reach a correct diagnosis.

In some cases an abnormally situated appendix gives rise to characteristic symptoms. With a retro-caecal appendix, local signs in the right iliac fossa may be absent, there being instead great pain and tenderness in the loin, and rigidity without great tenderness of the right rectus. These cases are specially apt to develop subdiaphragmatic abscess, and later empyema. An appendix running down into the pelvis is apt to give diarrhoea and bladder irritability, local rigidity may be slight and a mass can usually be felt per rectum. An appendix running directly inwards may occasionally give rise to left-sided symptoms.

Course.—Where a correct diagnosis is made, early operation should be undertaken at once, for reasons to be discussed later, but if for any reason operation is delayed the case may take one of three possible courses.

(a) Gradual recovery may ensue, and in first attacks this will occur in a large number of cases. Improvement begins about the second or third day and the acute symptoms generally subside in a week. In such cases the patient is extremely liable to have further attacks, a liability which is increased in proportion to the degree of change which has occurred in the appendix.

(b) In many cases, as the result of ulceration or perforation of the appendix, the local symptoms not only do not disappear at the end of the first week, but persist and become aggravated. The temperature usually rises and there may be rigors, while at the same time a tumour becomes palpable in the iliac fossa. In some cases the abdominal wall may become oedematous and indurated, and the patient frequently begins to lose weight rapidly, to sweat profusely and to show all the signs of closed suppuration. If an operation be now performed, an abscess is found in connection with the appendix, having definite walls composed of adherent and matted intestine, omentum and parietal peritoneum. Such abscesses often contain large quantities of very foul-smelling pus, and if left alone may burst into the rectum or general peritoneum, or more rarely on to the surface, usually in the neighbourhood of the umbilicus. Spontaneous recovery may follow rupture into the rectum or on to the surface, but in the other cases death is almost certain to ensue.

(c) The third result of an unoperated attack of acute appendicitis, and by far the commonest cause of death in this disease, is generalised peritonitis. This may occur either from perforation of the appendix before limiting adhesions have had time to form, or it may occur without any perforation at all. In the latter case bacteria pass through the wall of the inflamed appendix and set up suppuration in the neighbourhood; if the resistance is poor, this involves the neighbouring peritoneum and ultimately leads to a

generalised infection. In other cases a localised abscess may form and later burst into the peritoneum, a result often precipitated by sudden exertion on the part of the patient, injudicious palpation, or the administration of aperients. The great danger of appendicitis, and one that can only be met by immediate operation in all definite cases, is that general peritonitis may occur from the very beginning, and its symptoms may be indistinguishable from those of the acute appendicitis itself. In the hands of competent abdominal surgeons, operation in the early stages is one of almost absolute safety, and in these circumstances any delay, with the shadow of possible peritonitis menacing the patient at any time, is quite unjustifiable.

Diagnosis.—As appendicitis is by far the commonest acute inflammatory condition occurring in the abdomen in people under middle age, it must always be thought of in the presence of acute abdominal disease. In a typical case, with acute onset of abdominal pain, generalised at first and later settling into the right iliac fossa, with vomiting, constipation and local rigidity and tenderness, the diagnosis is easy, but one or more of these signs may be absent, and in such cases it is well to remember that a single positive sign is worth several negative ones. The most constant single sign is tenderness on deep pressure in the iliac fossa, and if this is present even in moderate degree, the case must be carefully watched before a diagnosis of acute appendicitis can be safely discarded.

Rectal examination may reveal bulging of the rectal wall by an abscess, particularly with a pelvic appendix, which, if palpable, is extremely tender.

A general examination of the patient is essential in order to eliminate certain other conditions which sometimes lead to mistakes. Right-sided pneumonia may cause difficulty, as the onset is sometimes associated with considerable pain and rigidity in the right side of the abdomen, but as a rule the accompanying respiratory symptoms and signs, especially the rapid respiration, will prevent error. In children contraction of the right psoas muscle with flexion of the hip may suggest an acute arthritis or even a psoas abscess, whilst a psoas abscess is occasionally mistaken for appendicitis. Of the abdominal lesions most likely to cause confusion the most difficult to differentiate is acute tubo-ovarian disease in women. In some of these cases, appendicitis coexists from spread of infection, and where doubt remains after a thorough pelvic examination it is safer to operate than to risk leaving a possible acute appendicular lesion.

In perforation of gastric or duodenal ulcers, the general shock is more profound, the rigidity is more general and board-like, and the pain is diffuse and not localised; in biliary, renal, and intestinal colic, the nature and distribution of the pain usually suffice to prevent mistakes. Twisting of a small ovarian cyst may be impossible to differentiate, but operation is called for in either case. In certain cases of typhoid fever the clinical picture may simulate appendicitis very closely. The relatively slower pulse and higher temperature, the constant headache, and the absence of any definitely acute onset, are of the greatest help in distinguishing, and a leucocyte count may be of considerable assistance, as leucopenia is present in typhoid fever in contrast with the leucocytosis of appendicitis.

Prognosis.—If left alone a considerable proportion of cases of acute appendicitis tend to recovery, but it is at present impossible to give an accurate prognosis of the course of any particular case within the first 48 hours. The

chief cause of death is peritonitis, and less often pylephlebitis, septicæmia, or pulmonary embolism. Even if recovery from a first attack does occur, the patient is left with a far greater liability to subsequent attacks, and is in some danger of acute or chronic obstruction from the adhesions which so frequently develop. Successive attacks of appendicitis tend to be more severe, and a patient who has had two is almost certain to have further trouble.

With early operation the prognosis is extremely good, death being rare after operation within 36 hours. Even when operation is undertaken later in the attack, the prognosis is still good, unless general peritonitis has ensued, in which case the prognosis without operation is uniformly bad. A further great advantage of early operation is that drainage of the abdomen can be avoided in these cases, whereas in later operations drainage is frequently necessary with a consequent increased risk of post-operative hernia.

Treatment.—In acute appendicitis operated on within 36 hours of the onset, the mortality in the hands of most surgeons is negligible, and since it is quite impossible to determine the course which any particular attack is going to take, there can be no doubt that when the diagnosis is definitely established, operation should be undertaken at once. Some surgeons are of opinion that when the case is seen later than 48 hours from the onset and is tending to improve, medical treatment should be undertaken until the attack has subsided, and the appendix should be removed during the quiescent period. Since operation in these cases is, with modern technique, very little more difficult or dangerous than in early cases, such a view has little to recommend it, since it condemns the patient to two tedious periods of sickness instead of one, and there is, in addition, the risk of the patient's natural objection to an operation, when he feels perfectly well, overcoming the advice he has been given and leaving him exposed to all the risks of a further attack. When peritonitis or localised abscess formation has occurred, there are no two opinions as to the necessity of operation. If, for any reason, operation is impossible or refused, the patient should be kept in the Fowler position, should have nothing but water by mouth, and may be given morphine to diminish both pain and intestinal movement, provided always that the question of operation has been finally and definitely decided.

Where an appendicular abscess has developed, it was formerly held that the abscess should be drained and the appendix removed subsequently. Modern surgical opinion is in favour of doing both at one operation, and in the hands of an experienced operator this procedure is undoubtedly best, but where skilled surgical aid is not available, simple incision and drainage of the abscess meet the immediate emergency.

E. G. SLESINGER.

CHRONIC APPENDICITIS AND APPENDICULAR DYSPEPSIA

Symptoms.—Chronic appendicitis may give rise to gastric symptoms, which may either be the sole manifestation of the disease, or may be accompanied by constant discomfort or short attacks of pain in the right iliac fossa. Epigastric pain, which may radiate downwards to the umbilicus or below, and occasionally towards the right iliac fossa, occurs after meals. The time

of its onset is very irregular. Most commonly it occurs immediately after meals, but occasionally it may be delayed for 2 or 3 hours. It is at the most only slightly relieved by alkalis, and food very rarely gives even momentary relief. It is aggravated by fatigue to a greater extent than is the case with the indigestion of gastric and duodenal ulcer and gall-bladder disease. The degree of discomfort varies from time to time; it is rarely completely absent, and may sometimes be sufficiently severe for the patient to go to bed. Nausea is common and is often present in the absence of vomiting. Vomiting may occur, especially after food and when the pain is severe, but it gives much less relief than in gastric ulcer. Heartburn and acid regurgitation are uncommon. Hæmatemesis may occur from an acute gastric or duodenal ulcer secondary to the appendicular infection.

A fractional test-meal shows that in only 12 per cent. of cases gastric secretion is unaffected; in 55 per cent. of a series of 65 cases, in most of which the symptoms were mainly epigastric, there was hyperchlorhydria, and in 33 per cent. of cases, in most of which the pain was situated chiefly in the right iliac fossa, achlorhydria was present. It is probable that hyperchlorhydria is a reflex effect of the appendicitis, whereas achlorhydria dates from a period preceding the appendicitis and predisposes to its development owing to the loss of the antiseptic properties of the normal gastric juice.

Tenderness is generally more marked in the right iliac fossa than in the epigastrium, even when there is no spontaneous pain in the former situation. Occasionally the localised tenderness can only be discovered when pressure is exerted directly over the appendix after it has become visualised with the X-rays. In many cases pressure in the right iliac fossa leads to no local pain, but to discomfort in the epigastrium with nausea, exactly simulating the spontaneous symptoms. Constipation is commonly present. In rare cases there may be chronic diarrhoea, but more frequently a form of pseudo-diarrhoea, in which frequent small stools are passed, is present owing to irritation of the rectum caused by a chronically inflamed appendix situated in the pelvis. Pelvic appendicitis may also lead to irritability of the bladder with frequent micturition, and in women to dysmenorrhœa.

Diagnosis.—The diagnosis of chronic appendicitis may be exceedingly difficult, and it is consequently not uncommon for an appendix to be removed without benefit. The operation is not justifiable for chronic appendicitis, unless the diagnosis has been confirmed by means of the X-rays and, if possible, by means of Bastedo's inflation sign. The X-rays show where the appendix is in almost all normal individuals and about 80 per cent. of cases of appendicitis, and its discovery in the pelvis or immediately under the liver may explain anomalous symptoms. In chronic appendicitis, the appendix itself is always found to be the point of maximum tenderness, definitely more tender than the end of the ileum or the cæcum. By manipulating the cæcum so that the position of the appendix in the abdomen is altered, the tender point moves with it. In some cases, pressure on the appendix produces epigastric discomfort, either with or without local tenderness. Indirect evidence of appendicitis is occasionally afforded by the presence of ileal stasis, and by the recognition of adhesions in the right iliac fossa, which are most commonly due to chronic appendicitis.

On inflating the colon with air through a tube introduced into the rectum,

normal individuals feel a generalised discomfort in the abdomen. Bastedo's sign of chronic appendicitis is the production under these conditions of localised pain in the right iliac fossa with increased tenderness, sometimes associated with or even entirely replaced by epigastric discomfort. This is present in a large proportion of cases, but never in salpingitis, ureteral calculus, gall-bladder disease or other conditions, which might simulate chronic appendicitis. Inflation should be carried out during the X-ray examination, as it raises a pelvic cæcum and brings the appendix within reach of the palpating fingers. It also unravels confusing pelvic shadows and makes it possible to decide to what extent adhesions are present in connection with the terminal ileum, cæcum and appendix.

If repeated attempts fail to visualise the appendix it is probable that its mouth is obstructed; in the presence of suspicious symptoms and tenderness in the ileo-cæcal angle the absence of an appendicular shadow favours the diagnosis of appendicitis. In such cases Bastedo's sign is also negative, as it depends upon distension of the appendix itself, which is only possible when barium can also mark its lumen.

Treatment.—Medical treatment gives little or no relief; this is an important point in diagnosis, as in any case of chronic dyspepsia, which does not yield to ordinary treatment, the possibility of chronic appendicitis should be considered. In mild and doubtful cases the effect of removal of any source of infection in the teeth and tonsils should first be tried, and in cases associated with complete achlorhydria dilute hydrochloric acid should be taken with meals for some time, as this occasionally results in complete disappearance of the symptoms.

Recovery should follow the removal of the appendix, but it is not infrequent for the symptoms to persist for a time after the operation, especially if the disease is associated with some functional nervous disorder or with chronic typhlitis or cholecystitis. Such associated conditions require attention both before and after the operation, and if the gall-bladder is infected it should be removed at the same time.

ARTHUR F. HURST.

DISEASES OF THE LIVER

TESTS FOR HEPATIC FUNCTION

In our experience the lævulose test for hepatic efficiency is the only one of sufficient value to deserve description. In considering the diagnosis of jaundice, van den Bergh's reaction for excess of bile pigment in the blood will be described, and the direct investigation of the bile obtained by means of a duodenal tube will be considered in connection with cholecystitis.

Lævulose tolerance test.—In normal individuals the blood sugar does not rise more than about 20 mgr. per 100 c.c. 1 hour after 50 grm. of lævulose have been taken in 100 c.c. of water on an empty stomach, and in 2 hours it falls again to the fasting level. If, however, the liver is diseased, the rise at the end of 1 hour is greater, and it is still considerably above the fasting level at the end of 2 hours.

JAUNDICE

Synonym.—Icterus.

Definition.—Jaundice is the condition caused by the presence of excess of bile-pigment in the blood, which manifests itself clinically by yellow coloration of the conjunctivæ and skin.

Ætiology and Pathology.—All cases of jaundice may be divided into three groups—hæmolytic jaundice, toxic and infective hepatic jaundice, and obstructive hepatic jaundice (McNee).

(a) **HÆMOLYTIC JAUNDICE.**—In hæmolytic jaundice bilirubin is produced from hæmoglobin set free in the general circulation by the destruction of red cells as a result of abnormal fragility, as in acholuric jaundice, or of the presence of hæmolytic toxins in the blood, as in Addison's (pernicious) anæmia. The hæmoglobin set free is broken down, and bilirubin is formed by the action of the endothelial cells of the spleen and to a less extent the similar endothelial cells of Kupffer, which lie along the portal capillaries adjacent to the bile capillaries of the liver, and the endothelial cells of other organs. The excess of bile pigment in the blood is thus formed quite independently of the glandular cells of the liver.

(b) **TOXIC AND INFECTIVE HEPATIC JAUNDICE.**—This includes the jaundice caused by infection with *Spirochæta (Leptospira) ictero-hæmorrhagica* (p. 183) as well as that occurring in yellow fever, malaria, typhoid fever, pneumonia and septicæmia. This form of jaundice is one of the characteristic symptoms of acute yellow atrophy. It may occur in snake and mushroom poisoning, and in rare cases after large doses of salvarsan and allied preparations, chloroform, chloral, acetanilide, atophan, santonin, filix-mas, and in poisoning with phosphorus, arseniuretted hydrogen and aniline. Poisoning with trinitrotoluene and tetrachlorethane was the cause of the epidemic of jaundice in aeroplane and munition workers during the Great War (p. 381). Severe cases of toxæmic jaundice are sometimes grouped under the name of *icterus gravis* or *malignant jaundice*.

Toxic and infective jaundice is due in part to damage to the hepatic cells, which may vary from cloudy swelling in pneumonia, fatty degeneration in chloroform poisoning and partial necrosis in spirochætal jaundice to almost complete necrosis in acute yellow atrophy. The damaged hepatic cells are unable to convey the bile pigment from Kupffer's endothelial cells lining the portal capillaries into the bile capillaries; the pigment consequently passes to the hepatic vein and thence into the general circulation. At the same time any bile pigment which is excreted by still active liver cells is obstructed by inflammatory swelling of the walls of the small bile-ducts caused by toxins excreted in the bile; it is consequently reabsorbed. The jaundice is thus in part due to insufficiency of the hepatic cells and in part obstructive, the proportion of the two factors varying in different cases. The degree of hepatic insufficiency can be judged by the lævulose test, which is unaffected in pure obstructive jaundice.

(c) **OBSTRUCTIVE HEPATIC JAUNDICE.**—In obstructive jaundice bile excreted by the hepatic cells is reabsorbed by the hepatic blood capillaries together perhaps with the lymphatics, owing to the rise in pressure caused by obstruction of the bile-ducts. The obstruction may occur (1) within the ducts, or it may be due to (2) changes in their walls or (3) pressure from without.

1. *Obstruction within the ducts.*—This is almost always due to gall-stones. In very rare cases a hydatid cyst has ruptured into a duct, which became obstructed by a piece of membrane or a daughter cyst, or a round worm has entered the common bile-duct from the duodenum.

2. *Obstruction due to changes in the walls of the ducts.*—Primary carcinoma of the bile-ducts and biliary papilla quickly leads to jaundice. Simple stricture is almost always congenital (p. 620), as an acquired stricture from cicatrization of an ulcer produced by a gall-stone is excessively rare except in the cystic duct, where it does not lead to jaundice. Catarrhal jaundice is generally due to the obstruction produced by inflammatory swelling of the mucous membrane in the biliary papilla; infective and suppurative cholangitis also lead to jaundice, but in some cases, at any rate, the obstruction to the ducts is associated with changes in the liver cells which are in part responsible for the production of the jaundice.

3. *Pressure on the ducts from without.*—Malignant tumours of the liver, and much less frequently gummata and hydatid cysts, give rise to jaundice by pressing on the intrahepatic branches of the bile-ducts; if some of the latter escape, bile still passes into the duodenum from other parts of the liver, and the fæces remain coloured. The tumour may project into the portal fissure and give rise to jaundice with colourless stools by pressing upon the hepatic ducts or common bile-duct.

Enlarged glands in the portal fissure may cause jaundice by pressure upon the ducts. The most common cause is primary or secondary cancer of the liver, as these glands drain the liver, but not the other abdominal viscera or peritoneum; for the same reason they rarely become tuberculous. They may be enlarged in Hodgkin's disease, but never in syphilis.

Jaundice may occur in cancer of the stomach, even when no secondary deposits are present in the liver or in the glands in the portal fissure; this is due to the pressure of glands in the neighbourhood of the head of the pancreas, or to direct spread of the growth into the lesser omentum, where it compresses the common bile-duct and may invade its walls.

A movable kidney may give rise to typical attacks of biliary colic associated with jaundice, owing to the traction it exerts on the common bile-duct itself or indirectly by drawing down the duodenum. The diagnosis of a movable kidney from cholelithiasis is suggested by the fact that the attacks never begin in the night and are rapidly relieved by lying down, and is confirmed if a movable kidney is found and relief follows its successful treatment.

Jaundice is produced by obstruction of the common bile-duct when chronic pancreatitis occurs in an individual in whom the duct is embedded in the head of the gland. Jaundice is generally present in cancer of the head of the pancreas, and very rarely with a pancreatic cyst or calculus.

Symptoms.—Jaundice appears first in the conjunctivæ and then successively on the face, neck, body and limbs. The mucous membrane of the lips and palate becomes yellow very soon after the conjunctivæ. In chronic jaundice the pigment in the skin becomes dark green. In a small proportion of cases which have lasted for a very long period, multiple xanthoma (or xanthelasma) develops, but this condition also occurs without jaundice. The patches are generally flat and are sometimes very painful; they consist of cholesterol, which the blood in jaundice

contains in excess. They are most frequent in the eyelids, but in rare cases they are found in the hands and feet and even over the whole body. In chronic jaundice there is a tendency for telangiectases to develop over the body and face and occasionally on the mucous membrane of the tongue and lips; they may disappear at the same time as the jaundice. Purpura and hæmorrhage from mucous membranes, especially the nose and gums, may occur.

The urine becomes bile-stained before the conjunctivæ and skin, the interval being sometimes as long as 24 hours, but it generally returns to normal before the yellow colour of the skin has disappeared. The urine may be yellow, olive, dark brown or even black. The colour can be distinguished from that in urobilinuria, hæmaturia and melanuria, and that produced by rhubarb, senna, sautonin and chrysophanic acid by Gmelin's test for bile-pigment.

When obstruction to the bile-ducts is complete, no bile reaches the intestines and urobilin is absent from the urine; when the obstruction is incomplete, decomposition of the bile which reaches the intestines may occur and urobilinuria results. Bile-salts are only present in the urine for the first few days, the disappearance being probably due to inhibition of their production in jaundice. In chronic obstructive jaundice bile-stained casts are almost always present in the urine, and less frequently albuminuria occurs. The urine often reduces Fehling's solution owing to the presence of glycuronic acid.

The faces are bulky and often extremely offensive; when the obstruction is complete they are clay-coloured, partly owing to the absence of bile-pigment and partly to the presence of excess of fat.

The sweat may contain bile, which is also sometimes present in the tears and in the milk; but the saliva, cerebro-spinal fluid and mucus of the alimentary canal are free from bile, although the salivary glands and other organs are deeply bile-stained. The sputum in pneumonia and the effusion in pleurisy and peritonitis contain bile-pigments. The blood plasma is tinged with bile. Coagulation is considerably delayed, perhaps owing to the fixation of the lime salts of the blood by the bile-pigment. There is very little anæmia except in severe cases, when granular degeneration of the red corpuscles may occur, and leucocytosis is common.

In catarrhal and recent jaundice the pulse is slow, but in other cases it is generally normal; there may be an abnormal tendency to acceleration on assuming the erect position. The slowing is probably due to the bile-salts, which cease to be formed after the jaundice has persisted for a few days. The blood-pressure tends to be low, and mitral incompetence may occur owing to myocardial weakness. The liver is often enlarged owing to retention of bile.

Pruritus occurs in about 20 per cent. of cases, especially when the jaundice is well marked; it may be very severe and interfere with sleep. It is not directly due to the jaundice, as it may occur before the jaundice appears and continue after its disappearance; when present before the jaundice, it may subside with the onset of the latter, and it has also been observed in association with gall-stones, when no jaundice was present. Like bradycardia, it is probably due to retention of bile-salts.

The yellow vision or xanthopsia of jaundiced patients is less marked than

that caused by *santonin*, and is rarely sufficiently obvious for the patient to mention it unless directly asked.

The absence of bile and sometimes also of pancreatic juice from the intestines leads to deficient digestion in the small intestine, especially of fat. Loss in weight results, and the excess of undigested food which reaches the colon is likely to cause excessive bacterial decomposition. This may lead to intestinal intoxication, especially if the hepatic cells are damaged and their antitoxic action impaired in addition to the bile channels being obstructed. Intestinal intoxication and the other effects of the primary disease which causes the jaundice account for the various symptoms which may be associated with jaundice.

Diagnosis.—(a) RECOGNITION OF JAUNDICE; VAN DEN BERGH'S REACTION.—Bilirubin is normally present in the blood. Just as the kidneys in diabetes do not excrete sugar until the concentration in the blood has reached the leakage point, which is considerably higher than the normal concentration, so no bilirubin passes into the urine until the concentration in the blood has risen from the normal of 1 in 250,000 to the leakage point of 1 in 50,000. About the same concentration is required to cause jaundice, but the appearance of a trace of bile pigment in the urine is easier to recognise with certainty than the first trace of pigmentation of the skin or conjunctiva. Moreover, the pigmentation is somewhat slower to develop, and it remains for a time after all pigment has disappeared from the urine.

Van den Bergh has shown that excess of bilirubin in the blood can be recognised by a colour reaction, now commonly known as van den Bergh's test, which is given by Ehrlich's diazo reagent. The *direct reaction* may be "prompt," the maximum being reached within 30 seconds; it may be "delayed" for 1 to 15 minutes or entirely negative; or it may be "biphasic," giving a slight prompt reaction followed after a delay by gradual deepening of the colour. The *indirect reaction*, obtained after precipitation with alcohol so as to bring the bile into alcoholic solution, is always prompt.

With van den Bergh's test it is possible to distinguish two different forms of bilirubin. In all cases of hyperbilirubinæmia the indirect reaction is obtained. The direct reaction is prompt with the bilirubin reabsorbed into the blood after it has been excreted by the hepatic cells in cases of obstructive jaundice, but is negative or delayed when the excess of bilirubin is a result of over-production, as in hæmolytic jaundice; it is negative, delayed or biphasic when the jaundice is due to inability of the hepatic cells to excrete it, as in toxic and infective hepatic jaundice.

By means of van den Bergh's test it is also possible to recognise latent jaundice. Thus the hyperbilirubinæmia present in Addison's *anæmia* gives a positive indirect reaction, although there is no jaundice except in occasional acute hæmolytic crises, which may result in the concentration of bilirubin in the blood being sufficient to colour the conjunctivæ and skin the yellow colour of ordinary jaundice. Excess of bilirubin in the blood at a concentration below the leakage point may also result from a very slight degree of biliary obstruction, such as occurs in cirrhosis of the liver, some cases of secondary growth and rarely of gall-stones; it is recognised by giving a positive direct van den Bergh's reaction in spite of the absence of jaundice and of bile from the urine. In other cases of obstructive jaundice a positive direct reaction is

given at a stage before jaundice develops and bile appears in the urine, and still longer before any change is noticed in the stools.

(b) **FACTORS HELPING IN THE DIFFERENTIAL DIAGNOSIS OF THE CAUSE OF JAUNDICE:**

1. *Age, sex and history.*—The differential diagnosis of jaundice present at birth or developing a few days later is considered elsewhere (p. 620). Jaundice occurring in childhood or before the age of thirty is most commonly catarrhal; after thirty, gall-stones are frequent, especially in women; and after forty, cancer of the liver is common in both sexes, and cirrhosis is common in men. Jaundice developing in pregnancy should raise a suspicion of acute yellow atrophy. When more than one member of a family are affected, an infection, such as spirochætal jaundice, or a toxæmia is probably the cause in acute cases; in chronic cases acholuric jaundice should be considered.

2. *Course.*—Jaundice of short duration is generally catarrhal or due to gall-stones. Jaundice, which progresses until it becomes extremely deep, suggests cancer, whilst chronic jaundice, which varies from time to time, is generally due to gall-stones.

3. *Condition of the gall-bladder.*—Enlargement of the gall-bladder indicates obstruction of the cystic or common bile-duct, though the former is not likely to be associated with jaundice. The enlargement is present in over 90 per cent. of cases in which obstruction is due to causes other than gall-stones, but only in 20 per cent. of cases of calculous obstruction. This difference is known as Courvoisier's law, and is due to the contraction of the gall-bladder as a result of chronic inflammation in cholelithiasis, in which, moreover, the obstruction is often incomplete.

4. *Condition of the liver.*—Jaundice associated with great enlargement of the liver is generally due to growth if it is irregular, and to chronic pancreatitis if the liver is smooth; the irregular enlargement due to syphilis is less extreme and less often associated with jaundice, and that due to hydatid cysts or an abscess is rarely associated with jaundice. The presence of ascites points to a growth or to cirrhosis; but the jaundice is generally more marked in the former.

5. *Examination of duodenal contents.*—A specimen of the duodenal contents should be obtained by means of Einhorn's tube when the patient is fasting. The presence or absence of bile shows whether the common bile-duct is incompletely or completely obstructed, and the presence or absence of diastase, trypsin and lipase shows whether the pancreatic ducts are free or obstructed. Complete obstruction of both bile and pancreatic ducts indicates obstruction of the common bile-duct by a growth or chronic pancreatitis. Incomplete obstruction of the bile-ducts and a normal quantity of pancreatic ferments point to gall-stones or catarrhal jaundice.

6. *Pain.*—Constant pain suggests growth, attacks of pain gall-stones, and absence of pain catarrhal jaundice, chronic pancreatitis or cirrhosis; but many exceptions to this general statement occur.

7. *Syphilis.*—Vigorous anti-syphilitic treatment should be tried if syphilitic lesions or scars are found in other parts of the body, or if there is a history of syphilis. In all cases in which there is the slightest chance that the disease is syphilitic in origin, the Wassermann reaction should be tested.

Treatment.—The treatment of jaundice is the treatment of the condition which causes it. The subject, therefore, requires no further con-

sideration here, except for the pruritus and tendency to hæmorrhage, which are results of the jaundice itself. A warm alkaline bath may give relief to the pruritus, or moistening the irritable parts of the skin with 1 in 40 carbolic acid, 1 in 50 ichthyol, or 1 in 70 solution of menthol in spirit. The tendency to hæmorrhage is much reduced by the subcutaneous injection of calcium salts, and it is advisable to treat every jaundiced patient in this way for a few days before any operation is performed.

JAUNDICE IN THE NEWLY BORN

Jaundice frequently occurs in the newly born. In a large proportion of cases it is only temporary and gives rise to no symptoms; the term *icterus neonatorum* is commonly applied to this condition alone, although strictly speaking the other and more serious forms of jaundice in the newly born should be included under the name.

I. SIMPLE JAUNDICE IN INFANTS (ICTERUS NEONATORUM).

Ætiology.—Simple jaundice occurs in about 50 per cent. of infants, and especially among the premature.

Pathology.—The number of red corpuscles is high in the newly born, but quickly falls during the first few days of life. The excessive blood destruction is associated with an excess of bile-pigment in the blood, as shown by van den Bergh's reaction, which gives a positive indirect but negative direct reaction in all new-born infants. The jaundice is therefore hæmolytic, and when death occurs from some independent cause, nothing abnormal is found in the liver, bile-ducts or other parts of the body.

Symptoms.—The jaundice generally begins on the second or third day of life; it increases in intensity for 2 or 3 days, and then gradually diminishes until it disappears after 1 or 2 weeks; but occasionally it lasts for a longer period. The jaundice begins on the face and spreads over the whole of the body; unlike other forms of jaundice, the conjunctivæ are only affected after the skin, and in slight cases they are not stained at all.

Diagnosis.—If the jaundice is slight, its presence can only be recognised by pressing the blood out of the cutaneous vessels, when the normal redness of the infant disappears, and the yellow colour remains. Its short duration and the absence of enlargement of the liver and spleen distinguish simple *icterus neonatorum* from congenital obliteration of the bile-ducts, and the healthy condition of the infant distinguishes it from the infective forms of jaundice.

Prognosis and Treatment.—Rapid recovery always occurs, and no treatment is required.

II. OBSTRUCTIVE JAUNDICE.

Obstructive jaundice may occur in infants as a result of congenital obliteration of the bile-ducts, or congenital syphilis of the liver.

CONGENITAL OBLITERATION OF THE BILE-DUCTS

Ætiology.—This rare disease occurs rather more frequently in male than female infants. It is occasionally familial, and is not associated with congenital syphilis.

Pathology.—Some unknown toxin probably passes from the mother by the umbilical vein to the foetus. Part of the toxin reaches the liver direct and causes multilobular cirrhosis. The rest passes into the general circulation and reaches the liver by the hepatic artery; it is excreted in the bile and gives rise to unilobular cirrhosis, with cholangitis affecting the small and large ducts and gall-bladder, which, being extremely small at birth, become more or less completely obliterated. The disease is thus a combination of portal and biliary cirrhosis with obstruction of the ducts.

Symptoms.—Jaundice is generally present at birth, but may not appear for two or more weeks. The meconium is normal, but the stools are free from bile from the first, and the urine is deeply bile-stained. The liver and spleen are large and hard. Hæmorrhages from the mucous membranes and umbilicus and under the skin are common.

Diagnosis.—Deep jaundice, with a large liver and spleen and hæmorrhages without any early evidence of infection, in a new-born infant is generally due to this disease.

Prognosis.—Life may last from a few days to as much as 11 months.

Treatment.—No treatment is of any value.

III. INFECTIVE JAUNDICE.

Infective jaundice is rare in infants, but may occur in various forms.

(a) *Mild infective jaundice.*—This condition may occur sporadically or in epidemics, and is identical with the catarrhal jaundice of older children and adults. It is probably due to the invasion of the previously sterile alimentary canal with organisms in the first few days of life, a mild degree of inflammation of the bile-ducts resulting. The jaundice appears a few days after birth, and is accompanied by anorexia, vomiting, diarrhoea, slight pyrexia and drowsiness. The urine contains bile, but the fæces may be normal. Recovery generally occurs, but the infant may be very ill. The treatment is that of the infective entero-colitis of infants.

(b) *Severe infective jaundice.*—**Ætiology.**—Epidemics of very fatal jaundice were formerly not uncommon in lying-in hospitals: but they have become rare since the introduction of antiseptics. Sporadic cases also occur. The infection may enter by the umbilicus, causing suppurative phlebitis of the umbilical vein; this leads to jaundice by infecting the liver. In other cases the infection is probably conveyed by the alimentary canal.

Symptoms.—Jaundice appears about the fifth day of life, and is accompanied by high fever and other symptoms of severe septicæmia or pyæmia. When the umbilicus is the channel of infection, it is red and swollen, and severe hæmorrhage may take place from it. Gastro-intestinal hæmorrhage may occur independently (Buhl's disease), or in addition to hæmorrhage from the umbilicus. In some epidemics, hæmaturia has occurred (Winckel's disease). The skin has a bronze colour, owing to the combination of jaundice with cyanosis. The infant finally becomes comatose, and death almost always follows.

Treatment.—The treatment is that of severe epidemic diarrhoea of infants; the bowels should be washed out, fractional doses of calomel administered, and anti-streptococcic serum should be injected subcutaneously.

IV. HEREDITARY AND FAMILIAL JAUNDICE.

Jaundice is hereditary and familial in acholuric jaundice and in "grave familial jaundice of the newly born."

FAMILIAL ICTERUS GRAVIS NEONATORUM

The jaundice, which affects successive members of the same family, though the first-born often escapes, begins within a few hours of birth. The colour rapidly deepens till the skin is deep bronze. The infants are drowsy and take the breast badly. The stools are normal in colour. The urine is dark and contains urobilin and often bilirubin in excess. The liver and spleen are not enlarged.

The bilirubin in the blood at birth is greater than normal; the blood contains no hæmolyisin, but the cells show a slightly increased tendency to hæmolysis (Hampson).

Death generally occurs within a few days and almost always within 3 weeks: post mortem nothing abnormal is found. Hampson has shown that complete recovery occurs if 5 to 10 c.c. of the mother's blood serum are injected daily into the infant's muscles.

ACHOLURIC JAUNDICE

Synonym.—Chronic Splenomegalic Hæmolytic Jaundice.

Ætiology.—The disease may be hereditary and familial, when it is either congenital or only appears some years after birth, the two varieties sometimes coexisting in the same family. The disease may occur in as many as four generations and may be transmitted through healthy parents. It may also be acquired in adult life without obvious cause or after some infection.

Pathology.—The red corpuscles are abnormally "fragile," undergoing hæmolysis with remarkable ease. This fragility leads to the liberation of hæmoglobin and the formation of excess of bilirubin in the blood. No hæmolytic toxin is present in the blood, the hæmolysis being apparently due to the fragility of the corpuscles as a result of inheritance or an infection.

There is no evidence that the jaundice is obstructive, as the bile-ducts are free from inflammation or evidence of obstruction, and the bile is not abnormally thick. It appears, therefore, that the jaundice is hæmatogenous and due to the formation of bilirubin from hæmoglobin in the tissues.

Symptoms.—(a) *Familial type.*—The jaundice may vary in degree from time to time, and may temporarily almost disappear; it is increased by excitement, over-exertion and exposure to cold. None of the symptoms of chronic jaundice, such as pruritus, xanthoma and a slow pulse, are present. The urine is free from bile, but is dark and generally contains urobilin, and the fæces are normal in colour. In the exacerbations, however, bile may appear temporarily in the urine, and the fæces become pale.

In some cases attacks of colic, which may be accompanied by pyrexia and aggravation of the jaundice, occur; they are caused by pigment calculi, which are generally found in the gall-bladder in cases requiring the operation, though in most cases they do not give rise to symptoms. Except for these attacks the general health is hardly affected.

The red blood corpuscles are abnormally fragile; they begin to undergo hæmolysis in a 0·6 per cent. sodium chloride solution, and the process is complete in a 0·42 per cent. solution, whereas hæmolysis in normal blood begins in a 0·42 per cent. sodium chloride solution, and is complete in 0·3 per cent. solution. The corpuscles are smaller than normal, but as they are also thicker their total volume is not reduced. Stained films show well-marked polychromatophilia and basophil granules. Moderate anæmia is generally present, the colour-index being less than one. The blood plasma contains excess of bilirubin, but no free hæmoglobin. The spleen is enlarged, but the liver is unaffected.

(b) *Acquired type*.—In the acquired form of the disease the jaundice is less marked, but the anæmia is more severe; it may resemble that of Addison's anæmia with a high colour-index and nucleated corpuscles. Leucocytosis is present and myelocytes with excess of eosinophil cells are found. The fragility of the corpuscles is less marked than in the congenital form. Attacks of febrile colic occur, and symptoms of anæmia are present.

Diagnosis.—The diagnosis depends upon the characteristic fragility of the red blood corpuscles. In the acquired form, in which the fragility is less marked, Addison's anæmia with jaundice may be closely simulated; but in the latter condition the resistance of the corpuscles to hæmolysis is actually greater than normal and the leucocyte count is different. The febrile and painful attacks are indistinguishable from ordinary biliary colic, and are, indeed, commonly due to gall-stones, but the history and the condition of the blood should prevent a mistake in diagnosis. An examination of the blood also helps to distinguish those cases in which jaundice is slight from splenic anæmia.

Prognosis.—The symptoms in the hereditary and familial forms of the disease have no tendency to disappear; but the condition does not interfere with normal growth or shorten life, and the patient cannot really be considered ill. On the other hand, in the acquired form, although the symptoms are much more serious, spontaneous recovery is possible.

Treatment.—The patient should avoid everything, such as exposure to cold and over exertion, which is likely to lead to exacerbations. In severe cases splenectomy should be performed, as it is followed by rapid disappearance of the jaundice and anæmia, and in most cases the fragility of the red corpuscles returns to normal.

CATARRHAL JAUNDICE

Ætiology and Pathology.—Catarrhal jaundice is a condition in which jaundice results from obstruction of the mouth of the common bile-duct by the swollen mucous membrane and thick mucus caused by catarrh of the biliary papilla. This is generally a sequel of gastro-duodenal catarrh, the inflammation spreading through the biliary papilla for a short distance up the common bile-duct. The primary gastro-duodenal catarrh most commonly develops without obvious cause; but it may follow food-poisoning and also occur as a symptom of an acute infection, such as influenza, pneumonia and very rarely typhoid and paratyphoid fevers. The epidemic jaundice which occurred during the Gallipoli campaign in 1915 was indis-

tinguishable from ordinary catarrhal jaundice. It was quite distinct from spirochætal jaundice and appeared to be due to infection with a paratyphoid-like organism. In some cases the cholangitis is associated with hepatitis, the jaundice being then partly "infective hepatic" and partly obstructive. Thus whereas the van den Bergh test sometimes gives a prompt direct action, in other cases, clinically indistinguishable, it gives a biphasic or delayed direct action. In the former cases, which are in my experience the most common, the lœvulose test shows no impairment in hepatic efficiency; in the latter it shows more or less impairment.

Symptoms.—Jaundice is almost invariably preceded for 1, 2 or 3 days by symptoms of gastric catarrh. The patient complains of epigastric discomfort most marked immediately after meals, with nausea and often vomiting, which relieves the discomfort. The appetite is lost, headache and general malaise are present, and there may be diarrhœa. Slight pyrexia is common. The stools become pale, and the urine contains bile before jaundice is obvious. As the jaundice develops the gastric and general symptoms abate. The patient becomes deeply yellow, but is by now often quite comfortable so long as he keeps quiet, though activity tends to bring on vomiting. The liver is generally enlarged, and the gall-bladder may be palpable. The liver is slightly tender, but there is no increased tenderness over the gall-bladder. The spleen may also be enlarged.

In slight cases the jaundice begins to disappear in a week, but more commonly it persists without abating for a month or even for as long as 3 or 4 months. The stools become more coloured before the jaundice is obviously less; the quantity of bile in the urine then gradually diminishes, but 3 or 4 weeks may elapse before the last trace of jaundice and the last trace of bile in the urine disappear.

Diagnosis.—When jaundice, unaccompanied by pain and with very slight constitutional symptoms, develops in a patient with mild gastric symptoms of a few days' duration, catarrhal jaundice is the probable diagnosis. When the initial gastric symptoms are absent and the jaundice persists for more than 6 weeks, especially in elderly patients, or when the colour changes from yellow to green, the possibility of chronic pancreatitis or of a growth must be considered. When pain of any severity occurs, especially after the onset of jaundice, and when the gall-bladder is tender, fever persists, or the jaundice recurs, gall-stones are probably present.

Treatment.—The patient should be kept in bed on a plain diet containing as little fat as possible. The bowels should be opened daily with Epsom salts, which at the same time promote biliary drainage. The patient should not be allowed to get up until the jaundice is beginning to disappear.

CONGESTION OF THE LIVER

Congestion of the liver may result from increased inflow of blood—active congestion, and from obstructed outflow—passive congestion.

ACTIVE CONGESTION

Ætiology.—The most common cause of active congestion of the liver is habitual indulgence in rich and highly seasoned food and alcoholic drinks—

the latter being the more important. As congestion and catarrh of the stomach and intestines are likely to result from the same causes, it is probable that the congestion of the liver is due in part directly to the excess of irritating food, and in part to the congestion and catarrh of the alimentary canal. Middle-aged stout individuals, who lead a sedentary life, are most frequently affected.

Acute congestion of the liver is much more common in Europeans living in tropical countries than in England, where well-marked cases are rarely seen, but it is comparatively uncommon among natives. This is partly due to the richness of the diet and the frequency of alcoholic excess among Europeans in the tropics; but malaria, dysentery and other tropical disorders may themselves cause acute congestion of the liver. Patients who have suffered from congestion of the liver whilst living in the tropics are liable to recurrences after their return to England, especially in cold and damp weather. Exposure to cold whilst in the tropics is also likely to bring on an acute attack.

Symptoms.—In addition to the symptoms of gastro-intestinal catarrh, a feeling of discomfort, rarely amounting to actual pain, is felt in the liver; the patient's complexion is sallow, and there is often a slight degree of jaundice. The liver is enlarged and tender, and the spleen is often increased in size. The patient is generally drowsy, irritable and depressed, and often complains of headache. The urine is concentrated and loaded with urates.

Prognosis.—An attack of acute congestion of the liver generally subsides with suitable treatment in about a week. If the attack is neglected, or if the patient is not in the future careful to avoid the causes which gave rise to it, the condition may become chronic, and may finally develop into cirrhosis.

Treatment.—The patient should be dieted on the same lines as in cirrhosis of the liver (p. 633). The bowels should be well opened by means of Epsom salts during an acute attack, and the patient should be careful to keep his bowels regular afterwards. Regular exercise, especially riding, and residence in a cool but dry climate help to prevent a recurrence. The patient should avoid getting chilled, and should wear a cholera-belt. An occasional visit to a spa, such as Harrogate, Llandrindod Wells or Vichy is often very useful.

PASSIVE CONGESTION

Ætiology.—When the outflow of blood from the hepatic vein is impeded as a result of right-sided heart failure, due to primary disease of the heart or to obstructive pulmonary disease, passive congestion of the liver may result. It is also produced by thrombosis of the hepatic veins, which is a rare condition, generally secondary to some neighbouring malignant, syphilitic or inflammatory disease.

Pathology.—The sublobular and intralobular veins are dilated. The centre of each lobule thus appears as a dark spot, whilst the outer part is pale, owing to fatty infiltration; the mottled appearance resembles the section of a nutmeg, and has led to the name "nutmeg liver."

Symptoms.—In addition to the symptoms of the cardiac or pulmonary disease which has led to the right-sided heart failure, special symptoms result from the passive congestion of the liver. The capsule of the liver is

~~stretched and pain~~ results, especially if the enlargement of the organ is rapid. When the increase in size is more gradual, there is a feeling of fullness and weight in the right hypochondrium. The liver can be felt to extend considerably lower than normal, its size varying from time to time according to the condition of the heart. It is firm and tender, especially if the congestion is recent and acute. Distinct expansile pulsation can sometimes be felt by placing one hand in the loin and the other just below the right costal margin; this corresponds with ventricular systole if tricuspid regurgitation exist, and with auricular systole if there is tricuspid stenosis. It must be distinguished from the non-expansile pulsation transmitted through the diaphragm from the hypertrophied and labouring right ventricle.

The congestion of the liver leads in turn to congestion of the organs which are drained by the portal vein. Anorexia, discomfort immediately after food, flatulent distension of both stomach and intestines from deficient absorption of the gas swallowed with the food or produced by fermentation, and constipation are commonly present. The combination of slight jaundice with cyanosis produces a characteristic dusky green colour of the face.

Ascites is common, but is rare in the absence of general œdema, being mainly due to the same causes; it is also in part a direct result of portal congestion and sometimes of chronic peritonitis. The spleen is very rarely enlarged, in spite of the interference with the outflow of blood in the splenic vein caused by the hepatic congestion.

Diagnosis.—When the heart disease is obvious the diagnosis is easy. Sometimes, however, the most prominent symptoms are due to the congestion of the liver, and the diagnosis from cirrhosis may be difficult. In congestion of the liver the spleen is not enlarged, and the symptoms rapidly improve and the liver diminishes in size with rest and cardiac tonics; moreover, hæmatemesis, though common in cirrhosis, very rarely occurs in passive congestion in spite of the congestion of the gastric mucous membrane.

A history of alcoholism does not necessarily point to cirrhosis. If the heart is failing and there is no valvular disease, the enlargement of the liver is probably due to congestion, and the heart failure to alcoholic poisoning. The diagnosis would be confirmed if the ankle-jerks are lost, as latent alcoholic neuritis is frequently associated with an alcoholic heart and congested liver, but very rarely with cirrhosis.

Treatment.—Apart from the treatment of the primary condition, the local pain and discomfort are rapidly relieved by the application of 6 leeches over the hepatic region. Mild purgation by means of calomel and saline aperients also helps to relieve portal congestion.

ACUTE YELLOW ATROPHY

Definition.—Acute yellow atrophy is a rare and very fatal disease, in which jaundice, diminution in the size of the liver, fever and nervous symptoms are caused by acute necrosis of the liver cells.

Ætiology.—Most cases occur between the ages of 20 and 30. Adult females are affected twice as often as adult males, owing to the fact that pregnancy is one of the chief exciting causes, but the proportion is reversed in childhood. The disease has followed influenza and typhoid fever. In

rare cases, especially in females, the jaundice, which may occur in the secondary stage of syphilis, develops into acute yellow atrophy, instead of yielding rapidly to treatment. Very rarely acute yellow atrophy has been an immediate sequel of excessive indulgence in alcohol, and delayed chloroform poisoning has manifested itself as acute yellow atrophy. In many cases, however, no cause is found for the disease.

Pathology.—Acute yellow atrophy is due to a very acute toxic necrosis of the liver cells, the intracellular ferments of which are set free and cause autolysis.

Acute yellow atrophy is closely allied both pathologically and clinically with the icterus gravis which results from phosphorus poisoning, but in the latter the liver is generally enlarged and contains only 5 per cent. of fat, its yellow colour being due to bile. These differences may be due to death occurring earlier in phosphorus poisoning, as in exceptional cases, in which life is more prolonged, absorption of fat and necrotic liver cells occur, the condition being then indistinguishable from acute yellow atrophy.

The necrosis of the liver cells results in diminution in the size of the liver, which may weigh only half or a third of the normal. Its surface is smooth and the capsule loose and wrinkled. Externally the liver is greenish-yellow or normal in colour, and on section bright yellow with red areas, which represent a late stage of the yellow atrophy, the fat and necrotic tissue having been absorbed, so that the vascular fibrous tissue is alone left.

Symptoms.—In the first stage jaundice is present with fever, malaise, vomiting, constipation and muscular pains, the condition closely resembling catarrhal jaundice. In about a third of the cases the patient suffers from general malaise for some time before the jaundice appears, and in rare instances jaundice is absent throughout. This first stage generally lasts for 5 or 6 days, but it occasionally persists for several weeks.

The second stage begins suddenly with drowsiness, headache, photophobia, restlessness and delirium. Muscular twitching and occasionally general convulsions follow, and the patient may become violent. Transient squint is sometimes present, the pupils are generally dilated, and an extensor plantar reflex has been observed. The symptoms may closely resemble those of meningitis. Severe vomiting occurs, and the vomited material may contain altered blood. The tongue is dry and tremulous. The pulse becomes rapid and feeble, but the temperature is generally subnormal, though it often rises just before death. An erythematous rash is sometimes present. Purpura is common, and hæmorrhage may also occur from the nose, kidneys, uterus and alimentary canal, and in the retina. Coma finally develops, with stertorous breathing and incontinence of urine and feces, the whole of the second stage lasting less than a week and often only 3 or 4 days.

The liver is often enlarged and tender in the first stage, but at the onset of severe symptoms it rapidly diminishes in size, until the hepatic dullness disappears, owing to the atrophied and flabby liver falling back and allowing the intestines to pass between it and the abdominal wall. The spleen is sometimes enlarged. Ascites is rarely detected during life, though it may be found after death.

There is no anæmia, but moderate leucocytosis.

The urine contains bile and albumin, and casts are often present. There

is no glycosuria. The percentage of nitrogen excreted as ammonia increases from the normal of about 5 to 20 owing to the acidosis, which causes ammonia to be fixed by organic acids before there is time for it to be converted into urea. Rounded discs of leucin and needle-shaped crystals of tyrosin, derived from autolysis of the liver cells, may be deposited in the urine when it cools, but they are sometimes only found after concentration, and may be absent altogether, though they are subsequently discovered in the liver. They are also occasionally found in the urine in typhoid fever, erysipelas, small-pox and leukaemia, so that their presence is not pathognomonic of yellow atrophy.

Diagnosis.—The diagnosis depends upon the occurrence of severe general symptoms and diminution in the liver dullness in association with jaundice. In phosphorus poisoning the diagnosis may be obvious from the history; the symptoms differ from those of acute yellow atrophy in the absence of progressive diminution in the hepatic dullness, and in the slighter severity of cerebral symptoms. In phosphorus poisoning an interval elapses between the severe gastric symptoms and the onset of jaundice, but in acute yellow atrophy the second stage is continuous with the first.

It is sometimes impossible to distinguish between subacute yellow atrophy and acute cirrhosis, as clinically and pathologically they merge into each other.

Prognosis.—More than half the cases are fatal within a fortnight, but the first stage of the disease may be prolonged over many weeks or months, or even as long as 2 years. Prolonged and subacute cases occur most frequently in children; they are difficult to differentiate from subacute cirrhosis with jaundice. As nodular hyperplasia of the liver has been found in cases surviving six months, a year and a half, and two years, there is a possibility of permanent recovery, but it is probable that most of the recorded cases of recovery were really examples of spirochaetal jaundice. As children more often show the changes of subacute atrophy, the prognosis is rather less hopeless in them than in adults.

Treatment.—When jaundice occurs in pregnancy or in secondary syphilis, or when a patient with supposed catarrhal jaundice becomes drowsy or shows other toxic symptoms, the possibility of acute yellow atrophy developing should be remembered, as treatment is much more likely to be successful if begun at this stage than when the second stage has fully developed. The diet should consist of milk and carbohydrate food only, and large quantities of fluid should be drunk; if there is much vomiting saline solution should be given by the rectum and in severe cases under the skin. The bowels should be kept freely opened. An attempt may be made to disinfect the bile with very large doses of hexamine. Large quantities of sodium bicarbonate may be required to counteract the acid intoxication. Intravenous injection of dextrose, with small doses of insulin, with the object of "fixing" the glycogen in the liver has recently been tried with success.

HEPATITIS

The only form of non-suppurative hepatitis which is of any clinical importance is that due to the *Amaba histolytica*, although acute yellow atrophy, icterus gravis and some forms of infective jaundice might perhaps be included under the heading of hepatitis.

AMOEBIIC HEPATITIS AND HEPATIC ABSCESS

Ætiology.—Amoebic hepatitis is very rare before the age of 20 and is most common in the third and fourth decades. Like amoebic dysentery, it is uncommon in women. Amoebic hepatitis and amoebic abscess of the liver are invariably secondary to amoebic dysentery. In 98 per cent. of fatal cases Rogers either obtained a history of dysentery or found amoebic ulcers or scars of ulcers in the large intestine. The patient has had dysentery in the past or is still suffering from it in about 75 per cent. of cases, and in an additional 15 per cent. there is a history of diarrhoea, which was doubtless a mild form of amoebic dysentery: in the remaining cases amoebic ulcers had probably been present in the caecum or ascending colon, situations in which they do not necessarily give rise to any symptoms. Dysentery may precede the development of an abscess by months or even years, and when hepatitis develops during an attack of dysentery, the latter generally becomes less severe as the inflammation in the liver progresses.

The geographical distribution of the disease is identical with that of amoebic dysentery, but as it may develop in chronic cases and long after the onset of dysentery, it is not uncommon among individuals who have returned to Europe from the tropics. Chronic alcoholism is an important, but not an essential, predisposing cause.

Amoebic dysentery was very common during the Great War in Gallipoli, Egypt, Mesopotamia and India. Treatment with emetine was not always continued for a sufficient period, especially at the beginning of the Gallipoli epidemic, and as a considerable number of slight cases must have escaped treatment altogether, hepatitis, especially the chronic non-suppurative form, is still seen in England in 1928 among men who had served in the East between 1915 and 1919.

Pathology.—The amoebae, which collect in the thrombosed veins at the base of dysenteric ulcers, pass to the liver by the portal vein. Nothing more is known as to the pathology of non-suppurative amoebic hepatitis, as death does not occur unless an abscess forms, but the infection appears to be widespread and uniform through the liver. An abscess forms if a local accumulation of amoebae gives rise to thrombosis in a portal radicle. The circulation is obstructed and necrosis of the surrounding tissue occurs; at the same time pus is secreted as a result of the irritant action of the amoebae on the liver tissue. The wall of the abscess is at first formed by necrotic liver tissue, but the cavity gradually becomes limited by a fibrous capsule produced by the inflammatory reaction.

In 70 per cent. of cases a single abscess is present; in nearly half of the others there are 2 abscesses, in a quarter there are 3, and in the remainder there are 4 or more. A single abscess is found five times as often in the right as in the left lobe of the liver.

The pus generally contains amoebae, but no bacteria; in chronic cases all the amoebae may have died, but they can still be found in the material obtained by scraping the wall of the abscess. In rare cases an amoebic abscess becomes spontaneously sterile, and its dried remains have been found at a post-mortem examination years afterwards. When an hepatic abscess reaches the surface, adhesions form between the liver and the adjoining

structures, so that the contents of the abscess may burst into the lung, stomach or bowel, or open externally without infecting the serous cavities.

Symptoms.—The symptoms vary so greatly in different cases that it is convenient to describe separately the fulminating variety—in which the whole liver is riddled with small collections of pus, with no fibrous tissue separating them from the surrounding liver substance, the common subacute form, and the chronic form: but every gradation occurs between these three types. As most cases of the subacute type, including some with severe symptoms, subside completely with emetine injections, it is clear that in the early stages acute hepatitis without actual suppuration is present. The symptoms of subacute amoebic hepatitis and those of hepatic abscess can therefore be described together.

1. *Fulminating multiple abscesses of the liver.*—About one-tenth of the cases are of this type in India, but it rarely, if ever, occurs outside the endemic areas. There is always a definite history of dysentery, which is often still present when the hepatitis develops. The liver rapidly increases in size; it is very painful and extremely tender. Slight jaundice may be present. The temperature is high with rapid remissions, the rise being often accompanied by rigors and the fall by copious sweating. Leucocytosis is well marked. Death generally occurs between 6 and 18 days from the onset of symptoms.

2. *Subacute hepatitis and subacute abscess of the liver.*—Discomfort and a sense of weight are felt in the right hypochondrium in the slighter cases, but in the more severe ones the pain may be so great that the patient is hardly able to move, and often he is unable to lie on his left side owing to the dragging pain caused by the change of position. Pain may also be referred to the right shoulder and occasionally to the right arm, especially when the upper part of the liver is involved. The liver is enlarged and tender, but the rigidity of the abdominal muscles may be so great that it is impossible to feel its edge. Slight jaundice is occasionally present in the severer cases. The appetite is impaired or lost, and the patient rapidly becomes weak and emaciated.

The temperature is generally remittent, varying between 100° in the morning and 103° or 104° in the evening. In severe cases it remains high with only small remissions, but in more chronic cases, especially when the abscess bulges through the capsule of the liver and the tension within its cavity consequently falls, the fever is less marked; it may then be low, continued or relapsing, and may finally disappear. Copious sweating is common in the more severe cases. Moderate leucocytosis is always present, and the proportion of polymorphonuclear cells is considerably increased, especially when actual suppuration has occurred; if the percentage is less than 70, simple hepatitis and not an abscess is probably present.

The upper part of the liver is most frequently involved, and the main increase in dullness is then in the upward direction, but the lower border is also abnormally low. The lower ribs bulge and the intercostal spaces become wider; the skin may become œdematous even in acute hepatitis without suppuration. At an early stage the breath sounds become feeble and the percussion note impaired at the right base; the X-rays show that the right side of the diaphragm is abnormally high, and when suppuration occurs its movements are diminished and finally cease completely. If the diaphragm

is perforated by an abscess of the liver a pulmonary abscess or less frequently an empyema develops. In the former case large quantities of thick reddish pus are expectorated, and if emetine is given, rapid recovery generally results.

An abscess in the anterior and lower part of the right lobe produces a tender tumour in the right side of the epigastrium; the lower ribs often become prominent and the lower border of the liver can either be felt or is found by percussion to be displaced downwards. A rub may be heard when an abscess reaches the surface of the liver, but it disappears on the formation of adhesions with the anterior abdominal wall. In advanced cases the skin becomes œdematous, fluctuation is present, and the abscess may open externally just below the costal margin. Less frequently the abscess reaches the under surface of the liver, when it may rupture into the duodenum or hepatic flexure of the colon; pus is then passed per rectum and the tumour suddenly diminishes in size. The general condition of the patient immediately improves, the temperature falls, and spontaneous recovery may follow.

An abscess in the left lobe of the liver generally gives rise to a tender tumour in the epigastrium; if it becomes adherent to the anterior abdominal wall, definite fluctuation is obtained. An abscess bulging from the lower or upper surface of the left lobe is less easily diagnosed; it may escape recognition till it ruptures respectively into the stomach, when the characteristic thick reddish pus is vomited, or into the left lung or pericardium.

In some cases the X-rays show a localised increased density in the hepatic shadow, especially if the abscess is in the left lobe or if it is large and surrounded by a thick fibrous capsule. Localised subdiaphragmatic, subhepatic and retroperitoneal abscesses are uncommon complications, and general peritonitis rarely develops.

3. *Chronic hepatitis*.—The symptoms of chronic hepatitis are sometimes, but not always, preceded by a period of alternating diarrhœa and constipation, and there may be a definite history of dysentery. The patient sometimes feels ill, his appetite is poor, he loses weight and strength, and his temperature may rise to about 100° every night, but in the more chronic cases his general health is only slightly impaired and there is no pyrexia. The area of hepatic dullness is increased, especially upwards, and the lower border is felt below the costal margin. There is often a dull dragging ache in the right hypochondrium. In chronic hepatitis without any localised abscess, the whole of the liver below the costal margin is uniformly tender on palpation in contrast with the local tenderness over the gall-bladder in cholecystitis. The abdominal wall is often slightly rigid over the tender liver. The blood changes and the X-ray appearances may be similar to those of a subacute abscess, but are less marked and are often entirely absent.

Diagnosis.—The possibility of amœbic hepatitis or hepatic abscess should be considered whenever an individual, who has been in the East, is suffering from progressive deterioration in health with more or less pyrexia, especially if the latter is remittent and accompanied by chills and sweats, and if obscure abdominal symptoms are present. The possibility of amœbic hepatitis should also be considered when chronic pain is felt in the region of the liver even in the absence of other symptoms. A history of dysentery or simple diarrhœa, occurring in India, Egypt or Mesopotamia, or during the summer and early autumn of 1915 in Gallipoli, would strengthen the suspicion, which would be further increased if no emetine or only 1 or 2 injections had been

given, but the diagnosis would not be excluded in the absence of such a history. The most characteristic local symptoms are progressive enlargement of the liver, pain in the region of the right hypochondrium and in the right shoulder, and tenderness over the liver. In all cases the lævulose test shows some impairment of hepatic efficiency.

Subacute hepatitis is most commonly confused with malaria; but the rise of temperature in hepatitis is generally in the evening instead of during the day, and the liver is enlarged out of proportion to the spleen instead of vice versa, leucocytosis is present with a relative increase of polymorphonuclear cells and only 2 to 4 per cent. large mononuclear cells, in contrast with the normal or subnormal count with 15 to 20 per cent. large mononuclear cells found in malaria; the malarial parasite cannot be found in the blood, and emetine gives good results, whilst quinine fails to influence the pyrexia.

A localised tumour in the liver in a man who has been exposed to amœbic infection is generally an amœbic abscess; it is elastic or fluctuating, unlike the hard solid tumour formed by a gumma and a growth, which are unaccompanied by leucocytosis or marked pyrexia. A suppurating hydatid cyst is a much less probable diagnosis in such an individual, and in most cases eosinophilia is present, while it is absent in amœbic cases.

Prognosis.—Until 1907 hepatic abscess was the second commonest cause of death in the British Army in India, but the incidence of the disease has become much smaller since amœbic dysentery has been treated by emetine injections, and the mortality has been greatly reduced since the necessity for operation has become comparatively rare, owing to the frequency with which treatment is instituted in the pre-suppurative stage. The prognosis is best if the abscess is single, as multiple abscesses are difficult to locate and their evacuation may be impossible, especially in the rare fulminating cases.

Treatment.—In acute and chronic hepatitis without suppuration very rapid improvement follows the subcutaneous injection of 1 grain emetine hydrochloride on 12 or more consecutive days; the hepatic tenderness diminishes within 8 hours of the first injection, and the temperature may fall to normal in 24 hours. As there are no definite signs which distinguish hepatitis without suppuration from hepatic abscess, unless a definite tumour is present, no local treatment should be adopted until emetine injections have been given daily for a week without producing any improvement. Even a small abscess may be completely absorbed without aspiration after the amœbæ in its walls have been killed by subcutaneous injections of emetine.

The most satisfactory treatment of an abscess is evacuation by aspiration, emetine being injected subcutaneously in order to kill the amœbæ in the abscess wall and in any ulcers which are still present in the colon. If the pus reaccumulates, a grain of emetine hydrochloride dissolved in an ounce of water should be injected into the abscess cavity after it has been aspirated. The results with this treatment are so successful, that the open operation, which is frequently followed by prolonged convalescence or death owing to secondary infection, is now only required in the comparatively rare cases, in which the situation of the abscess cannot be determined or bacteriological examination of the pus obtained by aspiration shows that the abscess already contains pyogenic bacteria.

When an abscess has ruptured into the lung, stomach or bowel, subcutaneous emetine injections should be continued until the temperature has

remained normal for a week. Recovery generally takes place without aspiration or drainage becoming necessary.

CIRRHOSIS OF THE LIVER

Synonyms.—Portal or Multilobular Cirrhosis.

Definition.—The portal or multilobular form of cirrhosis of the liver is so much the most common that it is generally described shortly as cirrhosis of the liver. It is a disease in which degeneration of the hepatic cells occurs in association with fibrosis spreading from the portal spaces to enclose various numbers of lobules.

Ætiology.—Cirrhosis of the liver is generally fatal about the age of fifty ; but a distinct group of cases occurs in childhood. It is three times more common in men than in women, but only slightly more so in boys than in girls. It is more common in individuals who follow a sedentary occupation than in those who lead an active life, and among the poor than the well-to-do, though since the Great War it has become less common among the former and more common among the latter.

A large majority of patients with cirrhosis of the liver have indulged excessively in alcohol ; it is three times more common among people connected with the liquor trade than among the general public. Cases occur, however, especially in Indians and Egyptians and in children, in whom alcoholic excess can be excluded with certainty. Thus, cirrhosis is not infrequent among Brahmins, the majority of whom indulge in large quantities of ginger, cardamoms, red pepper and other spices, but never touch alcohol. It is probable, therefore, that excessive indulgence in highly seasoned food may lead to cirrhosis. I have seen a typical case with severe ascites in a lady of 30, who was teetotal and had always taken an ordinary diet.

Pathology.—Cirrhosis very rarely develops experimentally in animals as a result of chronic alcoholic poisoning, although fatty changes and occasionally necrosis with a slight degree of small-celled infiltration may be produced. It occurs in less than 3 per cent. of drunkards dying from the effect of alcoholism, and its geographical distribution does not correspond with that of chronic alcoholism, cirrhosis being rare, for example, in Scotland and Ireland ; and when excessive indulgence in alcohol leads to nervous or cardiac symptoms the liver is rarely involved. It is probable, therefore, that alcohol produces cirrhosis of the liver indirectly by leading to gastro-enteritis ; the poisons produced in the stomach and intestines are absorbed and pass to the liver. As ordinary gastro-enteritis does not lead to cirrhosis, an additional factor must be present. This is probably the direct poisonous action of alcohol and occasionally of other toxins, such as those of amoebic dysentery, typhoid fever, malaria and congenital syphilis, on the liver cells, which are thus made more liable to injury by gastro-intestinal toxæmia.

Cirrhosis of the liver may result from the action of other poisons which reach it from the spleen. This is the cause of Banti's disease, in which a terminal cirrhosis of the liver develops in a patient with splenic anæmia, as the liver does not become affected if the spleen is removed at a sufficiently early stage.

It is probable that the poisons which cause cirrhosis of the liver lead both

to degeneration of the hepatic cells and to irritative hyperplasia of the connective tissue; the degeneration of the hepatic cells is increased by the connective-tissue hyperplasia, which in turn is exaggerated by replacement fibrosis due to the atrophy of the hepatic cells.

The size of the liver varies greatly; it may be much smaller or much larger than normal. The large liver is due to compensatory hyperplasia of the liver cells, and to a less extent to fatty change in them.

The surface of the liver is irregular. The projections may be as small as those of a granular kidney, but more frequently they give rise to a hob-nailed appearance.

The obstruction to the intrahepatic branches of the portal vein produces a rise in pressure in its tributaries; this results in dilatation of the collateral circulation which normally exists between the portal and general venous systems. This compensatory circulation is carried out by the following groups of vessels:

1. An anastomosis may develop within the liver between the branches of the portal vein and the intralobular veins. Large branches pass from the liver and its capsule to the phrenic and intercostal veins, where the liver and diaphragm are uncovered by peritoneum. Occasionally a single large vein passes from the liver in the falciform ligament by the side of the obliterated umbilical vein to join the veins of the abdominal wall at the umbilicus; the subcutaneous veins around and above the umbilicus are consequently dilated, and a large bunch of dilated veins—the *caput Medusæ*—may form at the umbilicus.

2. The gastric veins anastomose with the oesophageal veins, which open into the azygos veins; the veins in the lower end of the oesophagus may become greatly dilated.

3. The inferior mesenteric vein communicates through the superior and middle hæmorrhoidal veins with the inferior hæmorrhoidal vein, which is a branch of the internal iliac vein; this might be expected to give rise to hæmorrhoids, but they are hardly more common among patients with cirrhosis than in individuals with healthy livers.

4. The veins of Retzius unite the radicles of the portal veins in the intestines and peritoneum with the inferior vena cava and its branches. These include the retro-peritoneal veins, which are often greatly enlarged, especially in the neighbourhood of the kidneys.

Symptoms.—About 50 per cent. of patients with cirrhosis of the liver die from some intercurrent disease or accident. Such cases are generally described as latent; but in the majority symptoms due to the condition were probably present before death, and the fatal result of the intercurrent disease or accident was often due to the diminished power of resistance which results from cirrhosis. In some cases, however, the disease may be genuinely latent, owing to compensatory hyperplasia of the liver cells and to the development of an efficient collateral circulation between branches of the portal vein and systemic veins.

In a large majority of cases symptoms of alcoholic gastritis are present for a considerable period, which may amount to years, before any definite evidence of cirrhosis of the liver appears. The patient habitually wakes in the morning with a feeling of nausea and no desire for breakfast; violent retching often occurs, and he then vomits a small quantity of alkaline watery

fluid, after which some bile-stained mucus may appear. A sense of uncomfortable fullness is also felt in the epigastrium after other meals, and the nausea and vomiting may recur. The appetite is poor, and there is a special repugnance for meat. When cirrhosis develops, the symptoms due to catarrh are exaggerated by the congestion of the gastric mucous membrane caused by portal obstruction; this leads to the secretion of still more mucus, and by preventing absorption of gas leads to flatulence, which aggravates the feeling of distension already present.

The complexion is generally sallow and bloated, with dilated capillary or arterial angiomata, especially over the nose and cheeks. In the later stages, the face is drawn, the cheeks and eyes are sunken, and the conjunctivæ are congested and often slightly tinged with bile. The skin of the body is dry and inelastic; numerous spider angiomata appear on the face, neck and back as the disease progresses, and red or purple areas of skin may be produced by the uniform distention of small venules. Purpura and various forms of erythema may occur.

The tongue is flabby and furred, the gums readily bleed, and pharyngitis is common owing to chronic irritation by alcohol. The breath is often offensive as a result of oral sepsis.

The patient is generally constipated, owing to weakness of the intestinal musculature, and to dryness of the feces if ascites is present; but there may be attacks of diarrhœa, especially during the last few weeks of life.

In a large proportion of cases the liver is enlarged. Its lower border can generally be felt below the costal margin in the right nipple line; but ascites and occasionally flatulent distension of the intestines or obesity may render it impalpable. It is always abnormally firm; its edge can consequently sometimes be felt, even when it is not enlarged, by the fingers dipping under the costal margin. In rare cases, an enlarged liver can be observed to shrink as the disease progresses, until it ceases to be palpable, and after death it may be found to be considerably smaller than normal. In the early stages the enlargement may be partly due to congestion; a drinking bout may thus cause a rapid increase in size, which disappears with treatment. The irregular surface of the liver can occasionally be recognised by palpation.

Discomfort is often felt in the right hypochondrium; but pain only occurs if the disease is complicated by an attack of perihepatitis. The discomfort is increased, and tenderness is present, if the capsule is rapidly stretched as a result of acute congestion.

In about 35 per cent. of cases jaundice occurs. It is generally slight and is often transient. Well-marked jaundice is generally due to gastro-duodenal catarrh; but in subacute cases it is probably a result of inflammation of the small intrahepatic bile-ducts. Even in the absence of jaundice van den Bergh's test may give a positive direct reaction, indicating that some bile pigment has been re-absorbed owing to incomplete obstruction of the ducts.

In 80 per cent. of cases the spleen is enlarged; owing to its hardness it is easily felt, unless it is obscured by ascites or intestinal flatulence, when its enlargement can be recognised with the X-rays. Discomfort or actual pain may result from stretching of the capsule if rapid enlargement occurs; more frequently it is due to perisplenitis. When both the liver and spleen are much enlarged, the left lobe of the former may overlap the latter.

Hæmatemesis occurs in about 25 per cent. of all cases of cirrhosis. It is

generally an early symptom, and is often the first indication of the presence of serious disease, though it is most frequently preceded by symptoms of gastritis. It is uncommon after ascites has developed. Occasionally it is directly preceded by a period of increased indigestion, which may be associated with fever and enlargement of the spleen; in such cases the patient often feels more comfortable and the spleen diminishes in size after the hæmorrhage. The hæmatemesis generally takes the form of a single large hæmorrhage; but sometimes a smaller quantity is vomited during the next few days. It is generally only repeated after a considerable interval.

The blood collects slowly in the stomach, and often passes into the intestine, causing melæna without hæmatemesis. When a considerable quantity has collected in the stomach, the distension causes it to be vomited: small quantities are not brought up unless vomiting occurs from some independent cause. The blood collects more slowly than in gastric ulcer, and is therefore generally more clotted and darker, as there is more time for digestion to occur; for the same reason fainting occurs less frequently. Death from hæmatemesis is very unusual in cirrhosis, and accounts for less than 5 per cent. of the mortality.

In the majority of cases hæmorrhage results from the rupture of varicose œsophageal veins, which form in the development of the collateral circulation. Occasionally superficial ulceration occurs over a vein. The dilated veins occur in the lower 3 inches of the œsophagus; the blood consequently runs into the stomach, though in severe cases it may well up directly from the œsophagus. In rare cases the hæmorrhage comes from a varicose vein of the stomach, or from the congested pharynx; in the latter case the blood is swallowed and then vomited. The hæmatemesis may be due to minute erosions associated with acute gastritis: they are often very difficult to discover post mortem, and there may perhaps be no actual loss of surface, the hæmorrhage corresponding with the bleeding which occurs from other mucous membranes and under the skin as a result of the toxæmia.

Epistaxis is common. The hæmorrhage generally comes from a point on the anterior part of the septum. In the late stages oozing from the nose may occur, as well as from the gums, lungs, kidneys and uterus, as a result of the toxæmia caused by hepatic insufficiency, and small hæmorrhages often occur under the skin. Hæmoptysis, however, is generally due to the cirrhosis being associated with pulmonary tuberculosis.

Ascites is present in most cases of cirrhosis which run their full course; it is a late symptom in uncomplicated cases, and is often absent if the patient dies from some independent cause or from hæmatemesis at a comparatively early stage. The onset is generally gradual, but it occasionally develops suddenly after a blow on the abdomen, a chill, or an acute infection, such as influenza; it is also acute if portal thrombosis occurs. It sometimes disappears spontaneously shortly before death.

Ascites is due in part to portal congestion, as the intrahepatic branches of the portal vein are compressed, some being completely obliterated; occasionally others are thrombosed, and in rare cases thrombosis of the portal vein itself occurs. This is not the sole cause of ascites, as the fluid may collect with extreme rapidity instead of *pari passu* with the changes in the liver, and it is often absent when the portal pressure is high, as shown by the occurrence of hæmatemesis; moreover, it is often present when the

collateral circulation is well developed, although this should prevent it. In uncomplicated cases the ascites is probably always in part due to the lymphagogue action of toxins normally destroyed by the liver, which increase the flow of fluid into the peritoneal cavity by injuring the vessel walls.

In many cases ascites is a result of chronic perihepatitis, or of more generalised chronic peritonitis, which may be due to irritation of the peritoneum by toxic substances present in the ascitic fluid or to chronic alcoholism.

The ascitic fluid is clear and sometimes slightly bile-stained. Its reaction is alkaline, its specific gravity between 1008 and 1015, and a large proportion of the cells it contains are endothelial. When the ascites is due to chronic peritonitis the specific gravity is greater than 1015, more albumin is present, flakes of fibrin may form on standing, and polymorphonuclear cells are found. When 50 per cent. or more of the cells are lymphocytes, tuberculous peritonitis is probably present. In rare cases the ascites is chylous or chyloform; still more rarely it is hæmorrhagic.

Edema of the ankles is frequent, but it is rarely very marked, though occasionally it spreads up the legs to the abdomen and back. It may develop before or at the same time as the ascites, in which case it must be toxic in origin, but most frequently it follows it and is caused by pressure of the ascitic fluid on the inferior vena cava and the abdominal lymphatics; it rapidly diminishes when the abdomen is tapped.

Muscular weakness and loss of energy may be the earliest symptoms; they are constant in the late stages. The muscles are flabby and atrophied, and marked wasting of the whole body occurs.

The urine is diminished in quantity and the specific gravity is high. It is very acid and high-coloured, and a large deposit of urates generally forms on standing. It contains excess of urobilin, but even when slight jaundice is present bile-pigment is often absent. In the late stages the percentage of nitrogen excreted as ammonia increases at the expense of urea; this is due to ammonia being required to unite with the excess of organic acids present, and not to inability of the liver to form urea, as ammonia given by the mouth is still excreted as urea. In the last days of life leucin and tyrosin are sometimes found.

Albuminuria is occasionally present as a result of intestinal toxæmia, granular kidney, or, much more rarely, chronic parenchymatous nephritis, or congestion of the kidneys from heart failure. Glycosuria is rare, as the glycogenic function of the liver is maintained to a certain extent even in advanced cases, but the lævulose test for hepatic efficiency shows some impairment throughout the course of the disease.

The blood pressure is generally low, and in the later stages the heart may be dilated and the pulse rapid. The blood is generally normal, except when severe hæmorrhages have led to secondary anæmia. I have seen two cases in which the secondary achlorhydria caused by the associated alcoholic gastritis led to the development of typical Addison's anæmia.

The temperature is often raised in rapidly progressing cases, apart from complications, such as tuberculosis, pleurisy, infective endocarditis or gastro-enteritis.

In the late stages of cirrhosis, the toxæmia which results from hepatic insufficiency gives rise to restlessness, irritability and low, muttering delirium, and finally to coma.

Nervous symptoms may also be present as a result of chronic alcoholism. Delirium tremens may follow a drinking bout and occasionally hæmatemesis; slight mental disturbance and muscular tremor are not uncommon, but alcoholic neuritis is a rare complication.

Active tuberculous disease is found more frequently in patients dying with cirrhosis of the liver than with other diseases. This is probably due to the diminished resistance to tuberculous infection caused by chronic alcoholism. The lungs are most often affected, phthisis being the cause of death of 15 per cent. of cases of cirrhosis, and tuberculous pleurisy is not uncommon. Either the cirrhosis or the phthisis may give rise to no characteristic symptoms, being only discovered at the autopsy.

Tuberculous peritonitis is found in 10 per cent. of cases; the ascites which it produces is often thought during life to be due to the cirrhosis. The lungs are generally also involved. The majority of cases of tuberculous peritonitis in adult males are associated with cirrhosis.

Diagnosis.—A regularly enlarged, hard liver in an alcoholic individual, especially if symptoms of gastritis are present, is generally due to cirrhosis. The occurrence of hæmatemesis, enlargement of the spleen, slight jaundice, or simply a positive direct van den Bergh reaction, makes the diagnosis still more probable, especially if the lævulose test shows the presence of hepatic insufficiency. The enlarged hard liver, which is produced by the chronic venous congestion in heart failure, may be difficult to distinguish from cirrhosis, if the patient is seen when the heart is no longer failing. A history of heart failure with pain in the hepatic region and any evidence of existing heart disease point to congestion. The difficulty is greatest when the patient is alcoholic and the heart failure is the result of alcoholism. In such cases I have always found the ankle-jerks are absent when congestion is the cause, the heart failure being apparently due in part to vagal neuritis, whereas the ankle-jerks are almost always present and there is rarely any other evidence of latent alcoholic neuritis when the enlargement of the liver is caused by cirrhosis.

The diagnosis from syphilis and from malignant disease of the liver is discussed elsewhere (p. 615 and p. 648).

Splenic anæmia with hæmatemesis can be distinguished from cirrhosis by the much greater enlargement of the spleen and the presence of leucopenia. It must, however, be remembered that splenic anæmia is liable to give rise to cirrhosis of the liver.

The symptoms in the last stages are often indistinguishable from those of uræmia, and the diagnosis may be very difficult in the absence of a full history; but a high blood-pressure, increased blood-urea, albuminuric retinitis or the presence of a large quantity of albumin with casts in the urine would prove that uræmia was present.

Prognosis.—If an individual with cirrhosis permanently gives up alcohol in the pre-ascitic stage, there is a good chance that the disease will not progress and that his symptoms will disappear. Even the damage done to the liver can be repaired to some extent by hyperplasia of its cells, and the danger of hæmatemesis, together with the other ill-effects of portal congestion, may be overcome by a sufficient development of the anastomoses between the portal and general venous systems.

Much, therefore, depends upon the patient's character, as, if he is unable

to control his desire for alcohol, the disease is certain to advance to a fatal issue. The younger the patient the more chance there is for functional compensation to occur, but the prognosis is always bad in children. However completely latent the disease may become, much of the damage to the liver is of course permanent, and the patient's power of resisting acute infections and all other diseases is materially reduced.

Hæmatemesis in itself is not a serious symptom, as it is very rarely fatal.

When ascites is present, if it is due to the cirrhosis, the prognosis is very bad, and the patient rarely survives the performance of paracentesis on more than two or three occasions. If, however, it is due to chronic peritonitis, it is much less serious, and the accumulation of fluid may eventually cease.

Fever is a serious symptom, as it indicates rapid advance of the disease, or the presence of some complication. The development of the typical cirrhotic facies, together with a loss of subcutaneous fat and atrophy of the skeletal muscles, is a very serious symptom. When the patient becomes drowsy, death is certain to follow rapidly, only very temporary improvement being possible as a result of treatment. Multiple hæmorrhages under the skin or from the mucous membrane are of equally serious import.

The prognosis is much aggravated if the kidneys are diseased and unable to excrete the excess of poisons present in the blood as a result of hepatic insufficiency.

In rare cases the disease runs a subacute course, death occurring within 6 months or even in 2 months from the onset of symptoms. Such cases are most frequent in comparatively young adults who are heavy drinkers. The liver is painful and tender, fever is present, emaciation is rapid, and multiple hæmorrhages are likely to occur. Pathologically the subacute cases can be regarded as examples of subacute hepatitis.

Treatment.—Alcohol must be absolutely prohibited for the rest of the patient's life, and no medicine containing alcohol should be allowed. Curries, pickles, ginger, all highly seasoned food, vinegar, mustard, pepper, high game and ripe cheese must be permanently avoided.

Apart from these restrictions, the diet in the early stages should be that required for the treatment of the associated chronic gastritis. In the later stages, when symptoms of hepatic insufficiency are present, the diet should consist entirely of milk, milk foods, vegetable purées and fruit, and even when improvement occurs very little animal food should be allowed.

Gastric lavage is often useful for the gastritis; as this improves, free hydrochloric acid generally returns, but if permanent achylia has developed, dilute hydrochloric acid should be taken with water as a beverage during meals (p. 528). The bowels should be kept regular by means of Epsom salts. No other drugs are required in uncomplicated cases. The treatment of the gastritis, ascites and hæmatemesis is considered elsewhere.

The regular life led at a spa, such as Harrogate or Vichy, combined with the use of a mild aperient water, is often very beneficial.

The drowsy toxæmic condition of the late stage should be treated by means of normal saline solution given by the rectum, or, if it is not retained, subcutaneously. If the urine contains diacetic acid, sufficient sodium bicarbonate should be administered to keep the urine neutral.

HÆMOCHROMATOSIS

Synonyms.—Pigmentary Cirrhosis; Bronzed Diabetes.

Definition.—Pigmentary cirrhosis is a condition in which cirrhosis of the liver is associated with hæmochromatosis or pigmentation of the organs and in most cases of the skin. In the late stages diabetes generally develops as a result of cirrhosis of the pancreas; the condition is then known as bronzed diabetes.

Ætiology.—Bronzed diabetes is a very rare disease, which is almost confined to the male sex.

Pathology.—The cells and connective tissue of the liver, pancreas and the secreting and lymphatic glands contain a ferruginous pigment—hæmosiderin; the muscle-fibres of the heart and intestines contain an iron-free pigment—hæmofuscin. The pigmentation of the skin is due to excess of its normal iron-free pigment. It is doubtful whether cirrhosis of the liver is the primary condition, or whether it is secondary and due to irritation by the pigment. The cause of the pigmentation is unknown, as there is no evidence of hæmolysis.

Symptoms.—The symptoms are those of cirrhosis and diabetes, associated with pigmentation. The liver and spleen become progressively larger; ascites may occur and the subcutaneous veins are sometimes enlarged. The skin is generally pigmented a slaty colour, especially in the exposed parts of the body. In the rare cases in which no pigmentation is present, the nature of the disease is only discovered after death. Occasionally purpura develops. In most cases severe diabetes with acidosis appears within a year of death, sometimes acutely, but it may be absent to the end.

Diagnosis.—The disease can only be diagnosed with certainty when pigmentation, diabetes and cirrhosis are associated together. When two of these conditions are present alone, a definite diagnosis cannot be made. It can, however, be made with a considerable degree of probability if well-marked bronzing is associated with cirrhosis even in the absence of diabetes.

Prognosis.—So long as no diabetes is present the prognosis is not necessarily worse than that of uncomplicated cirrhosis, but the onset of diabetes is always a very grave event.

Treatment.—The treatment is that of cirrhosis and diabetes.

BILIARY CIRRHOSIS

A condition has been described under the name of Hanot's biliary cirrhosis, which is said to affect children and young adults, often several in a family, and to be characterised by enlargement of the liver and spleen, with chronic jaundice and febrile attacks, but rarely ascites. Though I gave the usual description of the disease in the earlier editions of this book, I have never seen a case which could be accurately described as biliary cirrhosis, and I am exceedingly doubtful whether such a clinical entity exists. The term has probably been used to include cases of splenic anaemia with cirrhosis (Banti's disease), acholuric jaundice, or ordinary cirrhosis associated with infective cholangitis, and very chronic cases of infective cholangitis. I do not therefore propose to help to perpetuate what I believe to be a clinical myth.

SYPHILIS OF THE LIVER

CONGENITAL SYPHILIS

Ætiology and Pathology.—The liver is affected in quite 50 per cent. of infants with congenital syphilis. This great frequency is probably due to the *Spirochæta pallida* passing through the placenta and the umbilical vein direct to the foetal liver, which is the first organ it reaches, and which is consequently found to contain it in larger numbers than any other organ.

Congenital syphilis produces diffuse changes in the liver very different from the focal lesions of acquired syphilis, except in rare cases occurring in later childhood, in which caseous gummata are found. The liver is smooth and uniformly enlarged, and is firmer and paler than normal. The changes are due to intercellular (unicellular or pericellular) cirrhosis, the result of diffuse infiltration with embryonic connective-tissue cells between the individual liver cells. These may be associated with small collections of round cells or miliary gummata, which resemble tubercles when seen by the naked eye.

The spleen is generally enlarged and hard. Diffuse small-celled infiltration or fibrosis may be found in the kidneys, pancreas, testes, suprarenal glands and lungs.

Symptoms.—Symptoms pointing to disease of the liver are not often present in infants with congenital syphilis; but on examination the liver and spleen are found to be enlarged and abnormally firm. The liver normally extends further down in young children than in adults, owing to its relatively larger size and the more horizontal position of the ribs. Only a very definite enlargement of the liver can, therefore, be regarded as important in the absence of other evidence of congenital syphilis. The liver may be tender, and in very rare cases a localised gumma is felt.

Jaundice is only rarely present at birth; still less frequently it develops some weeks later. It is probably caused by pressure on the small intra-hepatic ducts, and corresponds with the jaundice sometimes seen in acquired secondary syphilis.

Diagnosis.—The diagnosis is generally easy owing to the well-marked signs of congenital syphilis present in other parts of the body. In the absence of such evidence the diagnosis must be made from rickets, tuberculosis and gastro-intestinal infection, and when jaundice is present at birth the possibility of simple jaundice and of congenital obliteration of the bile-ducts must be remembered. In doubtful cases the Wassermann reaction settles the diagnosis.

Prognosis.—The prognosis depends upon the general condition of the infant. The disease is less amenable to anti-syphilitic treatment if the liver and spleen are greatly enlarged, and if hæmorrhages occur or jaundice is present. The prognosis in delayed congenital syphilis is less favourable than in acquired syphilis, owing to the changes being generally more widespread.

Treatment.—The treatment is that of congenital syphilis.

ACQUIRED SYPHILIS

1. *Secondary syphilis*.—Jaundice occurs in about $\frac{1}{4}$ per cent. of cases of syphilis at the same time as the roseola and enlargement of glands. It is probably due to obstruction of the small intrahepatic bile-ducts, caused by hepatitis, the result of poisoning with the syphilitic virus. The onset is sudden, and the jaundice is not accompanied by any gastro-intestinal or general symptoms. The liver is slightly enlarged. It is very important to distinguish true secondary syphilis of the liver from the toxic jaundice, which occasionally results from the treatment of syphilis with organic arsenic preparations (pp. 210, 382).

Recovery is generally rapid with anti-syphilitic treatment; but in very rare cases acute yellow atrophy develops.

2. *Tertiary syphilis*.—*Ætiology*.—Gummata are found in only 0·3 per cent. of autopsies; but in more than half of the cases in which other active syphilitic lesions are found the liver is affected.

Syphilis affects the liver three times as frequently in men as in women. The disease is generally discovered between 10 and 20 years after infection; but in rare instances it has occurred within a year.

Pathology.—In the early stages a mass of pink syphilitic granulation-tissue, sharply separated from the healthy liver, is found; necrosis soon occurs in the centre, which becomes yellowish-white. The caseous mass is later surrounded by a fibrous capsule; as this contracts the liver becomes more and more deformed. The capsule of the liver in the neighbourhood of a gumma is thickened, and adhesions often develop between it and the adjacent organs, the diaphragm and anterior abdominal wall. Unless they are very large, gummata are slowly absorbed till they may finally be represented by nothing more than scars, from which fibrous tissue radiates into the capsule.

Gummata are generally multiple; much less often a large part of the liver is diffusely infiltrated. The right lobe and anterior surface are most commonly affected.

Symptoms.—Gummata and cicatrices are sometimes found after death without having led to any symptoms. The nature of the symptoms they produce depends upon the size, extent and position of the lesions. Before any localising symptoms appear the patient often complains of general ill-health, which is often associated with gastro-intestinal symptoms.

The first symptom pointing to disease of the liver is generally pain in the right hypochondrium, the result of perihepatitis over a gumma. The pain may radiate to the right shoulder, and is sometimes associated with local tenderness.

Cases of syphilis of the liver may be divided into six clinical groups, according to the disease they simulate.

1. *CIRRHOSIS OF THE LIVER*.—Ascites may occur owing to pressure of gummata or cicatrices on the intrahepatic branches of the portal vein, or less frequently on the vein itself in the portal fissure, in which cases thrombosis is likely to occur; it may also result from constriction of the hepatic veins, or from perihepatitis over gummata and much less frequently from universal perihepatitis or widespread chronic peritonitis. In rare cases the fluid is chyloform or hæmorrhagic.

The diagnosis from cirrhosis of the liver is suggested by the greater irregularity in the enlargement of the liver. When there is any reason for doubt the Wassermann reaction should be tried. Hæmatemesis, dilated veins on the abdominal wall, jaundice and symptoms of gastritis are much more common in cirrhosis, and the nutrition suffers at an earlier stage than in syphilis of the liver.

2. **LARDACEOUS DISEASE.**—When a gummatous liver is associated with lardaceous disease, the clinical aspects of the latter may be so prominent that the presence of a gumma is overlooked. The liver and the spleen are enlarged, ascites and œdema are present, and the urine contains albumin and casts. It must be remembered that similar evidence of renal disease occurs in syphilitic nephritis apart from lardaceous disease; the former, unlike the latter, may rapidly improve with specific treatment.

3. **HEPATIC TUMOURS.**—Irregularities on the anterior surface of the liver produced by gummata and by the contraction of cicatrices are easily palpable. The diagnosis from malignant disease can be made by the presence of a positive Wassermann reaction and the rapid disappearance of a gumma with anti-syphilitic treatment; jaundice and ascites are much more common in malignant disease, in which the constitutional symptoms are generally more severe, and there may be evidence of a primary growth in some other situation. In hydatid disease the liver is smooth apart from the tumour itself, but in syphilis it is often irregular, owing to the contraction of cicatrices. The presence of eosinophilia points to hydatid disease. A gumma near the gall-bladder or in the left lobe of the liver may simulate a growth of the gall-bladder or of the stomach respectively.

4. **GENERAL INFECTIONS; HEPATIC ABSCESS.**—Irregular fever sometimes occurs in syphilis of the liver. The general symptoms may simulate pylephlebitis, tuberculosis, typhoid fever or malaria, but they generally disappear under anti-syphilitic treatment. In rare cases an infected gumma may break down, when the symptoms and sequelæ do not differ from those of other forms of hepatic abscess.

5. **CHOLELITHIASIS.**—Jaundice is infrequent in syphilis of the liver, but it is occasionally produced by the pressure of a gumma or of a syphilitic cicatrix; in very rare cases this is associated with attacks of pain, indistinguishable from biliary colic due to gall-stones.

6. **SPLenic ANÆMIA.**—The spleen is sometimes greatly enlarged as a result of lardaceous disease when the liver is affected with syphilis. Apart from this a condition indistinguishable from splenic anæmia with secondary cirrhosis of the liver may be associated with syphilis; but it does not respond to specific treatment, though recovery generally follows splenectomy.

Diagnosis.—The possibility of syphilis should always be remembered in obscure hepatic disorders. Apart from a history of infection, and the presence of other syphilitic lesions, the Wassermann reaction should always be tested in doubtful cases. As, however, infection with syphilis does not prove that every lesion present is syphilitic, the final proof of the nature of the disease is only obtained if great improvement or complete recovery results from anti-syphilitic treatment.

Prognosis.—The prognosis of syphilitic lesions of the liver is good, if treatment is actively carried out at an early stage. In rare cases the symptoms

are due to pressure exerted by cicatrices and not by gummata ; little or no improvement can then occur.

Treatment.—As soon as the possibility of syphilis is recognised, large doses of iodide should be given. I have very rarely found ill results follow the administration of as much as 60 grains of potassium iodide every 6 hours ; a patient is more likely to suffer from iodism if the dose is gradually increased from a small quantity than if full doses are given at once. Mercury may also be given, and full doses of a salvarsan preparation should be injected at weekly intervals until the Wassermann reaction is permanently negative ; but neither of these drugs alone leads to such a rapid disappearance of a gumma of the liver as iodides.

HYDATID OF THE LIVER

Ætiology and Pathology.—Hydatid disease is produced by swallowing the ova of the echinococcus or hydatid worm (see p. 335). Food may be contaminated by the fæces of infected dogs, or infection may occur directly if an individual touches the tongue or muzzle of a dog, which has been soiled with eggs from the fæces or anus of another dog. The frequency of the disease thus depends upon the number of infected dogs in a district. It is most common in Iceland and in parts of Australia ; it also occurs in England, France and parts of Germany and Russia, but it is almost unknown in North America, except among foreigners.

When the eggs are swallowed, the embryos set free by digestion of the egg-shell pass through the walls of the stomach or small intestine into the radicles of the portal vein, by which they reach the liver, where they are generally arrested. The embryo now forms a small cyst, with an internal, nucleated, protoplasmic layer (the endocyst) and an external "cuticular membrane." The reaction in the surrounding tissues results in the formation of a fibrous capsule. After a time a dozen or more buds project from the endocyst, and develop into daughter cysts, identical in structure with the mother cyst ; these soon separate from the endocyst of the mother cyst and become free.

The fluid in the cyst is clear or very slightly opalescent, with a specific gravity of between 1·005 and 1·010. It contains chlorides, phosphates, traces of sulphates and succinates, and some unknown toxic substances, but only occasional traces of albumin and sugar. Hooklets and less often hydatid heads may be found in the fluid.

The liver is involved in 60 per cent. of cases of hydatid disease in man ; a single cyst is generally present, but there are occasionally multiple cysts, or single ones may develop in more than one organ.

The hydatid may live for many years. When it dies the cuticular membrane folds on itself and may become calcified ; its contents dry up and form a mass containing gritty material.

Symptoms.—The patient remains in good health until the weight of the cyst, its pressure on surrounding parts, or the occurrence of a complication, such as rupture or suppuration, causes symptoms. A hydatid cyst of the liver may remain latent and be only discovered after death, or in the course of a routine examination of the abdomen in a patient without abdominal symptoms.

The increasing size of the liver may give rise to a sensation of weight and fullness in the right hypochondrium, and pain may be felt in the right shoulder. Owing to its slow growth, pressure symptoms are rare; occasionally dyspepsia, vomiting and constipation result from pressure on the stomach and intestines. Upward pressure on the diaphragm may cause dyspnoea. Jaundice caused by pressure on the bile-ducts, ascites by pressure on the portal vein, and oedema by pressure on the inferior vena cava, are extremely rare.

A small cyst may rupture into the biliary passages; intense jaundice results and the patient generally develops suppurative cholangitis. A large cyst may burst into the general peritoneal cavity, the stomach or the intestine, especially after a blow on the abdomen. Rupture may occur through the diaphragm into the pleural or pericardial cavity.

The upper part of the right side of the abdomen and lower part of the thorax become prominent when the cyst is large. If the cyst reaches the front of the liver it becomes palpable in the hypogastrium. When it projects from the under surface, the liver is pushed forward and it may simulate a large gall-bladder or a renal tumour. A cyst near the convexity pushes the diaphragm upwards, and may compress the lung and simulate a pleural effusion. In such cases the irregularity in the upper surface of the liver can be recognised with the X-rays. When deeply embedded in the liver, it produces a more general expansion and no local tumour is palpable. The tumour is generally tense and elastic. In very rare cases, of which I have only seen two, percussion of the middle finger, when the left hand is placed flat over the cyst, produces a peculiar vibration—the hydatid thrill—which is almost pathognomonic, but as it is not due to the presence of daughter cysts, having been obtained in their absence, it can also in very rare instances be observed in other tense cysts.

Bacteria may invade the fibrous capsule and multiply between it and the cuticular membrane, with the result that the nutrition of the hydatid is impaired and the parasite dies. Its death results in a change in the cuticular membrane, which, when healthy, is impervious to bacteria and leucocytes, but now allows them to pass into the fluid, which acts as an excellent culture medium and gradually becomes filled with pus cells. Symptoms of hepatic abscess are now present, and the abscess may finally rupture into the general peritoneal cavity and give rise to general peritonitis.

Diagnosis.—The discovery of a tumour of the liver should lead to a consideration of cancer, syphilis and hydatid cyst. The general health is greatly affected in the first, comparatively little or not at all in the second and third. In cancer and syphilis the tumour is likely to be irregular and multiple; in hydatid it is a uniform rounded swelling, and most frequently only one can be felt. The two former are hard and obviously solid, while the latter is elastic, and in rare cases the characteristic hydatid thrill can be felt in it. The Wassermann reaction is positive with a gumma and generally negative in the other diseases. Eosinophilia is frequent in hydatid, but in no other liver disease; it was known to have been present for eleven years when a patient, who proved to have a hydatid of the liver, first consulted me. The proportion of eosinophil cells may be enormous. In the case of a boy of 18, in whom the cyst had grown very rapidly and the legs and scrotum had become oedematous, they amounted to 65 per cent. of 16,000 leucocytes

per cubic millimetre ; the total and differential counts fell to normal within 3 weeks of the removal of the cyst. I have seen two cases of very large tumours of the right suprarenal, which produced a rounded protuberance in the front of the displaced liver, closely simulating a hydatid cyst ; the diagnosis was made more difficult by the presence of eosinophilia of 15 to 20 per cent. A doubtful diagnosis can sometimes be confirmed by a precipitin serum reaction. Some of the patient's serum is mixed with an equal quantity of stock hydatid fluid ; a precipitate forms at 37° C. in 30 per cent. of cases of hydatid, but only very rarely in the serum of individuals with no hydatid.

Prognosis.—A cyst may continue to grow for as long as 20 years. It may, however, die, shrivel up and cause no further trouble. But suppuration may occur without obvious cause at any time ; this makes the prognosis much more serious. A rapidly growing cyst is always liable to rupture. The prognosis is worst with deeply-seated cysts and cysts situated near the upper and posterior part of the liver, owing to their inaccessibility to operation, and if multiple one or more of the cysts may escape observation at the time of the operation. Rupture into the stomach or intestine may lead to spontaneous recovery, but rupture elsewhere is very serious, unless early operation can relieve the condition.

Treatment.—*Prophylactic.*—In places where hydatid disease is common, the drinking water should be boiled, fruit and vegetables should be cooked or washed with boiled water, and care should be taken not to convey infection from dogs to food by the hands.

Surgical.—Hydatid cysts were formerly treated by tapping, with or without subsequent injection of antiseptic fluids. Apart from other dangers, the escape of some of the fluid into the peritoneal cavity not infrequently led to severe urticaria, and in rare instances to epileptiform convulsions, collapse and cardiac failure. This, however, only occurred if the cyst had died, as the fluid of living cysts is generally non-toxic. Such methods have now been completely superseded by an open operation, in which the fluid is run off and as much of the cyst wall as possible is removed. This operation should be performed whenever a hydatid cyst is diagnosed, even if it causes no symptoms, as there is always a danger of serious complications arising.

MALIGNANT DISEASE OF THE LIVER

Ætiology and Pathology.—(a) *Primary growths.*—Primary carcinoma of the liver is only found about once in each thousand autopsies, and primary sarcoma is considerably rarer. Primary carcinoma may occur as a single large mass, which is sometimes associated with smaller secondary deposits in the liver. More frequently several nodules of about the same size are present, and it is then impossible to say which is primary, the condition closely resembling a liver invaded by secondary carcinoma. In comparatively rare cases the growth is diffuse, when it may infiltrate the whole of a lobe. Secondary deposits occur in other situations in more than half the cases: the disease spreads by the lymphatics to the glands in the portal fissure, which may then press upon the portal vein and bile-ducts, and other

glands in the abdomen and thorax are frequently involved; malignant emboli may pass by the hepatic veins to the lungs.

Primary carcinoma of the liver occurs most frequently as an independent disease, but in about 25 per cent. of cases it is associated with cirrhosis of the liver (*cirrhosis carcinomatosa*), although a cirrhotic liver is rarely attacked by secondary growths. The carcinoma is secondary, and due to the excessive and atypical development of the compensatory hyperplasia of the liver-cells which may occur in cirrhosis. The symptoms are those of cirrhosis, and after death the cirrhosis is found to be universal and of long standing, whereas the carcinoma appears to be of recent origin. The liver contains numerous nodules of carcinoma, which often reach the surface, but are never umbilicated. They tend to grow into the portal and hepatic veins; they thus spread through the liver and produce secondary deposits in the lungs, pleura and elsewhere, but the glands in the portal fissure are not involved. The symptoms may be indistinguishable from those of cirrhosis, the liver being normal in size or slightly enlarged. In the latter case, however, nodules can sometimes be felt on the surface. The spleen is often enlarged, and ascites is always present owing to portal obstruction. Pain in the right hypochondrium and jaundice are more common than in uncomplicated cirrhosis.

(b) Secondary growths.—Secondary carcinoma of the liver is about thirty times as common as primary carcinoma; it is ten times as common as secondary sarcoma.

Secondary malignant disease occurs most frequently after the age of 50; it is rather more common in women than men, because carcinoma is more common in women, and also because secondary deposits frequently occur in the liver with carcinoma of the breast and female genital organs, but rarely with carcinoma of the lip, mouth or tongue, which are much more common in men than in women.

The most common seat of the primary disease in cancer of the liver is the stomach, and then in order the colon, œsophagus, pancreas and gall-bladder; it is a common sequel of primary disease of the breast and uterus, and may also occur when the primary disease is situated in any other organ. Cancer of the gall-bladder, extrahepatic bile-ducts and the stomach may invade the liver by direct continuity.

Symptoms.—The liver is almost always palpable, as it is enlarged and abnormally hard. It becomes progressively larger until it may be so enormous that it appears to fill the whole abdomen, the right lobe being generally most affected. The liver is irregular in shape and individual nodules of growth are often felt to be umbilicated or depressed in the centre. Deposits of growth may be felt at the umbilicus and in the falciform ligament near the linea alba. A rub is sometimes heard over part of the liver as a result of perihepatitis.

Persistent pain is generally felt in the right hypochondrium and in the back; it may pass to the right shoulder and occasionally down the arm. It is in part due to stretching of the capsule of the liver, especially when it grows rapidly, but the most severe pain is due to perihepatitis. Occasionally deep-seated growths, especially if primary, give rise to no pain throughout the illness.

Jaundice is present in 50 per cent. of cases, owing to pressure on the

main bile-ducts within the liver by the growth or on those in the portal fissure by glands. Jaundice is more frequent and more often severe in secondary than in primary growths, especially when the primary source of the former is in the pylorus or gall-bladder, from which it has spread directly to the portal fissure. The fæces sometimes retain their colour, as the jaundice may be due to pressure on the intrahepatic bile-ducts, one or more of which escapes. The jaundice is progressive and persistent, but it occasionally develops acutely with vomiting and pain, the symptoms being indistinguishable from those of biliary colic due to gall-stones. Long-standing jaundice in elderly people is rarely due to anything but cancer of the liver.

Ascites is also present in 50 per cent. of cases. It is most commonly due to malignant peritonitis or to perihepatitis; it may also be caused by pressure on the capillaries when the liver is extensively infiltrated with growth and by portal thrombosis caused by invasion of the portal vein. The fluid is generally serous, and when jaundice is present it is bile-stained; extravasation of blood into a superficial nodule may cause it to be hæmorrhagic; in rare cases it is chylous owing to obstruction of a main lymphatic, but more frequently it is chyloform. Perforation of the organ primarily involved or infection without perforation may cause it to become purulent. Œdema of the ankles is present in the late stages, as a result of the toxæmia and cardiac weakness; more widespread dropsy may be caused by obstruction, or thrombosis of the inferior vena cava or some other large vein.

Cachectic symptoms develop as a result of the cancerous toxæmia, and also from intestinal toxæmia, which is no longer kept in check by the anti-toxic action of the liver. The patient becomes weaker and weaker; the appetite is lost, and there is often a special distaste for meat. The body weight falls progressively, but occasionally the loss of weight due to the general emaciation is more than counterbalanced by the increase in weight of the liver and the accumulation of fluid in the abdomen. The skin is inelastic and sallow, and secondary anæmia develops. It is often possible to see the liver moving slowly up and down with respiration through the wasted abdominal wall.

Fever is often present, especially in rapidly advancing cases, quite apart from the fever which may be caused by infection of the primary growth or of a necrotic secondary deposit. Suppurative cholangitis may be caused by the infection of ducts which have become dilated as a result of obstruction.

Subcutaneous and submucous hæmorrhages may result from the intestinal toxæmia; it is often associated with jaundice, though it is not directly due to the bile in the blood.

The large liver and the ascites may push the diaphragm up and compress the bases of the lungs, which are then likely to become congested, but the main enlargement is always downwards. The growth may spread through the diaphragm and cause hiccough and cough; pleurisy generally develops and often gives rise to a bloodstained effusion, but empyema is rare.

In the late stages the patient becomes somnolent and he may be delirious. Coma is generally present during the last day or two of life; respiration becomes shallower and shallower, and death comes imperceptibly.

Diagnosis.—A painful and irregular enlargement of the liver is most frequently due to a growth, and the probability is increased if general symp-

toms of malignant disease are present; if there is evidence of a primary growth elsewhere, the diagnosis can be made with certainty.

The tumour produced by cancer of the liver must be distinguished from that due to syphilis and hydatid of the liver. The shape of the liver often helps in the diagnosis, and umbilication of a tumour is conclusive evidence of cancer. The general health is much more impaired, and the patient is generally older in cancer than in syphilis or hydatid disease. A history of syphilis or evidence of its effects in other parts of the body points to a gumma, and unless a primary growth is discovered the Wassermann reaction should always be tested. Whenever hydatid disease is possible, a differential blood count should be made, as eosinophilia is frequently present, but not in the other conditions. When there is much ascites it may be impossible to diagnose between cirrhosis and cancer, especially if the patient is slightly jaundiced. The abdomen should be tapped so that the liver can be palpated; the irregularities of the cirrhotic liver are so much less marked than those in cancer that they are rarely recognisable through the abdominal wall. The spleen is generally large in cirrhosis, but normal in size in cancer, and the liver is rarely very large in cirrhosis. Pain is generally more marked in cancer, and jaundice, when present, is more profound.

The diagnosis of a growth of the liver from a displaced, but otherwise normal liver, from an enlarged liver caused by chronic venous enlargement, chronic malaria, lardaceous disease, or the impaction of a gall-stone in the common bile-duct without a previous attack of colic, and from a tumour of the right kidney, or an accumulation of fæces in the transverse colon, ought to cause no great difficulty.

Diagnosis between primary and secondary malignant disease.—In secondary cancer of the liver the primary disease is often latent, especially when it is situated in the stomach or colon. But when a thorough investigation fails to reveal a primary growth elsewhere in the body, if jaundice and ascites are absent and emaciation is slight, a single, rapidly growing tumour of the liver is more likely to be primary than secondary.

Prognosis.—Cancer of the liver is always fatal. The course of primary cancer is very rapid, as it rarely lasts more than four months, and death may even occur within four weeks of the onset of the symptoms. The duration of the illness in secondary carcinoma of the liver depends upon the primary disease, death being often due to the latter. If the primary disease has been removed by operation, or is latent, death may not occur for a year or even longer after the disease of the liver is discovered; but most cases prove fatal within six months. The disease generally advances steadily; but occasionally it may remain almost stationary for a time, and then rapidly progress to a fatal issue.

Treatment.—In very rare cases a primary growth of the liver or a growth invading it from the gall-bladder or stomach has been removed, but the disease has generally recurred, as it is impossible to tell at the time of the operation whether secondary deposits are not present in the deeper parts of the liver. It is never justifiable to operate when it is known that a growth of the liver is present; but if, during an operation for cancer of the stomach or gall-bladder, the liver is found to be involved in the immediate neighbourhood alone, an attempt should be made to remove the affected part.

The medical treatment of cancer of the liver is purely palliative,

but by means of morphine the patient should be spared pain throughout the illness. An injection of morphine should be given whenever pain is felt, and the dose should be increased as the disease progresses and the patient becomes accustomed to the drug. There is no reason to fear giving very large doses several times in the day, as with their aid patients often feel perfectly happy and comfortable up to the end. Acetyl-salicylic acid is also useful, especially in the early stages. The bowels should be kept regular by drugs, such as infusion of senna pods, the dose of which generally requires to be increased as more morphine is given. The patient should be allowed to eat and drink exactly what he likes, and no restrictions should be made on account of the supposed indigestibility of certain articles of food, nor should large quantities of food be forced upon a patient who has no appetite. When the diagnosis has once been made with complete certainty, frequent examinations of the abdomen distress the patient without doing any good. If the distension produced by ascites gives rise to pain, the fluid should be removed.

ARTHUR F. HURST.

DISEASES OF THE PORTAL VEIN

NON-SUPPURATIVE PYLEPHLEBITIS AND PORTAL THROMBOSIS

Ætiology and Pathology.—Cirrhosis of the liver accounts for about 30 per cent. of cases of portal thrombosis, but the latter is so rare that it only occurs in about $1\frac{1}{2}$ per cent. of cases of cirrhosis. Its occurrence in cirrhosis is due to stagnation of blood in the portal vein, associated with sclerosis of the walls caused by the local rise in blood-pressure, together with infection secondary to intestinal catarrh. Malignant disease of the liver, stomach and pancreas is the next most common cause; invasion of the veins of the affected organ leads to thrombosis, which spreads to the portal vein. Syphilitic changes in the walls of the portal vein, and non-suppurative pylephlebitis caused by spread of infection from neighbouring parts, may cause thrombosis.

Portal thrombosis may extend throughout the vein and its branches, but more frequently it is localised to the main trunk and one or more intra-hepatic branches or extrahepatic tributaries.

Symptoms.—In the presence of cirrhosis of the liver or intra-abdominal growth, especially if ascites is present, there may be no indication that portal thrombosis has occurred. If, however, the patient is in comparatively good health, sudden occlusion of the portal vein may lead to the rapid development of ascites, hæmatemesis and melæna, and the spleen becomes enlarged; when the splenic vein is occluded, the splenic enlargement is rapid and considerable. When mesenteric veins are suddenly involved, hæmorrhagic infarction results, which leads to intestinal paralysis, with severe melæna.

Diagnosis.—The sudden onset of ascites and hæmatemesis with splenic enlargement, with or without evidence of cirrhosis or intra-abdominal growth, is suggestive but far from conclusive evidence of portal thrombosis.

SUPPURATIVE PYLEPHLEBITIS

Synonym.—Portal Pyæmia.

Ætiology.—Suppurative pylephlebitis is almost always secondary to some intra-abdominal inflammatory disease, generally associated with the presence of pus under pressure. Acute appendicitis accounts for nearly half of the cases.

Pathology.—The veins leading from the source of infection to the liver, together with the trunk and intrahepatic branches of the hepatic vein, may all be involved, but the disease is generally less extensive and may be confined by firm clots to a part of the portal vein or one of its branches. The affected veins contain pus and broken-down blood clots; their walls are acutely inflamed and may give way, leading to the formation of abscesses; thus a large abscess may develop in the mesentery or behind the pancreas. The liver is almost always involved by extension to the intrahepatic portal branches, or by secondary abscesses formed from infective emboli from the part of the vein primarily affected. Innumerable minute abscesses are present, many of which may coalesce to form a honey-combed appearance or large abscesses. Superficial abscesses may rupture and lead to general or local peritonitis, which may also result from the primary disease. The infection is generally caused by streptococci, staphylococci or *B. coli*, and very rarely *B. typhosus* or *B. dysenteriae*.

Symptoms.—The onset is generally sudden, the symptoms due to the primary disease being complicated by the occurrence of a rigor or pain and tenderness over the liver. The clinical picture is eventually made up by symptoms of the primary disease, sepsis, and liver disease, with the frequent addition before death of pneumonia, pulmonary abscesses, or empyema, generally on the right side; evidence of portal obstruction is rarely present. The patient looks anxious and ill; he is sallow, and in about half the cases is jaundiced; the jaundice is generally slight, but may be severe from associated cholangitis. Fever is continuous, intermittent or remittent, and the pulse and respiration are rapid. Rigors, with profuse sweating, are common, especially in the early stages. Uniform enlargement of the liver occurs in about 60 per cent. of cases; it is often considerable. Pain and tenderness are generally present, and a rub may be heard over the liver. The spleen is only occasionally enlarged. Vomiting is common and diarrhœa may occur. Leucocytosis is common. Blood cultures are generally sterile.

Diagnosis.—The development of a septicæmic state, with rigors and enlargement and tenderness of the liver, in a patient with appendicitis or other intra-abdominal disease, is suggestive of suppurative pylephlebitis, but a correct diagnosis is rarely made. In amœbic abscess of the liver there is generally a history of dysentery, the progress of the disease is less rapid, and there may be signs of a single abscess, instead of a uniform enlargement of the liver. A history of gall-stones is much more common in suppurative cholangitis than in pylephlebitis, and jaundice appears earlier and is deeper. The diagnosis from a subdiaphragmatic abscess secondary to appendicitis may be impossible, and the two may be present together. Infective endocarditis, with enlargement of the liver and spleen without cardiac murmurs,

closely simulates suppurative pylephlebitis. Chronic malaria may also give rise to similar symptoms, but can be recognised by examination of the blood and by the improvement which occurs with quinine.

Prognosis and Treatment.—The disease is always fatal, and no treatment is of any avail.

ARTHUR F. HURST.

DISEASES OF THE GALL-BLADDER AND BILE-DUCTS

CHOLECYSTITIS

Ætiology and Pathology.—Chronic cholecystitis is an extremely common condition, though until recent years only the much less frequent acute and subacute forms were recognised.

Cholecystitis results from infection of the gall-bladder, which may be brought about in three ways. (1) Streptococci from foci of infection, such as the teeth, tonsils or appendix, may pass into the blood and be carried to the wall of the gall-bladder by the cystic artery. Thus streptococci isolated from infected teeth and tonsils in cases of cholecystitis often have a specifically selective action on the gall-bladder when inoculated into animals. (2) Bacteria present in the alimentary tract may pass into the portal circulation, from which they may be excreted in the bile and thus reach the gall-bladder. Thus *B. coli* is present in pure culture in the bile in a large proportion of cases of cholecystitis. The *B. typhosus* and *paratyphosus* also reach the gall-bladder in this way, but the mere presence of bacteria in the bile does not necessarily lead to cholecystitis, and although subacute cholecystitis is a not uncommon complication of the enteric fevers, chronic cholecystitis is a rare sequel. (3) Achlorhydria is present in over 40 per cent. of cases of gall-stones and probably with equal frequency in cholecystitis. This is due to the fact that the absence of the normal antiseptic action of the gastric juice permits the duodenum to become infected with the *B. coli* and less often with other organisms; infection then spreads up the common bile-duct and cystic duct to the gall-bladder and cholecystitis results.

Infection of the gall-bladder first leads to congestion and infiltration of the mucous membrane with lymphocytes. Necrosis of the mucous membrane of the apices of the villi may then occur; the latter become bile-stained and appear as yellow specks on a normal or congested mucous membrane, giving it a strawberry-like appearance ("strawberry gall-bladder"). The villi are gradually replaced by connective tissue, the velvety appearance of the normal mucous membrane being replaced by a smooth, grey or pigmented surface. The outside of the gall-bladder, which may look quite normal in the earlier stages, becomes grey and the walls thick and firm. Adhesions may form with neighbouring organs.

Cholecystitis may be acute, subacute or chronic from the onset, and acute and subacute cases may become chronic. Purulent or gangrenous changes may occur rapidly in the course of an acute infection, but very rarely in a chronically infected gall-bladder.

At any stage in a case of chronic cholecystitis gall-stones may develop,

but the condition may last for years and finally disappear spontaneously or as the result of treatment without the formation of any stones.

Symptoms.—The patient complains of intractable indigestion of an extremely irregular character, in striking contrast with the clock-like regularity of the pain in gastric and duodenal ulcer. As in appendicular dyspepsia, the time of onset and the severity of the pain vary greatly from meal to meal and from day to day; it sometimes begins immediately after food, and at other times it may not come until 2 or 3 hours after a meal, or it may only occur in the early part of the night. It is unaffected or only incompletely relieved by taking food and by alkalis. In most cases the patient complains of what he calls flatulence, but this is really only a sensation of fullness, which is not associated with increased fermentation, and only with eructation when it gives rise to aerophagy by causing the patient to make repeated but futile efforts to belch in the hope of relieving his discomfort.

Nausea is very common. It may occur on waking, when it is sometimes associated with vertigo, cold sweats or headaches, in which case migraine may be simulated, though the headache is not unilateral. It may be relieved by breakfast, unless eggs are eaten, when it is often aggravated. It is sometimes followed by vomiting, which gives much less complete relief than in ulcer.

Patients with ulcer generally lose all their pain in 2 or 3 days if put to bed on a strict diet, but improvement is less likely to follow in cholecystitis; the dyspepsia may, however, rapidly improve if yolk of egg and other fatty foods are excluded from the diet. Constipation is generally present, but in some cases intermittent or continuous diarrhoea of a mild grade occurs, and in rare instances profuse, watery diarrhoea heralds the onset of an acute exacerbation.

If attacks of biliary colic, whether of the abortive or acute variety, occur in association with symptoms of cholecystitis, gall-stones have probably developed.

The discomfort after meals is generally in the mid-epigastrium, but it often extends to the right and may be confined from its onset to the right hypochondrium. It is frequently associated with pain at the angle of the right scapula.

Tenderness of the gall-bladder is the most characteristic sign of cholecystitis. It is best elicited with the patient lying relaxed on his back; the fingers are then pressed beneath the right costal margin in the region of the gall-bladder. The pain is much increased when the fingers are brought into still more intimate contact with the gall-bladder by deep inspiration; at the same moment the latter is brought to a sudden end. The pain produced in this way is in striking contrast with the absence of tenderness when deep pressure is exerted under the left costal margin or a very short distance to the inner or outer side of the gall-bladder under the right costal margin. Pressure on the gall-bladder often causes nausea, which may even occur in the absence of pain.

Graham has shown that when pills of sodium tetra-iodo-phenolphthalein are taken in the evening the salt is absorbed and excreted in the bile, in which it reaches the gall-bladder the following morning. Owing to absorption of water in the mucous membrane the salt becomes sufficiently con-

centrated to throw a shadow of the gall-bladder which can be seen with the X-ray screen and a cholecystogram can be taken. A normal gall-bladder forms a uniform shadow with a uniform outline; it is not tender when directly palpated and it is freely movable, being quite independent of the shadow of the duodenal bulb, which can be seen simultaneously by giving a small opaque meal. The normal gall-bladder contracts and gets rid of the greater part of its contents an hour after a fatty meal consisting of scrambled eggs has been taken.

In simple cholecystitis the gall-bladder shadow is normal, but the visualised organ is found to be the seat of the tenderness previously discovered in the supposed position of the gall-bladder. Not infrequently the gall-bladder is found in an unusual position, and tenderness which would not otherwise have been found can then be elicited. In severe cases the outline may be deformed, or the gall-bladder is found to be adherent to the duodenal bulb. In some cases it throws a poor shadow or fills and empties too slowly.

Tenderness is also frequently present over the third to the tenth dorsal spines (Ryle), the muscles to their immediate right and the end of the eleventh rib. The upper part of the right rectus abdominis muscle is often tender and rigid; tenderness and rigidity of the lowest intercostal muscles may cause impeded respiration and a stitch in the right side of the chest.

In chronic cases there is generally no pyrexia, but occasionally the temperature rises to between 99° and 100° F. each evening, or during exacerbations of the inflammation accompanied by more marked symptoms. In acute cases the temperature is always raised, and jaundice, which is absent in chronic cases, is not uncommon owing to the participation of the common bile-duct in the inflammation.

Whenever cholecystitis is suspected an attempt should be made to obtain some of the contents of the gall-bladder for pathological examination. A sterilised Einhorn tube is swallowed up to the 23-inch mark first thing in the morning before the patient has had anything to eat or drink. The stomach is emptied and then washed out with sterile water. The tube is then slowly paid out up to 28½-inch mark, which allows sufficient length for the duodenum to be reached. Samples are aspirated every quarter of an hour until the comparatively abundant, acid, turbid and colourless fluid present in the stomach is replaced by the very small quantity of neutral or alkaline, clear, and generally bile-stained fluid present in the duodenum. The pylorus is generally passed in less than half an hour. The duodenum is washed out with sterile water, and from 2 to 4 drachms of magnesium sulphate in 25 per cent. solution are injected through the tube. This causes the gall-bladder and the bile-ducts to contract and the sphincter of the common bile-duct to relax. An abundant flow of pure bile rapidly appears; this is aspirated, and the tube is withdrawn. In the absence of gall-bladder disease the bile rarely contains any pus cells or epithelial cells and never any cholesterol crystals, but often a little mucus; it is generally sterile, but a few bacteria may be present if the duodenum has not been sufficiently washed out, especially in cases of achlorhydria, in which the duodenal contents generally swarm with bacteria. In cholecystitis the quantity of mucus is greater than normal, and columnar epithelial pus cells are often present; the bile contains bacteria, most commonly *B. coli* in pure culture, and rarely streptococci or staphylo-

cocci. In two cases of mine *B. typhosus* was isolated,—23 and 10 years respectively after typhoid fever. The presence of a yellow lipid material in the gall-bladder contents suggests the presence of a strawberry gall-bladder. Cholesterol crystals and pigment granules are rarely found in the absence of cholesterol and pigment stones respectively.

Treatment.—The majority of early cases of cholecystitis can be cured by medical treatment, and great improvement often occurs in very chronic cases. Hexamine is excreted by the bile; whereas it only acts as an antiseptic in acid urine which sets free formalin from it, the presence of bile salts makes it active in bile in spite of its alkalinity (Knott). As a maximal concentration of the drug is required, alkalis should be given simultaneously in sufficient quantity to make the urine alkaline; by this means the production of formalin in the urine is prevented and large doses can be given without irritating the bladder. A solution containing 100 to 150 gr. of hexamine in 1 oz. of water is made up, and another with 60 gr. each of sodium bicarbonate and potassium citrate in 1 oz. of water. The patient takes 4 dr. of the first solution with 1 oz. of the second three times a day, the first dose after breakfast, the second after tea and the third after a glass of water or milk on going to bed. Each day 1 dr. of the hexamine mixture is added to each dose till the full 1 oz. (100 to 150 gr.) is taken three times a day, and he continues with this quantity until all symptoms have disappeared. It is sometimes necessary to reduce the dose or to omit it altogether for a few days if the bladder shows signs of being irritated. An autogenous vaccine prepared from the *B. coli* or other organism isolated from the bile should be given.

Stasis of bile in the gall-bladder must aggravate the infection. It is fortunate therefore that thorough drainage can be assured by the oral administration of magnesium sulphate (1 to 4 dr.) in concentrated solution when fasting an hour before breakfast. This causes the gall-bladder and bile-ducts to empty their contents into the duodenum through the relaxed sphincter of the common bile-duct. Olive oil in $\frac{1}{2}$ oz. doses should be taken three times a day before meals, as it has the same effect as magnesium sulphate on the gall-bladder.

If cholesterol crystals were found in the bile from the gall-bladder, a cholesterol-free diet should be given. No eggs and nothing made from the yolk of eggs should be allowed. Butter must be used sparingly; cream, kidney, liver, sweetbread and brain are not allowed, and as little animal fat as possible should be taken.

If achlorhydria is present, hydrochloric acid should be given before breakfast and with lunch and dinner (p. 528). If hyperchlorhydria is present, belladonna should be given in addition to the olive oil before meals.

Foci of infection in the teeth and tonsils should be looked for and thoroughly treated. If the appendix is diseased, it should be removed and cholecystectomy should be performed at the same time. Apart from this, the indication for surgery in chronic cholecystitis is the failure of medical treatment after it has been thoroughly carried out for an adequate time. If it is likely that gall-stones are present, it is generally useless to delay. In all cases, cholecystectomy should be performed in preference to cholecystostomy.

GALL-STONES

Synonym.—Cholelithiasis.

Ætiology.—Clinically, gall-stones occur about twice as frequently in women as in men, but they are found post mortem about five times more often in women than men. They are very rare before the age of 15; 75 per cent. of clinical cases occur between 30 and 60, between 40 and 45 being the most common age. The most common age at which gall-stones are found post mortem is about 20 years later; they occur in about 25 per cent. of all women and 7 per cent. of all men dying after the age of 25.

Pathology.—(a) *Infection.*—Infection of the gall-bladder leads to cholecystitis. The agglutinated bacteria, precipitated mucus and cellular debris may form the nucleus of gall-stones if excess of cholesterol or bile-pigment is present in the bile, especially if the flow from the gall-bladder is less free than it should be. The nature and the path of infection have been discussed in the description of cholecystitis (p. 652). When gall-stones have once formed, the infection frequently dies out, and the bile, stones and wall of the gall-bladder may be sterile, though the latter always shows signs of old inflammation. In other cases the organisms commonly found in cholecystitis are still present.

(b) *Cholesterolæmia.*—The majority of gall-stones contain a considerable proportion of cholesterol. Normal blood contains cholesterol, which comes from endogenous and exogenous sources. The endogenous cholesterol is produced by the constant activity of the cortex of the suprarenal glands, and by the periodic activity of the corpus luteum at each menstrual period. During pregnancy the corpus luteum produces a very large quantity of cholesterol, so that the percentage in the blood gradually increases to nearly double and that in the bile to four times the normal. The exogenous cholesterol comes from certain articles of diet; it is abundantly present in eggs, and to a less extent in cream, and in liver, kidney, sweetbread and brain.

(c) *Biliary stasis.*—A stone is especially likely to form in the presence of infection and cholesterolæmia if biliary stasis is also present. This is particularly likely to occur in cholecystitis owing to partial obstruction caused by the swelling of the mucous membrane at the mouth of the cystic duct. Intermittent obstruction of the bile-ducts explains the occasional association of gall-stones with hepatoptosis, nephroptosis and general visceroptosis. Deficient exercise may also perhaps lead to biliary stasis, and in some cases there appears to be a congenital abnormality of the anatomy or neuro-muscular mechanism of the bile channels which impedes the evacuation of the bile.

By examining sections of gall-stones it is generally possible to get some idea of the history of their formation. Thus the centre of most stones is white and consists of pure cholesterol; only after the stone has reached a certain size is there as a rule any deposit of pigment or lime salts corresponding to a period of infection. Then there may be a further layer of cholesterol due to a return of cholesterolæmia owing to a second pregnancy; then another stratum of pigment and lime salts may form, and so on. A pure cholesterol stone corresponds to a pure oxalic acid or uric acid stone in the kidney, and the presence of pigment and of lime salts corresponds to that of phosphates in a urinary stone.

Symptoms.—It is rare for gall-stones to be present in the absence of symptoms. Most frequently their development is preceded and accompanied by continuous or intermittent dyspepsia. These "inaugural symptoms" are sometimes referred to as gall-stone dyspepsia: they are really due to cholecystitis (p. 652) and not to the presence of stones. Abortive attacks of biliary colic may occur independently or associated with gall-bladder dyspepsia. Typical attacks of acute colic are less frequent. They are commonly preceded by more chronic symptoms and rarely occur without any previous warning.

Many patients who suffer from gall-bladder dyspepsia, and a few who have no such symptoms, complain of short attacks of severe pain, which may occur at any time of the day or night without any obvious cause, such as an indiscretion in diet, although occasionally an attack is the direct sequel of a long railway journey, a drive in a motor-car on a bad road, or violent exercise. Attacks may occur daily or at long intervals, or there may be a series close together followed by a long spell of freedom. The patient may shiver during an attack, although his temperature never rises greatly and often does not rise at all. The shivering is occasionally accompanied by a sensation of "goose-skin," particularly in the epigastrium and right side of the upper part of the abdomen. When the pain is acute it is impossible to take a deep breath, the attempt producing a "catch" in the right side of the chest, which is very similar to what is felt in pleurisy.

Attacks of biliary colic most frequently result from impaction of the stone in the pelvis of the gall-bladder, close to or at the orifice of the cystic duct. They often occur in the night. The attack begins with extremely sudden acute pain in the epigastrium or in the region of the gall-bladder or both; it may pass through to the angle of the scapula or towards the tip of the right shoulder. The violent pain is accompanied by great restlessness, in marked contrast with the motionless state of a patient with a perforated ulcer or acute appendicitis. Some relief may be obtained by pressing upon the abdomen. The patient feels cold, but sweats profusely. Breathing is generally difficult. Nausea and vomiting almost always occur; the vomiting may give some relief. Aerophagy is generally present. The pain commonly disappears with absolute suddenness. The sudden onset and sudden cessation are especially characteristic of gall-stone obstruction in the cystic duct. There is often slight albuminuria during an attack, and constipation is complete.

Gall-stones are only passed in a very small proportion of cases. It is important to distinguish gall-stones or biliary sand from intestinal sand and concretions produced by drugs or by the administration of large quantities of olive oil. The majority of gall-stones consist of cholesterol and can, therefore, be recognised by being very light and inflammable. The rarest form of stone to be passed is a very small rounded one, which has probably traversed the normal passages during an attack of colic: as it may be the only one, a cure may result. More frequently faceted stones are passed; even if large numbers are found, it is very unlikely that all have left the gall-bladder. Lastly one, or less frequently two or three large stones, which may be formed by the agglomeration of several smaller ones, may be passed after traversing a fistulous communication between the gall-bladder and duodenum or colon. The fistula may develop very slowly without symptoms after chronic cholecystitis has led to the production of adhesions. More

frequently, the perforation appears to be sudden, and takes place during or after an attack of colic. In other cases, the fistula may be caused by the perforation of an empyema of the gall-bladder into the bowel. When a large stone traverses the whole bowel, pain is generally produced at one time near the right iliac fossa owing to obstruction in the terminal ileum. If it passes further, pain is later felt below the umbilicus and finally in the rectum, from which it may have to be dislodged by the finger. The passage may take from one to eight days.

It is generally impossible to palpate the gall-bladder during an attack of acute pain owing to the rigidity of the abdominal muscles, but when the attack passes off the tenderness generally becomes localised to the gall-bladder itself. In some early cases the gall-bladder is found to be enlarged owing to distension with clear fluid, especially if the stone is impacted in the cyst duct. Very commonly it gradually contracts on the stone or stones within it, probably after temporary dilatation, so that in long-standing cases it is rarely palpable. Even if a gall-stone passes into the common bile-duct, the gall-bladder does not become enlarged; thus a large gall-bladder in a case of chronic jaundice indicates chronic pancreatitis or a growth of the head of the pancreas or of the common bile-duct, whilst an impalpable gall-bladder suggests the presence of an impacted gall-stone.

Jaundice occurs only when a stone reaches the common bile-duct. But in 30 per cent. of cases no jaundice is present at the time of examination, though there is almost always a history of jaundice following an attack of colic, in contrast with the repeated attacks of colic without jaundice in stones in the neck of the gall-bladder or the cystic duct. The slightest yellow tinge of the conjunctivæ or a trace of bile in the urine is very valuable evidence that an attack of pain of doubtful origin is due to gall-stones. Sometimes the obstruction caused by a stone is sufficient to give rise to a positive direct van den Bergh reaction, though there is no obvious jaundice and no bile in the urine.

Pure cholesterol gall-stones are never visible with the X-rays, but when much lime salts are present, especially in thin patients, they often throw a characteristic shadow. The shadow must be distinguished from that produced by a renal calculus, a calcified tuberculous focus in a kidney, a calcified tuberculous gland or a calcareous deposit in a costal cartilage. This can now be easily done by means of cholecystography. This method also makes it possible to photograph transparent stones, as they are seen as pale areas surrounded by the dark shadow formed by the pigment filling the rest of the gall-bladder. Failure to produce a cholecystogram on two successive occasions indicates that the cystic duct is obstructed, probably by an impacted stone, or that the lumen of the gall-bladder is entirely occupied by stones.

In many cases of gall-stones there is never any pyrexia, but in a doubtful case it is advisable to have the temperature taken every half-hour during the attacks of severe pain, as the temperature often rises slightly.

Complications.—Cholecystitis is always present before gall-stones develop. Chronic inflammation often causes the gall-bladder to become adherent to the duodenum and pylorus or to the hepatic flexure. A fistulous communication between the gall-bladder and duodenum or colon may subsequently develop. In some cases inflammation may spread up the hepatic ducts or down the common bile-ducts; in the latter case the pancreatic

ducts may become infected, and chronic pancreatitis develops. In rare cases glycosuria or actual diabetes follows. Cancer of the gall-bladder is an occasional sequel of gall-stones. Acute suppuration or gangrenous cholecystitis may develop in connection with gall-stones and call for immediate operation.

Treatment.—During an attack of biliary colic the patient must remain in bed until it has terminated, and the pain should be controlled by the injection of morphine with atropine.

The early recognition and thorough treatment of cholecystitis can be regarded as a true method of prophylaxis of gall-stones.

Treatment of cholecystitis may also result in the solution or washing away of cholesterol deposited on the walls of the gall-bladder and of minute agglomerations of crystals—the basis of what might later become gall-stones. Moreover, even when definite stones are present it may cause the accompanying indigestion, the so-called gall-bladder dyspepsia, which is really due to the cholecystitis, to disappear. However, if the symptoms point definitely to the presence of gall-stones, an operation should be advised, unless on account of obesity or renal or cardiac complications the patient is a bad subject for operation. Under such conditions the accompanying cholecystitis should be treated medically, and an attempt should be made to improve the patient's condition in case an operation has eventually to be performed. Unless the case is urgent a short preliminary course of antiseptic treatment is always advisable before operating, and the liability to complications or the recurrence of symptoms is greatly reduced by the regular use of magnesium sulphate to prevent stagnation of bile after the operation. Wherever feasible cholecystectomy should be performed in preference to cholecystostomy.

BILIARY COLIC WITHOUT GALL-STONES

It occasionally happens, especially in otherwise healthy young adults of both sexes, that typical attacks of slight or severe biliary colic, generally unaccompanied by jaundice, occur in the absence of gall-stones. During an attack and for a short time afterwards the gall-bladder is found to be tender. The bile obtained through a duodenal tube from the gall-bladder is normal in every way, and cholecystography shows no abnormality, with the exception that pressure upon the visualised gall-bladder, especially in a direction from its vertex towards its neck, causes pain, and the gall-bladder is sometimes unusually large.

On abdominal exploration the gall-bladder looks healthy, but it may be tightly distended. Careful examination may show some abnormality in the anatomy of the cystic duct, which results in kinking when the gall-bladder is in certain positions, so that it may be difficult to empty it by direct pressure. The condition is analogous to Dietl's renal crises. Cholecystectomy is generally followed by permanent cure, though neither macroscopical nor microscopical examination shows any abnormality in its walls or contents.

When no anatomical abnormality is discovered, the condition is probably identical with that which gives rise to attacks of biliary colic after cholecystectomy for gall-stones or cholecystitis, and which leads to the assumption that a stone has been left in the common bile-duct, though at operation

no stone or other cause of organic obstruction is discovered. They are, I believe, caused by a disturbance of the neuro-muscular mechanism of the biliary ducts and the sphincter of the common bile-duct (Oddi's sphincter). When the gall-bladder has been removed, the common bile-duct often dilates to form a reservoir which to some extent takes its place; this can only be due to the resistance offered by the unrelaxed Oddi's sphincter to the flow of bile, corresponding with the dilatation of the œsophagus following achalasia of the cardia. It may take a long time for the neuro-muscular mechanism of the common duct and its sphincter to adapt itself to the conditions present after cholecystectomy, and during this period attacks of pain may result from temporary obstruction by the closed sphincter when the dilated common duct is attempting to empty itself.

Diagnosis.—Biliary crises can be diagnosed if, with typical attacks of colic, cholecystography shows that no stone is present and the bile obtained from the gall-bladder is normal. The tenderness of the gall-bladder present during the attack generally disappears, whereas in cholecystitis it rarely goes completely. When several attacks of colic occur after cholecystectomy has been performed for gall-stones by a competent surgeon crises of this kind are the most probable cause.

Treatment.—Regular contraction of the gall-bladder and ducts and relaxation of Oddi's sphincter can be promoted by giving Epsom salts when fasting in the morning and olive oil half an hour before meals. When this fails, the gall-bladder may have to be removed, as the obstruction is then probably due to an anatomical and not a neuro-muscular derangement. Post-operative cases can generally be relieved by Epsom salts and olive oil. They would probably occur much less frequently if this treatment was given to all patients for some months after cholecystectomy.

CARCINOMA OF THE GALL-BLADDER

Ætiology.—Carcinoma of the gall-bladder is more common among women than men. The relative frequency among women is due to the common association of gall-stones with carcinoma of the gall-bladder. Calculi are present in at least 80 per cent. of cases, and stones may have been present earlier and passed in some of the remainder.

Pathology.—Primary carcinoma of the gall-bladder may be columnar or spheroidal-celled. Columnar-celled carcinoma generally forms a papilloma projecting into the cavity of the gall-bladder; spheroidal-celled carcinoma more often infiltrates its walls and grows more rapidly. Carcinoma starts most frequently in the fundus of the gall-bladder; it may be situated in the centre of the gall-bladder, when it is likely to produce an hour-glass constriction, or at the neck, when the gall-bladder becomes distended with mucous fluid owing to obstruction to its outlet. Clinically, carcinoma of the cystic duct is indistinguishable from carcinoma of the neck of the gall-bladder.

Symptoms.—In 70 per cent. of cases there is a history of dyspepsia, probably due to cholecystitis, and much less frequently a definite history of biliary colic due to gall-stones. The first symptom of the disease itself is generally discomfort or pain in the right hypochondrium, often radiating to the right scapular region, with indigestion, anorexia and loss of weight. The

pain is generally worst after meals and aggravated by jolting. Flatulence, nausea and vomiting are common. A tumour can generally be felt; it may at first be smooth, but later becomes hard and irregular. It is generally not very tender, and there is less muscular rigidity over it than is commonly the case with an inflamed gall-bladder.

After a time secondary deposits lead to symptoms, and in some cases these are most prominent throughout, the primary disease remaining latent. Thus the liver is often large, hard and irregular from the presence of secondary deposits. Jaundice often occurs as a result of extension to the bile-ducts or compression by enlarged glands; it is occasionally remittent or intermittent, when it is generally due to catarrh or a gall-stone in the common bile-duct.

Ascites is present in about a quarter of the cases as a result of malignant peritonitis or pressure of glands on the portal vein. Extension of the growth to the pylorus or duodenum, or to the colon may lead respectively to symptoms of pyloric and intestinal obstruction. The constipation, which is generally present, tends to be replaced by distressing nocturnal diarrhoea if the pancreas becomes involved. In other cases septic complications, such as suppurative cholecystitis or cholangitis, or local or general peritonitis may occur. Death generally supervenes within 6 months of the development of definite symptoms apart from those due to the preceding cholecystitis or gall-stones.

Diagnosis.—The diagnosis is often exceedingly difficult, but the presence of a hard irregular tumour in the region of the gall-bladder with pain, anorexia and loss of weight in a middle-aged or elderly individual especially if he has had symptoms pointing to cholecystitis or gall-stones, is suggestive of a growth of the gall-bladder.

Treatment.—It is not often possible to remove a growth of the gall-bladder owing to the difficulty in making an early diagnosis. The operative mortality is high, and a very large proportion of cases recur within 6 months. Now that cholecystectomy is generally performed for gall-stones instead of cholecystostomy, very early carcinoma of the gall-bladder is sometimes discovered, and permanent recovery may follow.

CARCINOMA OF THE BILE-DUCTS

Ætiology.—In this rare disease males are affected slightly more often than females in contrast with primary carcinoma of the gall-bladder in which females are much more frequently affected.

Pathology.—The growth arises most frequently in the common bile-duct at its origin, its lower end, or in the ampulla of Vater, when a papillomatous projection into the duodenum develops. The common hepatic duct and the middle part of the common duct are next most affected, but a growth of either of the two hepatic ducts is very rare. Primary growths of the cystic duct can rarely be recognised, as at the time of death they are likely to have spread either to the gall-bladder or to the junction with the hepatic duct.

Symptoms.—The first symptom is jaundice, which develops gradually, and steadily progresses; but though the faces are clay-coloured, they generally contain a little stercobilin. Apart from loss of weight and strength, the symptoms are simply those of obstructive jaundice, but sometimes pain is felt in the epigastrium or right hypochondrium, and attacks of colic may occur.

The gall-bladder and less frequently the liver is enlarged. The primary tumour is never palpable. Ascites may occur as a result of secondary malignant peritonitis, or of pressure of glands on the portal vein. Death generally occurs within 6 months of the onset of jaundice from exhaustion or coma, but with a primary growth of the ampulla of Vater the course of the disease is generally much more prolonged and the jaundice is likely to be intermittent.

Diagnosis.—Progressive jaundice in a middle-aged or elderly man in the absence of pain, especially if the gall-bladder is enlarged, suggests the presence of chronic pancreatitis or much less frequently a growth of the head of the pancreas or of the bile-ducts; in a growth of the bile-ducts, but not in the other conditions, the faeces generally contain a trace of stercobilin. A growth arising from the duodenal mucous membrane over the biliary papilla may produce identical symptoms, but the jaundice is more often intermittent, and the disease is more frequently complicated by infective cholangitis than with a growth of the bile-duct, except when it arises in the ampulla of Vater. If a gall-stone is impacted in the common bile-duct, there is often a history of biliary colic before the onset of the jaundice, which is remittent instead of progressive, and symptoms of infective cholangitis are much more frequently present. Enlargement of the gall-bladder makes a diagnosis of gall-stones improbable, but it is also absent when the growth involves the hepatic duct. The presence of occult blood in the stools is in favour of a growth.

Treatment.—Life may be rendered more bearable as well as considerably prolonged by cholecystenterostomy if the obstruction is in the common bile-duct, or by external drainage of a dilated duct if it is at or above the junction of the cystic and hepatic ducts. In very rare cases, the growth has been excised.

ARTHUR F. HURST.

DISEASES OF THE PANCREAS

THE INVESTIGATION OF DISEASES OF THE PANCREAS

The pancreas normally produces an external secretion—pancreatic juice, and an internal secretion—insulin. The two functions are entirely independent, and in the diseases affecting the former, which are alone considered in this section, glycosuria due to deficient insulin is rarely present and never severe.

The pancreatic juice reaches the duodenum by the large duct of Wirsung and the small duct of Santorini. The duct of Wirsung runs by the side of the common bile-duct for a short distance, and then joins it to form the ampulla of Vater, a small cavity in the wall of the descending part of the duodenum, which opens in the biliary papilla. The duct of Santorini discharges through a small papilla a short distance nearer the pylorus, but in 30 per cent. of normal individuals it is not patent or is too small to perform the functions of the duct of Wirsung if the latter is obstructed. The common bile-duct is completely surrounded by the head of the pancreas in 62 per cent. of bodies; in the remainder it lies in a more or less deep groove in the gland.

It is clear from these anatomical facts that the pancreatic juice may fail to reach the intestine and deficient pancreatic digestion follow either as a result of disease of the pancreas, which inhibits the activity or actually destroys the secreting cells, or, in the 30 per cent. of people with an incompetent duct of Santorini, as a result of obstruction caused by a gall-stone in the ampulla of Vater or a growth of the ampulla or biliary papilla. The effect on digestion will obviously be the same in each case. It is further clear that in 62 per cent. of cases of chronic inflammation or cancer of the head of the pancreas jaundice will result; but, if the duct of Santorini is incompetent, jaundice accompanied by deficient pancreatic digestion may be equally well due to obstruction of the ampulla of Vater without disease of the pancreas.

The Stools in Deficient Pancreatic Digestion.—The stools are bulky and pale owing to excess of fat, the normal proportion of which in the dried faeces may be increased to 60 to 80 per cent. from the normal of 15 to 25 per cent. The pallor is still more marked in the presence of jaundice, as stercobilin is then absent or reduced in quantity. The fat is present chiefly in its neutral form, whereas normally only about 10 per cent. is unsplit; in rare cases it separates as oil, which solidifies on cooling. Microscopically oil droplets are seen, together with crystals of fatty acids and soaps, which are formed by bacterial decomposition of the undigested fat, but the proportion of neutral fat to fatty acids and soaps remains high, in contrast with the excess of the latter and small proportion of the former in chylous diarrhoea due to obstruction of the lacteals (p. 542). Meat fibres and vegetable food can sometimes be recognised with the naked eye, especially if the presence of excess of fat is prevented by giving a fat-free diet; they are always recognisable with the microscope, when the striation of the muscle fibres can also be seen. In severe diarrhoea with rapid passage through the small intestines meat may escape digestion in the absence of pancreatic disease.

The irritating products of bacterial decomposition of undigested food may give rise to diarrhoea: in such cases excess of mucus is often present.

Pancreatic Ferments in the Duodenal Contents, Faeces and Urine.—The duodenum normally contains trypsinogen, which is converted into active trypsin by the enterokinase of the intestinal juice, amyllopsin (diastase) and steapsin (lipase). Under the conditions already described in which no pancreatic juice reaches the intestine, the ferments cannot be isolated from the duodenal contents obtained through an Einhorn tube; but it is impossible to recognise with certainty a simple reduction in the quantity present, owing to the great variations which normally occur, and the technical difficulties in the quantitative estimation of the ferments. The same is true with regard to their presence in the stools, but a rough estimation of the quantity of pancreatic juice secreted can be made by estimating the tryptic activity of the faeces. On the other hand, the quantity of diastase present in the urine is fairly constant and not difficult to estimate. In destructive disease of the pancreas it is not reduced, as the ferment is apparently formed in the liver and simply excreted by the pancreatic juice. Consequently in acute pancreatitis the diastase index is increased from the normal of between 6 and 30 units to 200 or more, and in many cases of chronic pancreatitis and growth of the pancreas, especially during exacerbations which manifest themselves by increase in pain, and also in obstruction of the ducts, it is

increased to a less extent, a unit being the number of cubic centimetres of 0.1 per cent. starch solution digested by 1 c.c. of urine. The index is low in renal disease owing to deficiency in the excreting power of the kidney.

The Urine.—Although the secretion of insulin is rarely much affected in the diseases of the pancreas considered in this section, slight glycosuria or a rise in the blood sugar without glycosuria is sometimes observed; in doubtful cases this would be a strong point in favour of pancreatic disease. The diastase index has already been discussed. Cammidge's so-called pancreatic reaction is now generally recognised to be quite untrustworthy.

ACUTE PANCREATITIS

Ætiology.—Acute pancreatitis occurs most frequently in fat middle-aged individuals.

The infection generally reaches the pancreas by its ducts. Gall-stones are present or have previously been passed in about 50 per cent. of cases, and in a few additional cases pancreatic calculi have been found. In the absence of gall-stones the infection probably spreads from the duodenum, as a gastro-duodenal catarrh is often present, many of the patients being alcoholic, and occasionally a duodenal ulcer has been found. Acute pancreatitis has also been known to result from an injury, which has in most cases produced hæmorrhage into the gland, and to follow parturition.

Very rarely infection reaches the pancreas by way of the blood-stream in pyæmia and infective endocarditis, and abscesses may result from retrograde thrombosis in suppurative pyelophlebitis. Acute pancreatitis has been observed in influenza, typhoid fever and small-pox. It is also a rare complication of mumps, but suppuration and necrosis never occur in this variety.

Pathology.—Acute pancreatitis is always due to infection: obstruction of the ducts with stagnation of the pancreatic juice and reflux of bile into the pancreatic ducts being important but not essential factors. Hæmorrhages, suppuration and necrosis are found in varying proportions in the pancreas and in the neighbouring fat. Opaque white areas of fat necrosis are found in the fat of the pancreas, the retroperitoneal tissue, omentum and mesentery, and also occasionally in that of more distant parts, such as the pericardium. Bacteria, especially the *B. coli* and streptococci, can always be isolated from the inflamed gland and often from the gall-bladder. These organisms can activate the zymogens of the pancreatic juice and thus set free trypsin and steapsin, which are the active agents in the production of the characteristic necrotic and hæmorrhagic changes in the pancreas and of the fat necrosis. The peritoneal cavity often contains blood-stained fluid, especially in the lesser sac; in the later stages this fluid is infected and suppurative peritonitis may be present.

Symptoms.—Without any warning a sudden very violent pain is felt in the epigastrium. It continues without intermission, but paroxysms of still more severe pain occur from time to time. Severe pain across the back is also often present. After a short time vomiting begins and is repeated at frequent intervals; the gastric contents are first ejected, and after a time the vomit contains bile. Flatus may be passed, but the bowels are

not opened, and no sounds indicating gastro-intestinal activity can be heard on auscultation. The abdomen soon becomes distended; it is very tender on palpation, but the muscles are often not correspondingly rigid. The tenderness and rigidity begin in the epigastrium, but before long become general. In rare cases the enlarged pancreas can be felt, but the rigidity of the abdomen generally makes this impossible. Slight jaundice is occasionally present as a result of pressure of the swollen pancreas on the common bile-duct. The patient soon becomes collapsed, with a weak and rapid pulse and slight cyanosis; he appears more severely ill in the first few hours than is generally the case in acute peritonitis. The temperature is not greatly raised and may be subnormal, and leucocytosis is generally absent. Dyspnoea is occasionally observed. Glycosuria is rare, probably because death occurs too rapidly, as the diabetes produced in animals by the removal of the pancreas often does not develop until some days have elapsed. The diastase index of the urine is always raised above 100 and generally above 200.

Diagnosis.—The possibility of acute pancreatitis should be considered in all cases of acute symptoms in the upper part of the abdomen in adults, especially if the patient is an elderly, obese, alcoholic individual, who has previously suffered from symptoms which might have been due to gall-stones or gastro-duodenal catarrh. The symptoms may closely resemble those due to perforation of a gastric or duodenal ulcer, but in the latter there is generally a history pointing to the presence of an ulcer before the onset of acute symptoms; vomiting is continuous in pancreatitis, but occurs only at the onset or not at all in perforation, and the hepatic dullness does not alter in pancreatitis, but often disappears owing to the escape of gas through a perforated ulcer; and the abdominal muscles are generally less rigid in pancreatitis than in perforation. In other cases acute intestinal obstruction is simulated, but flatus generally continues to be passed, the abdomen is less distended and intestinal sounds disappear at once instead of being unusually loud at first. A rise in the diastase index to 200 or more is conclusive evidence in favour of acute pancreatitis. At the operation the discovery of fat necrosis at once makes the diagnosis clear.

The occurrence of sudden severe epigastric pain, incessant vomiting, with epigastric tenderness, and occasionally an elongated tumour in the situation of the pancreas on the third or fourth day in a case of mumps, is probably due to acute pancreatitis. Glycosuria and jaundice are extremely rare.

Prognosis.—The most acute cases are always rapidly fatal, unless an operation is performed. Some cases run a subacute course, especially if one or more localised abscesses form: the illness may then continue for a week or more with rigors and leucocytosis. Milder cases may perhaps recover or lead to chronic pancreatitis. Only one fatal case of pancreatitis due to mumps has been recorded, complete recovery generally occurring within a week without any operation being required.

Treatment.—An operation should at once be performed in all cases of acute pancreatitis, except in those complicating mumps, the pancreas being drained at the site of greatest damage. The gall-bladder also should be drained. The best results are obtained when a localised abscess is present, gangrenous pancreatitis being almost invariably fatal. The earlier the operation is performed, the greater is the prospect of recovery.

CHRONIC PANCREATITIS

Ætiology and Pathology.—Chronic pancreatitis is generally due to infection spreading up Wirsung's duct. This is most likely to occur if the pancreatic secretion stagnates owing to obstruction of the duct, especially in an individual in whom the duct of Santorini is insufficiently developed to drain the gland. A small gall-stone impacted in the ampulla of Vater obstructs the mouth of Wirsung's duct, and is therefore generally complicated by chronic pancreatitis: if it be impacted in the terminal part of the common bile-duct, this complication may also occur, especially in an individual in whom the duct is completely surrounded by the head of the pancreas.

In rare cases the duct is obstructed by a pancreatic calculus, but this is probably itself a result of catarrh of the pancreatic ducts. Cancer of the head of the pancreas and obstruction of the mouth of the common bile-duct by cancer of the ampulla of Vater or of the duodenum are generally complicated by chronic pancreatitis, as the flow of pancreatic juice is obstructed.

When no obvious obstruction is found to account for chronic pancreatitis, the disease may be due to a gall-stone which has been passed, but the infection can also ascend from the duodenum, or descend from the upper biliary passages, as non-calculous cholecystitis is sometimes present. The cases which occur in alcoholic individuals and those which follow influenza are probably secondary to gastro-duodenal catarrh, and a typhoidal infection of the bile passages probably accounts for the occurrence of chronic pancreatitis as a sequel of typhoid fever. When a chronic gastric or duodenal ulcer erodes the pancreas the neighbouring part of the gland becomes chronically inflamed.

In chronic pancreatitis the inflammation and the fibrosis to which it gives rise are mainly interlobular, coarse bands of connective tissue, often visible to the naked eye, separating the lobules of the gland from each other. The head of the pancreas is generally most affected: it is hard and somewhat enlarged.

Symptoms.—In chronic pancreatitis the normal functions of the pancreas must be more or less disturbed, but in the majority of cases no distinctive symptoms are observed, the condition being accidentally found during an operation performed for the relief of the primary disease, or at autopsy if the primary disease has proved fatal. When the secretion of pancreatic juice is deficient or absent owing to the inhibition of secretion which results from inflammation, and to the obstruction of the pancreatic ducts by the primary disease or the swollen gland itself, the stools are pale and fatty (p. 663) and diarrhoea may result. The deficient digestion causes gradual emaciation with increasing weakness, but this is generally very slow. Anorexia is sometimes present and may be extreme.

Diabetes rarely results from chronic pancreatitis, but it may occur in very chronic cases if the inflammation spreads into the lobules and invades the islands of Langerhans.

When the common bile-duct passes through the head of the pancreas, the swelling of the gland is likely to obstruct the duct and cause jaundice, the presence of which does not therefore indicate that the pancreatitis is due

to obstruction of the common bile-duct. The obstruction of the common bile-duct causes the gall-bladder to be dilated unless gall-stones are or have been present; the liver is often enlarged and abnormally hard.

Pancreatitis itself does not often give rise to pain, but severe attacks of colic are occasionally observed even in the absence of gall-stones; when present, the pain tends to radiate, as in other diseases of the pancreas, along the left costal margin, and to bore through to the muscles immediately to the left of the lower dorsal spine and to the angle of the scapula. Left-sided pain of this kind in gall-bladder disease and chronic ulcer should suggest the possibility that chronic pancreatitis is present as a complication. In rare cases the enlarged head of the pancreas can be felt just above and to the right of the umbilicus; more frequently some tenderness is present in this situation.

Diagnosis.—It is rarely possible to determine with certainty whether chronic pancreatitis is present as a complication of gall-stones or of the other conditions with which it may be associated. If glycosuria develops in such a case, it is extremely probable that the pancreas is becoming affected. The changes in the faeces, which result from the absence of pancreatic digestion, do not prove that the pancreas is affected in a case of chronic jaundice, as obstruction of the ampulla of Vater may prevent the pancreatic juice as well as the bile from reaching the duodenum, although the pancreas may be healthy. The rise in the diastase index of the urine, which may occur in chronic pancreatitis, is also only of importance in the absence of obstructive jaundice.

The possibility of chronic pancreatitis should be considered in all cases of chronic jaundice of which the cause is doubtful. Even in the absence of a characteristic history, the occurrence of attacks of pain makes it probable that gall-stones are present, especially if the gall-bladder be impalpable. In the absence of such attacks, especially if the gall-bladder be enlarged, either chronic pancreatitis or a growth is probably present. A growth is much more commonly associated with chronic pain, and emaciation and weakness develop more rapidly. It is often impossible, however, even at an operation, to distinguish between a growth of the head of the pancreas and chronic pancreatitis; only when a patient recovers completely and permanently is it possible to be certain that the condition was inflammatory.

Prognosis.—The prognosis depends upon that of the primary condition in secondary cases, and the presence of chronic pancreatitis does not alter the prognosis in operations for gall-stones. When the disease has appeared to be primary, recovery has taken place after an exploratory operation in which nothing was done. The disease is, however, likely to progress, and death to result from asthenia, unless some drainage operation is performed.

Treatment.—It is only necessary to consider the treatment of those cases which appear to be primary, as when the pancreatitis is secondary it requires no treatment beyond what is necessary for the primary disease. If jaundice does not abate within 3 months, or a shorter period if the patient rapidly loses weight and strength, an operation should be performed. If any obstruction is found, its cause should be removed when possible, and the gall-bladder should be drained if necessary, otherwise a cholecystenterostomy should be performed in order to cure the jaundice and to remove one source

of irritation of the pancreas by draining the infected bile. The operation has no ill-effects, and should therefore be performed in spite of the fact that some cases have recovered when nothing was done at the operation.

SYPHILIS OF THE PANCREAS

The pancreas is affected in 20 per cent. of cases of congenital syphilis in the new-born; in most cases the liver is simultaneously affected, and somewhat less frequently the spleen, bones, lungs and other organs. The gland is enlarged and hard owing to proliferation of the interlobular connective tissue; the gland-cells atrophy, but the islands of Langerhans escape.

Syphilis in adults occasionally gives rise to chronic pancreatitis, and much less frequently to gummata of the pancreas.

Symptoms.—The symptoms are those of chronic pancreatitis. The occurrence of diabetes in a syphilitic patient should suggest that the pancreas may be affected.

PANCREATIC CALCULI

Ætiology.—Pancreatic calculi are extremely rare. The majority of cases have occurred in middle-aged men.

Pathology.—Between five and ten calculi are generally found, but in rare cases one only, or as many as 300, may be present. They are white, yellow or brown, and vary in size from mere sand to smooth or irregularly-shaped masses, an inch or more in length. Although pancreatic juice contains no calcium carbonate, this is the chief constituent of the calculi. If they reach the ampulla of Vater, a deposit of cholesterol and bile-pigment may form over them, causing them to become externally indistinguishable from gall-stones. Calculi probably never form in a healthy pancreas, but are the result of infection of the ducts with stagnation of the secretion; thus the ducts behind the calculi are dilated and show catarrh of their walls; chronic pancreatitis is often present, but suppuration is very rare. The condition is often associated with gall-stones.

Symptoms.—In most cases the calculi have only been discovered after death. They may cause attacks of epigastric pain very similar to biliary colic, but the pain radiates along the left costal margin and may extend to the angle of the left scapula, and vomiting is generally absent; fragments of calculi may be passed after an attack. In chronic cases dyspepsia, malnutrition and the passage of fatty stools result from obstruction to the flow of pancreatic juice, and amylase disappears from the duodenal contents and stools, but is found in excess in the urine. Glycosuria sometimes develops. A stone may cause jaundice by pressing on the common bile-duct or by passing into the ampulla of Vater.

Diagnosis.—The colic caused by pancreatic calculi differs from that due to gall-stones in the pain being generally on the left instead of the right side; jaundice is less frequently present, and, owing to the large proportion of calcium they contain, pancreatic calculi form a much more definite shadow than gall-stones with the X-rays.

Treatment.—If the condition is diagnosed the calculi should be removed by operation.

PANCREATIC CYSTS

Ætiology.—The majority of true pancreatic cysts are produced by the retention of pancreatic juice owing to obstruction of the ducts by gall-stones and much less frequently by pancreatic calculi or a tumour; as obstruction also leads to chronic pancreatitis, this is almost invariably present.

A large proportion of so-called pancreatic cysts are really pseudo-pancreatic cysts, being collections of fluid in the lesser sac of the peritoneum, the foramen of Winslow having been occluded by peritonitis. About a quarter of these cases result from an injury to the pancreas, which causes the escape of blood and pancreatic juice into the lesser sac with secondary peritonitis. In the remaining cases serous fluid collects slowly owing to local peritonitis secondary to pancreatitis, the condition being analogous to a pleural effusion following pneumonia.

Pathology.—A single large pancreatic cyst may contain as much as 14 pints of fluid; in other cases there are multiple cysts of various sizes, which are often quite small. Fragments of gland substance may be found in their walls; they are sometimes in direct communication with the pancreatic duct, but in other cases the latter is obliterated. The cyst is often adherent to the surrounding parts. It may rupture into the lesser sac of the peritoneum, the general peritoneal cavity or the stomach.

The contents of true pancreatic cysts are generally turbid and dark reddish-brown or yellow in colour. The fluid is alkaline, slightly viscid and albuminous, and may contain altered blood; microscopically degenerated epithelial cells, leucocytes, and occasionally crystals of cholesterol and rarely of leucin and tyrosin are found. The pancreatic ferments are often absent, especially in old cysts.

Symptoms.—There are often no symptoms when the tumour is accidentally discovered. In other cases symptoms due to the disease which gave rise to the cyst may precede its discovery. When the cyst has reached a considerable size there may still be no symptoms, but sometimes attacks of epigastric pain, which may radiate to the left shoulder, occur; they are sometimes accompanied by vomiting, wasting and jaundice. Glycosuria is very rare.

The tumour is generally in the centre of the upper part of the abdomen, but it often extends farther to the left than the right. It does not move on deep respiration, and is only very slightly movable in each direction. As it grows it extends farther down and may finally appear to fill the entire abdomen. It is smooth, rounded and elastic; a thrill is often produced on striking it. A large cyst may push the diaphragm upwards and impede respiration. It may compress the stomach and intestines and cause indigestion and constipation; very rarely it obstructs the common bile-duct and causes jaundice, or obstructs the inferior vena cava and causes oedema of the legs.

Its relation to the stomach and colon can be readily determined by means of the X-rays after a barium meal and enema. It is first behind the stomach, but as it enlarges it generally reaches the anterior abdominal wall between the stomach above and the transverse colon below. Less frequently it comes forward above the stomach or below the transverse colon between

the leaves of the mesocolon. It generally grows very slowly, but sudden enlargement may result from hæmorrhage into it.

Diagnosis.—There ought to be no difficulty in diagnosing a pancreatic cyst from ascites, or from a hydronephrosis, enlarged gall-bladder, ovarian cyst or distended bladder. It is generally impossible to distinguish a true pancreatic cyst from a pseudo-pancreatic cyst; even at an operation the distinction may be impossible. Mesenteric cysts, however, are generally more movable than pancreatic cysts.

Treatment.—The cyst should be emptied and drained by operation. It is never wise to attempt to remove it owing to the dense adhesions which often fix it to its surroundings. The immediate results of operation are very satisfactory, but a recurrence is not uncommon.

MALIGNANT DISEASE OF THE PANCREAS

Ætiology.—Primary carcinoma of the pancreas occurs about three times as frequently as primary carcinoma of the liver, but whereas secondary carcinoma of the liver is very common, secondary carcinoma of the pancreas is three times as rare as the primary disease. In secondary carcinoma the pancreas is generally invaded by direct spread of the growth from the stomach; less frequently a small secondary deposit is found when the primary disease is situated in some distant situation. Both primary and secondary sarcoma are extremely rare.

Cancer of the pancreas occurs three times as frequently in males as in females.

Pathology.—The head of the pancreas is involved in 75 per cent. of cases, in some of which the disease probably originates in the pancreatic or biliary ducts. Cancer of the head of the pancreas obstructs the duct, which becomes dilated and occasionally forms retention cysts. The stasis of the pancreatic secretion frequently leads to chronic pancreatitis, but a pancreatic calculus is rarely present. Secondary deposits are often found in the neighbouring lymphatic glands, the liver and peritoneum, and less often in more distant organs.

Symptoms.—When the head of the pancreas is involved jaundice is generally present owing to pressure on the common bile-duct, but the latter may escape if it is not embedded in the gland. When the growth is confined to the body or tail of the pancreas there is no jaundice unless the duct is compressed by a secondary deposit. The jaundice increases until it is very intense, bile being then completely absent from the fæces. The gall-bladder is almost always distended and is generally palpable; the liver is also generally large and hard. Apart from jaundice, the symptoms are not distinctive, and in its absence a correct diagnosis is rarely made before death. Severe pain is present in most cases. It is generally left-sided and often radiates through to the back. Occasionally attacks of colic occur in the same region, especially at the onset of jaundice. Wasting is rapid in almost all cases, and the patient becomes progressively weaker. Diarrhœa may occur and the stools may have the characteristics described on p. 663.

The tumour is not often palpable, as it is deep-seated and likely to be hidden by the enlarged liver and the ascites, which is present in a third of

the cases as a result of malignant peritonitis or pressure on the portal vein. In thin patients it is, however, sometimes felt just above the umbilicus; it is hard, fixed, and sometimes slightly tender.

Diagnosis.—Unless a tumour can be felt, the diagnosis from chronic jaundice due to primary carcinoma of the common bile-duct is impossible, chronic jaundice with an enlarged gall-bladder being present in both; in primary carcinoma of the ampulla of Vater and of the duodenal surface of the biliary papilla, however, the jaundice may be intermittent, and suppurative cholangitis is a frequent complication. A calculus in the common duct may simulate growth of the pancreas; thus pain is not always present in cases of gall-stones, and colic may occur as an early symptom of a growth. It is generally possible to diagnose gall-stones from the history, and the jaundice is often intermittent instead of steadily progressive. Progressive jaundice with enlargement of the liver and gall-bladder, but with no pain or other symptoms, is generally due to chronic pancreatitis and not to a growth.

Prognosis.—Death generally occurs within 6 months of the onset of symptoms, and is rarely delayed beyond 12 months.

Treatment.—If there is the smallest doubt about the diagnosis in a case of chronic jaundice, an exploratory laparotomy should be advised. If a growth of the pancreas is found, a cholecystenterostomy should be performed in order to relieve the jaundice and thus save the patient from one of the most distressing of his symptoms. Moreover, in numerous instances, permanent recovery has followed this operation when performed for a supposed growth of the pancreas, the surgeon having mistaken chronic pancreatitis for a growth. No operation can be of any use in the absence of jaundice, even in the rare cases in which a correct diagnosis is made.

ARTHUR F. HURST.

VISCEROPTOSIS

Synonym.—Splanchnoptosis, Glénard's Disease, Enteroptosis.

Ætiology and Pathology.—Visceroptosis is most frequently due to a fall in intra-abdominal pressure, caused by weakness of the abdominal and pelvic muscles, the normal tone of which maintains the viscera in position. The tone of the abdominal muscles is often impaired by the stretching which they undergo during pregnancy and as a result of the accumulation of abnormal quantities of subperitoneal and omental fat. After parturition the sudden diminution in the volume of the abdominal contents is so great that a considerable fall in intra-abdominal pressure occurs, as the stretched muscles are at first very lax. If the patient remains in bed for a sufficient period, they gradually regain their tone, and the separated recti come together again, but otherwise they become permanently weakened. Weakness of the abdominal muscles is common among people who take too little exercise. Atrophy and degeneration of the abdominal muscles are also produced by malnutrition in rickets, anæmia and prolonged fevers.

The pelvic floor consists of a muscular diaphragm, which is formed by the levator ani together with other less important muscles. These may be damaged in difficult labour, and a slighter degree of weakness is frequently

present in addition to that of the abdominal muscles in individuals who lead a sedentary life.

When the intra-abdominal pressure is abnormally low, the viscera drop directly gravity comes into play, but at first they regain their normal position as soon as the individual lies down. At a later stage, when the daily descent of the viscera has continued for a considerable time, the displacement persists in the horizontal position.

The degree of ptosis of the different organs depends upon their weight and upon the length and elasticity of their peritoneal attachments, which, in the absence of their natural support, act as true ligaments.

True visceroptosis must be distinguished from the "hyposthenic habitus," a constitutional condition common in women, but comparatively rare in men, which is characterised by a long narrow chest and a small epigastric angle. In this the viscera are congenitally lower than in the average individual owing to the relatively small capacity of the upper part of the abdominal cavity.

Symptoms.—Most of the symptoms of visceroptosis occur only when the erect position is assumed; they consequently disappear on lying down and are absent at night; they are temporarily relieved when the lower part of the abdomen is compressed by means of the hand, and in women they frequently show a steady improvement as pregnancy advances, owing to the rise in intra-abdominal pressure and the support given to the viscera by the growing uterus. They are often worse in the latter part of the day than in the morning owing to the progressive relaxation of the abdominal muscles resulting from fatigue.

The symptoms have been ascribed in turn to the kidney, stomach, intestines or uterus, according to which happened to be the special object of study. It is certain, however, that the general effects are commonly of much more importance than those due to ptosis of individual organs.

GASTROPTOSIS.—Gastroptosis is uncommon, and even when present it is rarely the cause of symptoms. The normal stomach varies greatly in length. In the erect position it swings between the œsophagus, where it passes through the diaphragm, and the junction between the movable duodenal bulb and the descending retro-peritoneal portion of the duodenum. In a stomach of average length the umbilicus (or inter-iliac line) passes about half-way between the lesser and greater curvatures. The greater curvature of the short stomach of the hypersthenic gastric diathesis does not reach the umbilicus. On the other hand, in the long stomach, which is particularly common in individuals with a hyposthenic habitus, the lesser as well as the greater curvature is below the umbilicus, and the latter may reach the true pelvis. This condition has generally been called gastroptosis, but as it is congenital and the stomach has never occupied a higher position the name is quite inappropriate. Moreover, the long stomach is just as competent as a short one or one of average length.

When the abdominal muscles become weak, a long stomach is likely to be more affected than one of ordinary length, and a short one does not drop at all. But the gastroptosis caused in this way does not lead to kinking of the pylorus, as the pyloric end of the stomach together with the first part of the duodenum is surrounded by peritoneum and is freely movable. It may, however, give rise to a kink where the first part of the duodenum joins

the second or descending part, as the latter is situated behind the peritoneum and is normally fixed. Discomfort may then occur, which begins during the meal and reaches its greatest intensity as soon as all the food has been taken. It depends more upon the quantity than the quality of the food, milk producing just as much disturbance as an equal weight of solid food. In most cases, however, the duodenum drops with the stomach, and a considerable degree of gastropptosis may be present with little or no gastric disturbance. It is thus always necessary to note the position of the duodenum as well as that of the stomach during an X-ray examination: if the upper extremity of the duodenum is not at least an inch above the umbilicus duodenal ptosis is present.

After having determined the position of the stomach and duodenum in the erect and horizontal positions, it must next be determined whether the stomach is able to evacuate its contents in a normal manner. If the duodenum drops with the stomach, the passage of food out of the stomach and through the duodenum is generally normal in rate. This is also sometimes the case even if the duodenum has not dropped, but in the majority of cases, especially if the ptosis is well marked, it can be seen with the X-rays that although the food may pass without difficulty from the stomach into the first part of the duodenum, there is delay in the passage beyond this point.

A second examination should be made 6 hours after the opaque meal, no food having been taken in the interval. The patient should not lie down; but should follow his ordinary occupation until the second examination is made. Gastric stasis is present if the stomach still contains food at this second examination. In order to decide whether this is due to the ptosis or to some complication, such as organic obstruction of the pylorus, a second opaque meal should be given on another day, and the patient should lie on his right side in the interval between the two examinations. If the ptosis is the sole cause of the stasis, the stomach will be empty in 6 hours, and if an intermediate examination is made it will probably be found to be already empty in 3 or 4 hours. If there is no delay in the evacuation of the stomach in the erect position, indigestion is not likely to be due to the gastropptosis.

It is important to observe whether voluntary contraction of the abdominal muscles in the erect posture is sufficient to raise the stomach to its normal position, as if this is the case the prognosis is good, and abdominal exercises and massage together with the temporary use of an abdominal support will probably result in a cure. If the stomach cannot be raised to the normal position in this way, the back should be supported by the left hand whilst the lower part of the abdomen is pressed inwards and upwards with the right. In most cases this results in raising the stomach to the normal position, which indicates that an abdominal support is likely to give relief to symptoms, though it will not by itself cure the condition.

ENTEROPTOSIS (COLOPTOSIS).—Ever since Glénard drew attention to the condition he called "enteroptosis," it has generally been supposed to produce kinks of the intestines, especially at the flexures of the colon, which give rise to obstruction to the onward passage of fæces, and a pelvic cæcum and a dropped transverse colon are often referred to as if they were invariably associated with constipation. But I have seen a pelvic cæcum in almost

as large a proportion of strong healthy individuals, especially females, with perfect digestion and no constipation as of constipated patients. If visceroptosis caused obstruction at the intestinal flexures, the constipation would be associated with colic. But although much discomfort is often present in such cases, colic is rare and strong contractions of the intestines are never either visible or palpable. Moreover, chronic organic obstruction leads to hypertrophy of the intestinal musculature above the obstruction, but in operations and autopsies on cases of visceroptosis no hypertrophy is ever found.

The constipation, which is so often associated with visceroptosis, is generally due to the weakness of the abdominal and pelvic muscles and the ptosis of the diaphragm, which render the act of defæcation inefficient, so that the rectum and pelvic colon are never properly emptied. Ptosis of the transverse colon never leads to kinking at the hepatic flexure, as the cæcum and ascending colon drop with it. A definite sharp kink is occasionally produced at the splenic flexure, as the phreno-colic ligament is stronger than any other of the intestinal attachments. A dragging pain together with a sense of distension is then often felt in the left hypochondrium.

It is sometimes possible to recognise the presence of coloptosis by palpation, but accurate knowledge concerning the position of the colon and the passage of fæces through it can only be obtained by the X-rays; they are essential for the recognition of the numerous cases in which coloptosis is only present in the vertical position. It is important to remember that in the vertical position the lowest part of the transverse colon of normal individuals is almost invariably situated well below the umbilicus, even when the stomach is empty, and that in normal individuals examined with the X-rays the hepatic and splenic flexures often appear to be acutely kinked. This is the result of the shadow being cast in a single plane, as the limbs of the flexures belonging to the transverse colon are in front of those of the ascending and descending colon respectively, and the flexures appear to be acute, although they form a wide angle when looked at from the side.

The characteristic bulging of the lower part of the abdomen and retraction of the epigastrium seen on standing is due mainly to ptosis of the small intestine and is of no clinical importance.

CHRONIC DUODENAL ILEUS.—The drag of the small intestines in enteroptosis may lead to obstruction of the duodenum where it is crossed by the mesentery with the mesenteric vessels (Fig. 22). In many cases no other evidence of visceroptosis is present. The proximal part of the duodenum becomes dilated, and the violent peristalsis, which can be seen with the X-rays to give rise to backward and forward movement of its contents in its effort to pass the obstruction, results eventually in hypertrophy of its muscular coat. The condition often gives rise to no symptoms and is discovered accidentally during a routine X-ray examination, but it may cause right-sided discomfort, which sometimes simulates duodenal ulcer or gall-bladder disease; occasionally paroxysmal vomiting is the only symptom, especially in neurotic women. The duodenal stasis is probably a factor in the development of duodenal ulcer and of cholecystitis when chronic ileus is present in an individual who is already predisposed to these conditions.

HEPATOPTOSIS.—When the liver drops it rotates towards the right, or less frequently it falls forward so that its upper surface bulges in the

epigastrium. The condition can be recognised by palpation and percussion, the upper border of the hepatic dullness being abnormally low. A palpable liver is not necessarily an enlarged one, but may simply be displaced. It gives rise to no special symptoms beyond a vague pain in the right hypochondrium, which may radiate towards the shoulder; it is increased by jumping, walking and coughing and disappears on lying down. Very rarely the common bile-duct is kinked so that jaundice occurs, and gall-stones may result from the consequent stagnation of bile.

A *dropped spleen* can be easily recognised by palpation; it generally gives rise to no symptoms, but in very rare instances great pain is produced by twisting of its pedicle.

For *nephroptosis*, see p. 1236.

When the pelvic floor is weak, it allows the *pelvic viscera* to drop, and retroflexion of the uterus generally occurs simultaneously; it may also result in actual prolapse of the uterus and rectum.

Downward displacement of the *diaphragm* results in dyspnoea, as, being constantly in the position of extreme inspiration, it is no longer possible for its normal respiratory excursions to occur. This is particularly noticeable in patients with weak hearts, whose abdominal muscles have been stretched by an accumulation of ascitic fluid which has since been absorbed. The downward displacement of the diaphragm is accompanied by a similar displacement of the heart, which gives rise to no special symptoms.

Under normal conditions the abdominal wall and pelvic floor are the only support of the viscera; the peritoneal folds help to maintain them in position, but they do not support their weight. If as a result of weakness of the muscles of the abdominal wall and of the pelvic floor the viscera drop when the individual is erect, a pull

is exerted on the peritoneal folds, which become true suspensory ligaments. Their sensory nerves are constantly stimulated, the patient often complaining of vague abdominal discomfort, which is generally described as a weight or pressure or as being of a dragging nature; it is relieved by lying down and by pressure upon the lower part of the abdomen. The discomfort is most marked in neurasthenic individuals owing to the irritability of their nervous system; if the nervous system is healthy it may be completely absent. It is increased by exercise and physical fatigue and to a less extent by mental fatigue. The chronic pain aggravates the nervous depression, a vicious circle being thus produced, but neurasthenia is never a result of visceroptosis alone.

Visceroptosis leads to an alteration in the centre of gravity of the body. In order to maintain the upright position, certain muscles of the spine which

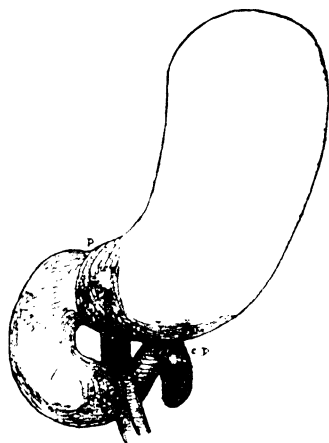

FIG. 22.—Chronic duodenal ileus. DP, dilated duodenum secondary to obstruction by MV, mesenteric vessels; P, pylorus; CD, undilated duodenum beyond obstruction merging into jejunum.

are ordinarily little used are brought into action ; this is a frequent cause of chronic backache.

The maintenance of the circulation when the erect position is assumed depends to a considerable extent upon the tonic contraction of the abdominal muscles ; when this is deficient, as it is in visceroptosis, the abdominal veins dilate and the pulse becomes abnormally accelerated on standing ; giddiness and syncope may also occur.

Treatment.—Much can be done to prevent visceroptosis and the associated constipation in women by proper management of the puerperium. The patient should remain in bed for the first 12 or 14 days after parturition, or, when much bruising has occurred, especially in the case of primiparae, for as long as 3 or 4 weeks. Most of the time during the first few days after getting up should be spent on a couch, and a return to full physical activity should only be permitted after 6 weeks.

The first indication is to raise the intra-abdominal pressure. In order to do this the condition of the abdominal and pelvic muscles must be improved. Exercise and Swedish gymnastics are of great value. It is essential to prevent the over-stretching of the muscles, which occurs whenever the erect position is assumed, as it is impossible for them to regain their normal postural tone so long as they have to bear the weight of the viscera for the greater part of every day. In many cases, therefore, a support is required until the abdominal muscles have had time to recover.

An abdominal support should fit closely to the symphysis pubis and Poupart's ligaments below ; above it should not extend higher than the umbilicus. It should be so made that it presses the abdominal contents upwards, backwards and inwards. In mild cases of visceroptosis in women all that is necessary is a special straight-fronted corset, which does not constrict the waist, but supports the lower part of the abdomen. In most cases, however, a light support, hinged in the middle line and fixed in position by steel springs, which pass over the hips to end in pads applied to the sacrum, is required.

The abdominal support should always be put on when the patient is lying down with the pelvis raised, so that the organs are held in proper position, and it should be worn all day. Not infrequently, however, the X-rays show that the stomach and colon drop on standing almost or quite as far when the support is worn as without it. This is particularly likely to occur in cases in which an organ falls into the true pelvis, as the support does not then reach low enough, and in thin patients upon whom it is impossible to exert sufficient pressure. Such a patient, however, often derives great benefit from wearing a support, although it does not hold the colon or stomach up at all. This shows that it acts chiefly by increasing the intra-abdominal pressure and that many of the symptoms ascribed to kinks are really the result of the low intra-abdominal pressure interfering with the circulation and with the proper performance of defæcation.

When visceroptosis is due in part to weakness of the pelvic floor, this may require treatment by pessaries and local operations, which have the object of restoring the injured parts to a more normal condition, but an exercise for the levator ani muscles is often of great value in such cases. The patient is instructed to perform the movement she would make were she attempting to overcome an urgent desire to defæcate. The exercise should

be repeated about thirty times twice a day while in the recumbent position. I have often seen a tendency to prolapse of the rectum and of the uterus overcome in this way, the associated dyschezia being cured at the same time.

In slight cases of gastroptosis the patient should lie down after meals, but in severe cases, in which there is much emaciation or the abdominal muscles are greatly atrophied, it is best for him to remain in bed for some weeks, as by this means the intra-abdominal pressure is reduced to a minimum, and all tension is removed from the abdominal and pelvic muscles. The foot of the bed should be raised as high as possible, as this helps the organs to return to their proper position, which is often maintained after the patient gets up again, especially if he gains weight during the rest.

He should lie on his right side during and for an hour after meals. He should only sit up to open his bowels and to wash when his stomach is empty before breakfast, and even then a pad should be bandaged over the lower part of the abdomen so that the stomach should not drop. After the complete rest is over he should continue to wear an abdominal support and should at first lie for an hour on his right side after meals.

Small meals should be given at frequent intervals, and food should be chosen which contains a maximum of nourishment in a minimum of bulk. Upward massage is useful, especially if the stomach or colon is low in the horizontal as well as in the vertical position: it is most effective if the masseuse gives her first treatment under the X-ray screen, so that she can see what manipulations are required to bring the stomach and colon back to their normal position.

In no circumstances should any operation be performed for raising dropped viscera. As it is unusual for one organ to drop alone, the effect of such operations is rarely permanent, and the neurasthenic condition of many of the patients makes surgical interference of any kind most undesirable. Short circuiting operations are very rarely required for the purpose of overcoming kinks in the alimentary canal. Gastro-jejunostomy is never followed by any improvement in cases of gastroptosis; in rare cases of severe kinking at the splenic flexure a short-circuiting operation, such as an anastomosis between its limbs, may be required, and the results obtained are generally satisfactory. When chronic duodenal ileus gives rise to definite symptoms, which do not disappear with postural treatment, abdominal exercises and a support, it may be necessary to perform a duodeno-jejunostomy. The results obtained, however, especially in neurotic patients, have not been satisfactory in my experience.

ARTHUR F. HURST.

DISEASES OF THE PERITONEUM

ACUTE PERITONITIS

Definition.—Peritonitis is the disease which results from infection of the peritoneum with bacteria. Owing to the large area of the peritoneum and its great powers of absorption the results are very severe, and because of its intimate relationship to the alimentary canal the risk of such an infection occurring is considerable.

Ætiology.—Infection may reach the peritoneum (1) from without; (2) by the blood stream; and (3) from the contained organs.

1. Infection from without is possible in the case of wounds, but is of infrequent occurrence. In most instances severe abdominal wounds injure the contained viscera also, and the consequent peritonitis is usually the result of this.

2. Infection by the blood stream is an occasional though uncommon mode of infection. In streptococcal and staphylococcal septicæmia peritonitis may occur as a terminal event; it frequently gives rise to such few symptoms, however, that its existence is unrecognised during life. When pneumococcal peritonitis complicates pneumococcal lesions elsewhere the infection is undoubtedly blood borne.

3. Infection from contained or neighbouring organs is by far the commonest cause of peritonitis. The majority of cases depend more or less directly on the passage of bacteria from within the alimentary canal owing to changes in its walls. The appendix is the most frequent seat of the primary condition. When there is no actual breach of continuity in the organ, bacteria escaping through its damaged walls generally lead to the formation of peritoneal adhesions and possibly to a local abscess. When, however, the infection is particularly virulent or the patient's resistance unusually poor, a sufficient local reaction does not take place, and spreading diffuse peritonitis results. This is commoner in children than adults, and may occasionally occur, even when the local reaction has been good, through manipulation or ill-judged surgery separating the adhesions and allowing the infection to spread. Diverticulitis and acute cholecystitis are occasional causes of this type of acute peritonitis, but more usually result in local adhesive changes. Peritonitis complicating typhoid fever in the absence of perforation, and pneumococcal peritonitis when associated with pneumococcal enteritis, have a similar origin.

In intestinal obstruction and strangulated hernia the changes which occur in the bowel wall speedily permit the passage of organisms through it to the peritoneum. This takes place first in the neighbourhood of the obstruction, but as paralysis and distension spread along the bowel, organisms can make their way through, and consequently most cases of this type are widely generalised. The infection, however, is gradual, and the reactive forces of the peritoneum have time to respond. By far the commonest organism in these cases is the *B. coli communis*, usually preceded by or accompanied by the *Staphylococcus epidermidis albus*.

Perforation of a hollow viscus into the peritoneal cavity is responsible for some of the most virulent and widespread cases of peritonitis; the lower the perforation in the bowel, the more virulent the resulting infection will be. The appendix is the commonest source, gangrene or a perforating ulcer leading to a sudden peritoneal infection before any gradual passage of organisms has had time to produce a local peritoneal reaction. Perforating ulcers of the stomach and duodenum come next in order of frequency; less common causes are perforating ulcers of the ileum, the most important of which is the typhoid ulcer, rupture of the gall-bladder, bile-ducts or ureters, and perforating wounds of any of the hollow organs, or leakage from surgical anastomoses. Abscesses of the liver, appendix, gall-bladder or Fallopian tubes occasionally burst into the general peritoneal cavity. Infection of the

peritoneum may also result by direct spread from neighbouring parts. This type of case is particularly common in women, spread taking place either directly through the Fallopian tubes, or by lymphatic permeation of the uterine walls. Peritonitis is a very rare sequel to infections of the lung and pleura, although the reverse is far from unusual. In the infant an infection of the thrombosed umbilical vein may lead to peritonitis by direct spread.

Symptoms.—As acute peritonitis is almost invariably a secondary condition, its symptoms and course are subject to very considerable variations, depending not only on the nature of the primary lesion from which it arises and on the nature and virulence of the infecting organism, but also on the general condition of the patient.

1. *Acute generalised peritonitis.*—This is usually associated with the perforation of a hollow organ or the sudden bursting of an abscess into the peritoneum, and owes its chief characters to the fact that in such cases the peritoneum is suddenly flooded with infection without any preliminary preparation. The patient may have been free from any symptoms of ill-health, and is suddenly seized with very acute abdominal pain, accompanied sometimes by a sensation of something having given way. The pain may at first be localised in position, and thus help in the diagnosis of the actual lesion; but it speedily spreads to the whole abdomen, and is followed almost at once by a feeling of syncope or collapse. Within a few minutes the patient becomes cold and pale; his features are pinched and betray the most intense anxiety; beads of sweat stand out upon the skin, and the pulse may be almost imperceptible. He complains of nausea, but does not often vomit, and his respirations are shallow and quickened. In a short time a certain amount of improvement takes place; the pulse, though rapid, is of better volume, and the pain may take on an intermittent colicky character. The abdomen is absolutely rigid, and is usually retracted, though it may be distended; it is very tender on pressure. The liver dullness is usually absent; but this is only important if an abdominal examination made at the onset of the attack revealed a normal area of dullness. These symptoms are caused by the perforation or other primary cause and the resultant flooding of the peritoneum with infective material. Occasionally they may be sufficiently severe to lead to death by themselves; but more usually they gradually merge into the symptoms of the consequent acute peritonitis itself. The latter are reactive in nature, and are due to Nature's attempts to limit the process.

The patient becomes extremely restless, this being one of the most characteristic and distressing features of nearly all forms of peritonitis. Owing to the loss of fluid by sweating, vomiting and exudation, the subcutaneous tissues become shrunken and give the patient the so-called "*facies Hippocratica*." The tongue is dry and furred, and the teeth become covered withordes. The pulse increases in rate and becomes thready and later running in character, and the temperature, which at first may be subnormal, rises. The abdomen is of a uniformly board-like rigidity and extremely tender. It is held immovable, respiration being entirely thoracic, and the patient lies with his knees drawn up to relieve the abdominal tension. There is usually absolute constipation, and the intestinal sounds are absent. Gradually the paralytic intestine becomes dilated and the abdomen distended. Vomiting is early and frequent. The vomited matter is usually only small

in quantity; it speedily becomes exceedingly foul, though it is rarely fecal, and the breath is extremely offensive. The urine is scanty and may contain traces of albumin, and its passage may produce a paroxysm of pain. It usually contains a large amount of indican.

Throughout the whole course of the disease the outstanding feature is the pain. This may at first be intermittent and colicky; but as the peritonitis develops it becomes constant and agonising, being increased by the smallest movement. In spite of this the restlessness persists, the patient being unable to resist the desire to move his limbs. The pain and restlessness, with the persistent vomiting, the intense thirst, which is hardly relieved by drinking, combine to make the patient's misery extreme. The pulse increases in rapidity until it can scarcely be counted, the extremities become cold, the eyes grow more sunken, and the features more pinched. As death approaches, the skin takes on a cyanotic hue; the persistent restlessness, the increasing voicelessness, and the remorselessly unimpaired consciousness bring death as a merciful release, even though the pain may be somewhat relieved towards the end.

The foregoing description applies to an acute fulminant case of peritonitis, running its course to death in from 24 to 48 hours; its outstanding features are a condition of profound shock and toxæmia, giving a measure of the high grade of peritoneal absorption. In the aged, and in patients with tabes or Bright's disease, the symptoms may be very atypical; pain may be but little marked, and vomiting and tenderness may be absent, while the bowels may act freely throughout. The striking restlessness, the condition of the tongue, the pulse and the ultimate meteorism will, however, usually indicate the true nature of the condition.

2. *Acute spreading peritonitis*.—This variety differs from the preceding in that the peritoneum is not suddenly flooded with infective material, but is prepared for infection by the more or less gradual spread of the condition. It accompanies many cases of appendicitis, and is a sequel of intestinal obstruction if unrelieved for a sufficiently long period. The peritoneal reaction is intense, and the coils of intestine become glued together with a sticky exudate, while pockets of pus form between them. If surgical interference is not undertaken these cases may progress for weeks. The pain is at first localised to the region of origin; but as the infection spreads it extends until it may become generalised over the whole abdomen. It is, however, never so intense as in the preceding variety, and may be distinctly spasmodic in character. The general abdominal symptoms are also less severe, the tenderness, rigidity, meteorism and constipation being of varying grade. The aspect of the patient betokens a profound septic infection, the tongue is furred and dry, the pulse rapid, and the temperature of the hectic type. Rigors and sweats are not uncommon, and if left alone the case may terminate with fatal septicæmia, suppurative pylephlebitis, or in rare cases the pus may accumulate and burst either externally in the region of the umbilicus or into one of the hollow viscera.

3. *Pneumococcal peritonitis*.—This presents certain fairly characteristic features, which in many cases enable the nature of the infection to be correctly diagnosed from the clinical picture alone. It is far more frequent in children than in adults, and in girls than boys in the proportion of nearly 7 to 3. It occurs in a diffuse and an encysted form, depending probably on

the resistance of the patient. In many cases there exists a definite pneumococcal enteritis, the organisms penetrating the wall of the bowel and so infecting the peritoneum. The predominance of the disease in girls is probably due to the female genitals being a source of infection, as the pneumococcus has been cultivated from the vagina in some instances. In the majority of cases, however, the peritonitis is part of a pneumococcal septicæmia; thus, when it is secondary to pneumococcal disease of the middle ear, local pneumococcal abscesses or pneumococcal arthritis, the blood stream appears to be the source of infection, and it probably is so also in those cases which follow pneumonia or empyema, since the physics of the upper abdomen renders a direct spread through the diaphragm unlikely.

There is a striking resemblance between the symptoms of most forms of pneumococcal infection, a resemblance which strongly supports the view of their origin in a septicæmia. The onset is usually sudden, often accompanied by a chill and a high temperature, the pain is violent and persistent, and the prostration severe. The patient has the characteristic flush, the respiratory rate is raised, and the accessory muscles of respiration are called into play. Vomiting is frequent, and tenderness and rigidity are marked; but in place of the usual absolute constipation there is frequently profuse diarrhœa, which, associated with the other symptoms of acute peritonitis, is often almost diagnostic. In the diffuse form, unless operation is undertaken, death takes place early; but if the patient lives long enough there may be a sudden fall of temperature about the seventh day, as in pneumococcal pneumonia.

The encysted and more common variety of pneumococcal peritonitis is less severe, and shows a remarkable tendency for pus to collect in the lower abdomen. There is the same acute onset as in the diffuse variety; but the patient then appears to improve for a few days. Later, however, he gets gradually worse, the abdomen becomes distended, the diarrhœa changes to obstinate constipation, and an abscess forms in the lower abdomen and finally bursts at the umbilicus. The exudate in these cases is a greenish, odourless pus, which is sufficiently characteristic to enable the infection to be diagnosed when it is discovered at operation.

4. *Gonococcal peritonitis*.—Gonococcal peritonitis is rare; it occurs both as an acute diffuse affection of the peritoneum and as a localised pelvic inflammation. It is commoner in females than in males, owing to the ready channel for infection through the Fallopian tubes, and when it occurs in males it is usually secondary to epididymitis. The infection is generally a mixed one, the more fragile gonococcus being readily overgrown, and some cases of unexplained peritonitis, which on culture show only *B. coli*, are possibly gonococcal in origin. The symptoms do not differ in the diffuse cases from those of other forms of acute peritonitis, although the primary focus usually gives rise to symptoms. The prognosis is, however, good, and the majority of cases, even those presenting severe symptoms, recover without operation.

5. *Streptococcal peritonitis*.—Peritonitis due to the *Streptococcus pyogenes longus* is occasionally secondary to lesions of the alimentary canal; but much more frequently it is a sequel of puerperal infections. It occurs commonly after a first delivery, and is frequently associated with retained products.

Infection takes place along the lymphatics of the damaged uterus or through the Fallopian tubes, and may be localised in the pelvis; but it often gives rise to generalised peritonitis. The symptoms are characteristic, and are associated with evidence of a marked septicæmia. The abdominal walls, being already greatly stretched, do not show the usual rigidity, and extreme distension occurs rapidly. Diarrhœa is commoner than constipation, and a high temperature with rigors is usual. The uterine discharges are offensive, the milk secretion is suppressed, and the cases frequently progress to death within the first week. This type of infection is more fulminant than any other, except certain cases of perforative peritonitis.

Diagnosis.—The diagnosis of acute peritonitis is not usually difficult, except in cases where the severity of the causal condition is so great that it masks the peritoneal response, or where the peritonitis occurs in a patient already so severely ill that no response is possible. It is often extremely difficult to make a correct diagnosis of the lesion to which the peritonitis is secondary, and in many cases this is only possible after laparotomy. The most valuable signs of acute peritonitis are the severe pain and tenderness, the rigid abdomen, the small, rapid, and thready pulse, the dry tongue, the restlessness, vomiting, and constipation, and the absence of sounds of gurgling on auscultation. Any of these symptoms may, however, be absent, and a diagnosis must be based on their occurrence in combination. In post-operative cases there is sometimes a remarkable absence of both pain and rigidity, and the all-important early recognition of the condition in these patients is often one of much difficulty.

Peritonitis is most likely to be mistaken for lead colic or acute intestinal obstruction. From the former it can be distinguished by the fact that the abdomen in peritonitis is usually extremely tender, while in colic pressure often, though not invariably, relieves the pain; in colic a blue line is present, and the red corpuscles show punctate basophilia, the pain is intermittent, and there is usually no vomiting and less extreme rigidity. From acute intestinal obstruction the diagnosis is often far more difficult, particularly since the two conditions frequently coexist. In the early stages of obstruction, before peritonitis has developed, the intermittent nature of the pain, the absence of great tenderness or rigidity, the copious nature of the vomit, and the evidence of increased peristalsis from inspection or auscultation should help to distinguish the two conditions.

In acute pancreatitis the pain is more definitely hypogastric, the patient is usually over middle age, and collapse is extreme. The menstrual history, the typical pallor, and the results of vaginal examination usually serve to indicate a ruptured tubal pregnancy, and in other acutely painful abdominal conditions the localised nature of the pain and the absence of any extreme general tenderness help to distinguish the condition from peritonitis.

The gastric crises of tabes are seldom likely to be a source of error; but the comparative absence of severe symptoms in tabetics, the subjects of peritonitis, is very apt to lead to a mistaken diagnosis.

Basal pneumonia and diaphragmatic pleurisy may lead to acute abdominal symptoms. The temperature and pulse, the raised respiration rate, and a routine examination of the thorax in all cases should prevent a mistake being made.

Prognosis.—The prognosis of acute peritonitis is always grave, even

with early surgical treatment. Without operation no case of acute perforative peritonitis can be expected to recover; such exceptions as have been recorded must be regarded as medical curiosities. Under these conditions death generally takes place within 48 hours, though it may be delayed a week or even longer when the perforation is high in the bowel and the latter is empty at the time.

In diffuse spreading peritonitis and streptococcal puerperal infections death is almost as invariable, unless operation is undertaken; but the process is less rapid, and a small proportion of cases undoubtedly recover without surgical aid. These cases occasionally merge into a form of chronic fibropurulent peritonitis, characterised by the progressive formation of collections of pus between neighbouring viscera, and by repeated outbursts of symptoms as other parts of the peritoneum become successively involved. This condition usually terminates in fatal septicæmia, with infections in the pleura, pericardium or endocardium. The prognosis in pneumococcal cases is considerably better, as, even without operation, a fair proportion recover, either with or without the formation of a hypogastric purulent collection, which may discharge at the umbilicus. In the rare gonococcal cases recovery is the rule, and the fatal cases recorded have almost invariably followed operation.

In forming a prognosis the chief importance must be placed on the degree of toxæmia and the severity of the intestinal paralysis, and to a less extent on the degree of meteorism and the frequency of the vomiting. Spontaneous bowel actions or their induction by enemata make the peritonitis relatively more favourable.

The rate of rise of the pulse and its ratio to the temperature are also of importance; cases with a subnormal temperature throughout are almost always rapidly fatal.

Treatment.—The principles that must underlie the successful treatment of acute peritonitis are, firstly, the removal or limitation of the process to which the peritonitis is secondary by a thorough and speedy exploration of the abdomen, followed by closure of a perforation, removal of an appendix, or such other measures as the pathology present may indicate; secondly, drainage and relief of tension in the peritoneal cavity; thirdly, the encouragement of the normal peritoneal response and the least possible damage to its protective agencies; and, fourthly, the combating of the shock and toxæmia.

By the adoption of the Fowler position, in which the patient is propped up in bed in a sitting position, not only is infective material removed from the dangerous diaphragmatic area and brought into contact with the much more highly resistant pelvic peritoneum, but at the same time the diaphragm is relieved from the pressure of the dilated stomach and intestines.

A further important adjunct to surgical treatment is the subcutaneous injection of large quantities of saline solution. This raises the blood pressure and redresses the fluid depletion which has taken place, and, being excreted by the peritoneum, it reverses to a certain extent the lymphatic circulation, and consequently largely prevents the absorption of toxic material as well as dilutes that already present.

Until a definite diagnosis has been made and operation advised and agreed to, the administration of opium in any form is definitely contra-indicated. It masks the symptoms, and by bringing to the patient and his

advisers a false sense of security may lead to a fatal delay in undertaking the operation. When, however, a diagnosis has been made, and operation is agreed to, morphine is beneficial in reducing both the mental and physical symptoms, while the necessary preparations are being made. The aperient method of treatment was introduced with the object of preventing the onset of intestinal paralysis and in order to eliminate as far as possible toxic material by the bowel. The great objection to it, however, is the fact that in practically no case is the peritoneal infection absolutely general, at any rate at first, and consequently there is a danger of spreading infection by means of increased peristalsis, while it is doubtful to what extent purgation prevents intestinal paralysis if the toxæmia is considerable. The exact opposite line of treatment has been the one adopted more and more of recent years, morphine being given deliberately and in doses sufficient to affect the respiration rate with the object of diminishing the activity of peristalsis, as well as of combating the shock, pain and restlessness, which help so largely to exhaust the patient's powers of resistance. It is very doubtful whether it ever prevents the response of the bowels to enemata in cases in which they would otherwise respond. If vomiting is a prominent symptom, lavage of the stomach is of value. It should, if possible, always be done before operation, as post-anæsthetic vomiting of faecal material is a fruitful cause of fatal broncho-pneumonia.

In pneumococcal cases there is not quite the same urgency for operation and it is sometimes justifiable to wait for a time in the hope of localisation. In gonococcal peritonitis, if a diagnosis can be made, conservative treatment should be followed; but if there is doubt, as there often must be, of the nature of the infection, or if the patient shows any increase of symptoms, laparotomy is the only safe course to follow.

E. G. SLESINGER.

CHRONIC PERITONITIS

(a) LOCALISED CHRONIC PERITONITIS; PERITONEAL ADHESIONS

Ætiology and Pathology.—Inflammation of the appendix and operations on the appendix, especially if followed by drainage, lead to the formation of adhesions in the neighbourhood. Adhesions near the hepatic flexure are often due to cholecystitis, which may be associated with gall-stones, and somewhat less commonly to a subacute or acute perforation of a duodenal and rarely of a gastric ulcer. Pelvic peritonitis, which is a common sequel of disease of the female genital organs, often involves the pelvic colon, and occasionally the cæcum and appendix; and tuberculous peritonitis is an important cause of local and generalised intestinal adhesions. Inflammation of the mucous membrane of the colon sometimes spreads to the surrounding peritoneum and leads to adhesions. Dense adhesions are also caused by diverticulitis, especially of the iliac and pelvic colon. In many cases, however, bands are found which differ in structure and anatomical relations from these inflammatory adhesions; they are most probably of congenital origin, but perhaps they persist and become thickened and altered as a result of mechanical factors. A membrane, the ileo-pelvic band, may pass from the

under surface of the mesentery of the end of the ileum to the under surface of the ileum itself, round which it passes to the point immediately opposite to the mesenteric attachment; it may involve the whole or part of the appendix. A veil-like membrane, known as Jackson's membrane, may pass from the parietal peritoneum at the outer side of the ascending colon and blend with the peritoneum over its anterior surface or extend to the great omentum. On dividing it, peritoneum is found beneath, but it often adheres to the anterior and lateral aspects of the bowel, so that the outer surface of the cæcum and ascending colon come to be connected with the postero-lateral abdominal wall by membranous bands.

These adhesions are often supposed to form kinks and obstruct the lumen of the bowel. Thus adhesions in connection with the end of the ileum are said to cause kinking ("Lane's ileal kink") and ileal stasis. There is, however, no evidence that any connection exists between Lane's ileal kink and ileal stasis, as structural abnormalities found at operation are no proof that functional abnormalities coexist, and the improvement which follows simple division of bands in connection with the end of the ileum is so inconstant that the operation is now rarely performed. The obstruction offered by an ileal kink is hardly ever as great as that offered by the normal ileo-cæcal sphincter 3 inches farther on. Nothing short of almost complete stenosis could lead to stasis of any importance, as the contents of the ileum are always so fluid that they can pass through a very narrow passage without difficulty.

If the adhesions caused obstruction they would lead to hypertrophy of the colon immediately behind the obstruction, but the bowel is unusually thin and translucent in the majority of cases. There is, however, no doubt that in exceptional cases localised adhesions give rise to partial obstruction, particularly in the more distal parts of the colon, the contents of which are hard, and therefore more easily held back by a slight narrowing in the intestinal lumen. In the more proximal parts, such as the hepatic flexure, adhesions can only cause any considerable degree of stasis if they give rise, as they doubtless not infrequently do, to a local spasm of the circular muscle-fibres of the intestine, except in the very unusual cases in which they produce a narrow stricture. Spasmodic strictures of this sort are intermittent, and the obstruction to which they give rise may be more or less overcome by anti-spasmodic drugs.

Symptoms.—When the symptoms point to the presence of stasis in one particular part of the bowel, especially if there is local tenderness and pain, which is increased when the intestinal movements are active after meals or during defæcation, the possibility of adhesions should be considered. Their presence is rendered more likely if there is a history of some inflammatory disease, which could have led to their development; but as adhesions are often present in the absence of such a history, an X-ray examination is essential. It is, however, important to remember that severe local stasis often occurs without any organic cause, so that radiograms alone can give no aid in diagnosis, palpation under the screen being always necessary in order to determine the mobility of the bowel.

The end of the ileum, as it rises from the pelvis to join the cæcum, bends in various directions; as the shadow on the screen is in one plane only, it is natural that it often appears as if it formed one or more acute angles or kinks;

by palpating the abdomen during the examination, especially after inflation of the colon with air in order to raise the terminal ileum out of the pelvis, it is easy to demonstrate that most of these "kinks" are only apparent. By manipulation of the abdomen during the screen examination it should be possible to separate from each other the limbs of the hepatic flexure and of the splenic flexure; if this cannot be done it may be presumed that they are bound together by adhesions.

Adhesions in connection with the pelvic colon can be recognised by palpation after an opaque enema; but a sigmoidoscopic examination should also be made.

Local intestinal adhesions occasionally give rise to so much congestion of the mucous membrane that occult blood may be constantly present in the stools and a growth of the colon may consequently be simulated.

Treatment.—In many cases considerable relief follows the administration of paraffin to render the stools soft, and the use of belladonna in small doses to prevent the intestinal spasm, which may increase obstruction and lead to colic. A diet which leaves a minimum of indigestible and irritating material but contains sufficient chemical stimulants of intestinal activity should be given. Abdominal massage is also often of use; and if the abdominal walls are weak, exercises to strengthen them and a suitable support help to prevent dragging upon adhesions.

Operative treatment is very unsatisfactory, as whatever care is taken, there is always a danger of recurrence of the adhesions. Only when they are very localised and lead to definite obstruction at one or more points is it clearly necessary to divide the adhesions and take steps to prevent their recurrence.

(b) DIFFUSE CHRONIC PERITONITIS; PERIHEPATITIS

Diffuse chronic peritonitis is the condition in which chronic progressive inflammation of the peritoneum occurs independently of tuberculous or malignant disease. The peritoneal covering of the liver is often the part most involved, and the condition has therefore been called perihepatitis; but, as the ascites is just as much due to inflammation of other parts of the peritoneum, this name is not very appropriate.

Ætiology.—1. Chronic peritonitis may be associated with chronic inflammatory changes in the thorax. Effusion may occur from all the serous membranes (polyrrhombentitis, polyserositis, or Concato's disease); this condition is probably in most cases tuberculous. In other cases chronic peritonitis is associated with chronic mediastinitis, adherent pericardium and pleural adhesions; the disease may apparently start either above or below the diaphragm. The peritoneum covering the liver and spleen is generally most involved.

2. In many cases of chronic peritonitis the kidneys are granular and the arteries thickened, the renal condition being probably primary.

3. Simple chronic peritonitis may be a widespread process of obscure origin, or it may start from local infection in connection with a gastric or duodenal ulcer or cholecystitis. In the absence of such sources of infection it may be associated with chronic gastro-enteritis caused by alcoholism. Ascites caused by cirrhosis of the liver, heart failure or renal disease may lead

to secondary peritonitis, especially after repeated tapping, probably owing to the irritant action of toxins present in the fluid.

4. *Chronic syphilitic peritonitis.* Very rarely a positive Wassermann reaction can be obtained from the blood serum and ascitic fluid of patients with cirrhosis and ascites. In these cases anti-syphilitic treatment may lead to considerable improvement and disappearance of the ascites.

Pathology.—The liver may be covered with a thick, hard and white coating of fibrous tissue, which can be peeled off to expose the smooth peritoneal surface. Perihepatitis is almost always associated with a similar thickening of the capsule of the spleen and with thickening of other parts of the peritoneum. The great omentum may be rolled into a hard cord, and the mesentery may be thick and short so that the intestines are tethered to the posterior wall of the abdominal cavity.

Symptoms.—The only important symptom is ascites. Its onset is generally gradual, but it may be acute. Frequent tapping is required, and the intervals between the performance of paracentesis tend to diminish and may finally be as short as a fortnight, when as much as a pint of fluid may be poured into the peritoneal cavity in a day. In exceptional cases paracentesis has been performed over a hundred times.

The liver is generally normal in size, but it may be enlarged at first and become smaller later. If the liver is palpable, its thick edge is felt just under the costal margin. It may be recognised as being bent either outwards or inwards. The spleen is not often enlarged, except in young patients.

Jaundice is almost invariably absent. (Edema, especially of the feet, is frequent in the late stages; it is generally cardiac or renal in origin, but may also be due to pressure on the inferior vena cava. The urine is diminished in quantity, and there may be evidence of granular kidney.

Course.—The course of the disease is very slow, death occurring between 2 and 16 years from the onset of the symptoms, generally from some intercurrent disease. The general health may remain good for a long time. The patient becomes weak and emaciated, but no symptoms of hepatic insufficiency occur. In cases associated with granular kidney, death is due to heart failure.

For the diagnosis and treatment, see Ascites (p. 693).

TUBERCULOUS PERITONITIS

Ætiology.—The peritoneum is involved in 15 per cent. of fatal cases of tuberculosis. Tuberculous peritonitis is rare in infants, and uncommon after 30; the majority of cases occur between the ages of 3 and 20. Boys and girls are equally liable to the disease; it is found much more frequently in women than men at operations, but more frequently in men than in women after death.

Primary tuberculous peritonitis is uncommon in children and rare in adults. It is probably due to infection conveyed by the intestines, which do not themselves become infected, primary tuberculosis of the intestines being rare at all ages. More often, especially in children, the mesenteric glands become tuberculous, generally without any lesion developing in the intestines, and the peritoneum is infected from the glands. In males the

primary focus may be the prostate, vesiculæ seminales or testes, and in females the disease frequently begins in the Fallopian tubes; but the latter may also be infected from the peritoneum. Although tuberculous ulcers are found in 75 per cent. of fatal cases of pulmonary tuberculosis, the peritoneum is only involved in 4 per cent. of cases. The peritoneum, the pleura, and occasionally the pericardium, may be involved together in the absence of any other tuberculous focus. Tuberculous peritonitis is found in 9 per cent. of fatal cases of cirrhosis of the liver; this is partly due to the liability to tuberculosis of individuals whose resistance has been lowered by chronic alcoholic poisoning, the localisation in the peritoneum being due to the portal obstruction and chronic intestinal catarrh.

Pathology.—Tuberculous peritonitis may occur in three forms—the ascitic, loculated and obliterative.

1. In the ascitic form, which may be acute, subacute or chronic, miliary tubercles are scattered over the whole peritoneum, which is free or nearly free from adhesions. In chronic cases the tubercles are larger and more fibrotic than in the acute; the peritoneum is thickened; the mesentery is shortened so that the intestines are tethered to the posterior abdominal wall. This form may closely resemble malignant peritonitis.

2. In loculated tuberculous peritonitis the fluid may be clear, the condition being then intermediate between the ascitic and obliterative forms, or it may be turbid or purulent. In the latter case masses of tuberculous material, separated from each other by adherent coils of intestine, have broken down to form suppurating foci, which may erode the intestine or open at the umbilicus or even into the vagina.

3. Chronic obliterative, adhesive, or fibrous tuberculous peritonitis may result after absorption of fluid in the ascitic form or may develop primarily. No effusion is present, but universal adhesions obliterate the lumen of the peritoneum, all the viscera being inextricably bound together and to the parietal peritoneum.

In each form of tuberculous peritonitis the mesenteric glands are generally caseous and may break down in the centre; the mediastinal glands may also become tuberculous. The omentum is often rolled into a solid mass, which sometimes contains caseous nodules.

Symptoms.—Tuberculous peritonitis is sometimes completely latent, and may be discovered accidentally during an operation for some independent disease or for a hernia, when the sac may be the only part involved.

The onset of abdominal symptoms is generally preceded by a period of ill-health; the patient loses weight and strength, his appetite is poor, and his temperature may rise slightly at night. After a time he complains of general abdominal discomfort. Nausea and vomiting are rare. Constipation is common, especially in the obliterative form. In other cases diarrhoea may occur, owing to tuberculous ulceration of the intestines, fistulous communications between adjacent coils of intestines or simple enterocolitis. The stools are sometimes bulky owing to deficient absorption of fat caused by obstruction of the lacteals by caseous mesenteric glands (*vide* p. 572). The spleen and less often the liver may be enlarged. The skin, especially over the abdomen, is dry, inelastic and sometimes so pigmented that Addison's disease is simulated. In chronic cases there is sometimes no pyrexia; more often the temperature is intermittently slightly raised. In acute and sup-

purative cases the temperature is generally high and irregular, and the pulse is rapid. The urine is often concentrated, especially in ascitic cases, and traces of albumin may be found, owing to the pressure on the renal veins caused by a large accumulation of fluid in the abdomen or to the effect of the toxæmia on the renal cells. A moderate degree of anæmia is often present, and leucocytosis develops if suppuration occurs.

In the ascitic form the abdomen gradually becomes distended; at first it is tympanitic, but after a time evidence of the presence of free fluid is obtained, but the quantity is not often very great. Less frequently a large amount of fluid collects with great rapidity; the sudden stretching of the abdominal muscles is likely to cause a considerable amount of pain. Moderate tenderness of the whole abdomen is generally present. A large accumulation of fluid may compress the inferior vena cava and give rise to œdema of the legs; the diaphragm is pushed upwards and respiration becomes shallow and thoracic. The skin over the abdomen is shiny and the veins are enlarged. The ascitic fluid is generally clear; it contains a large proportion of lymphocytes and often coagulates on standing; less frequently it is turbid or blood-stained. Tubercle bacilli are rarely found in the effusion, although they must be present, as the fluid produces tuberculosis when injected into guinea-pigs.

In the loculated form with suppuration the abdominal pain is generally greater; attacks of colic are common, especially after exercise. The abdomen is distended and doughy; on percussion, irregular tympanitic and dull areas are found. Large caseous glands and collections of pus between adherent coils of intestines may form palpable masses, which are immobile, tender and dull on percussion. The omentum can often be recognised as a thick cord stretching across the upper part of the abdomen; the transverse colon generally forms a resonant band immediately above it, which helps to distinguish it from the lower edge of an irregularly enlarged liver. The case with which the masses are felt varies from time to time with the amount of flatulent distension of the intestines. When an abscess is about to point at the umbilicus, the latter becomes indurated, red and tender; a similar condition is occasionally observed in pneumococcal peritonitis and in pelvic peritonitis in women. On rectal and vaginal examination, thickened Fallopian tubes, enlarged glands or collections of pus may be felt.

The signs of obliterative tuberculous peritonitis are ill-defined; the abdomen gives a characteristic rubbery resistance on palpation and is generally somewhat distended. Irregular masses may be felt in it, and the peristaltic waves of the small intestines are often visible, especially in children. This does not necessarily indicate that partial obstruction is present, as it may be simply due to the adhesion of the intestines to the abnormally thin abdominal wall.

Symptoms of tuberculous disease of other organs, especially of the lungs, pleura, intestines and Fallopian tubes are often present. Generalised tuberculosis may develop at any time, especially in children; vomiting and constipation, which suggest intestinal obstruction, may be the first symptoms of tuberculous meningitis.

In very rare cases acute peritonitis may develop as a result of rupture of a softened caseous gland or perforation of a tuberculous ulcer.

When a patient recovers from tuberculous peritonitis, the tubercles and

adhesions may completely disappear. More frequently localised adhesions remain, and calcified tuberculous mesenteric glands are often found at operations and after death. They may give rise to confusion when the abdomen is X-rayed on account of suspected renal calculi. In a very small proportion of cases the bands, which sometimes form from localised adhesions, may cause acute intestinal obstruction, even years after the active disease has disappeared.

Diagnosis.—In the presence of tuberculous disease of the lungs or other organs, abdominal distension, especially if associated with ascites or irregular abdominal masses, generally indicates that tuberculous peritonitis is present. The discovery of tubercle bacilli in the sputum, and their much less common discovery in the faeces or vaginal discharge, is very strong confirmatory evidence. Ascites in children, and in females with symptoms pointing to tuberculous salpingitis, is generally due to tuberculous peritonitis.

Acute cases may at first closely simulate pneumococcal peritonitis or even appendicitis; but in non-tuberculous inflammatory exudates of the peritoneum most of the cells are polymorphonuclear leucocytes instead of lymphocytes. Ascites due to cirrhosis of the liver in children is almost always mistaken for tuberculous peritonitis; on the other hand, the ascitic form of tuberculous peritonitis in middle-aged alcoholic individuals is likely to be mistaken for ascites due to cirrhosis. When cirrhosis is undoubtedly present, ascites may still be due in part to tuberculous peritonitis; a large proportion of lymphocytes in the fluid is very strong evidence in favour of this, as the ascitic fluid in uncomplicated cirrhosis contains few except endothelial cells. In simple chronic peritonitis there is no fever and little or no pain, and the ascitic fluid contains few if any lymphocytes. The presence of irregular masses, together with fluid in the abdomen, generally indicates tuberculous peritonitis in children; but it is more frequently due to malignant disease in adults, especially in males. The history of the case and any evidence of tuberculous or of malignant disease in other parts of the body help to settle the diagnosis.

Fever, inflammation of the umbilicus, and the presence of lymphocytes in the ascitic fluid point to tuberculosis, whilst nodular infiltration without inflammation of the umbilicus, hard and enlarged glands in the groin or neck, and the presence of large, multinuclear cells or groups of cells in the effusion point to cancer.

A localised collection of fluid may be mistaken for an ovarian cyst, or, if it is in the pelvis, for a hydro- or pyosalpinx, especially if it is associated with tuberculosis of a Fallopian tube; but it forms a less defined tumour than in these conditions.

Prognosis.—Recovery takes place in a large proportion of cases of the ascitic form of tuberculous peritonitis. When localised abscesses develop complete recovery is rare, and when a faecal fistula forms death almost always follows. Prolonged fever, rapid emaciation and intractable diarrhoea are the most serious symptoms. The prognosis also depends on the severity of any tuberculous disease of the lungs or other organs which may be present. Apparent recovery is sometimes followed by a relapse, generally owing to reinfection from an unhealed primary focus, such as a tuberculous gland, appendix or Fallopian tube.

Treatment.—The patient should be kept in bed so long as the temperature

is raised. He should be in the open air all day and night when the weather permits, and if indoors an abundant supply of fresh air is essential. Heliotherapy or artificial sunlight should be employed, but care must be taken to avoid over-exposure. The mercurial ointment, which is often applied on a binder to the abdomen, is probably quite valueless. Diarrhoea should be treated by a non-irritating diet, and in intractable cases by opium preparations. If chylous diarrhoea is present, fat must be excluded from the diet. With this exception, the food should be as abundant and nourishing as possible. Tuberculin has been much employed, but I am not convinced that it is of any use.

The improvement, which often results from allowing the fluid to escape in ascitic cases, is probably caused by flushing the peritoneum with a new exudation of fluid richer in anti-tuberculous substances than that which was allowed to escape. This result can be obtained by simple paracentesis; but an operation has the advantage of making it possible to remove the primary focus, such as a tuberculous gland, a tuberculous appendix with the infected ileo-cæcal glands, or a tuberculous Fallopian tube. All ascitic cases, which do not improve in 3 months with general treatment, or which get worse instead of better, should therefore be subjected to operation, particularly if there is any evidence pointing to the presence of localised tuberculous disease which might be removed.

Operation should never be performed in obliterative peritonitis, in infants less than a year old, or in the presence of extensive tuberculous disease elsewhere. The occurrence of intestinal obstruction is an indication for operation, though it is rarely possible to do anything useful owing to the extensive adhesions present and the danger of tearing the intestines.

PERITONEAL CYSTS

(a) *Hydatids*.—The peritoneum is involved in 1·4 per cent. of cases of hydatid disease. Nearly all cases are secondary, enormous numbers of cysts developing as a result of rupture or leakage of a hydatid of the liver. The cysts grow slowly, and are rarely of sufficient size to give rise to symptoms until two years have elapsed since the primary cysts ruptured.

Hydatid cysts cause a gradual enlargement of the abdomen, which may be diffuse, or separate cysts may be recognised by inspection and by palpation. They are movable, and do not appear to be connected with any definite organ. Symptoms may result from pressure on the stomach, intestines, diaphragm, inferior vena cava, and—in the case of pelvic hydatids—the ureters, bladder and rectum. Single hydatids are generally mistaken for ovarian cysts; but the presence of multiple cystic tumours should suggest the possibility of hydatid disease, which would be confirmed by the presence of eosinophilia, or by the history of a primary cyst in the liver.

(b) *Dermoid cysts* may originate in the mesentery or omentum, especially in women. Ovarian dermoids may also become detached and adhere to any part of the peritoneum, or they may rupture and multiple cysts result from implantation.

(c) *Mesenteric cysts*.—Apart from dermoids and hydatids, cysts may develop in the mesentery or omentum. They may be derived from the dila-

tation of lymph spaces, and be filled with clear, chylous or hæmorrhagic fluid. Mesenteric cysts, lined with endothelium, arise from the distension of shut-in peritoneal pouches with serous fluid. Cysts may project from the free border of the intestine, or grow from its attached border between the layers of the mesentery.

Mesenteric cysts form definite, round, tense tumours, which are generally situated to the right of the middle line and a little below the umbilicus. They are dull on percussion; but, if attached to the intestines, the latter may form a resonant band around them. They may give rise to colic and vomiting, and in rare cases to acute intestinal obstruction.

CANCER OF THE PERITONEUM; MALIGNANT PERITONITIS

Ætiology.—Cancer of the peritoneum is almost always secondary. The primary disease is generally in the abdomen, especially the stomach and the ovary, the peritoneum becoming involved by spread along lymphatics or blood vessels, by direct contact, or most commonly by malignant cells being set free and scattered widely over the peritoneum. The disease may also spread from cancer of the breast by the deep lymphatics of the chest and abdominal wall, and by lymphatics from malignant disease of the testis.

Pathology.—Malignant deposits may be minute tubercles, or they may form larger white non-caseating nodules or even very large masses. The parts most generally involved are the omentum, mesentery and pelvis. Chronic fibrotic changes frequently occur, and result in the omentum being rolled up and the mesentery shortened as in tuberculous peritonitis. The diaphragm is often invaded with growth, which spreads to one or both pleura. Acute or subacute peritonitis may occur.

Symptoms.—The symptoms are due in part to the primary disease and in part to the secondary malignant peritonitis. As the former is generally situated in the abdomen, it is impossible to distinguish between the symptoms due to the two causes. Malignant peritonitis generally results in ascites; the fluid is clear or turbid, hæmorrhagic, chyliform, or less frequently chylous owing to obstruction and subsequent rupture of lacteals. The umbilicus is often infiltrated with growth, and nodules may be felt along the falciform ligament. Tumours are often felt in the abdomen or on rectal examination; they are sometimes too small to be palpable, and in other cases they can only be felt after the fluid has been removed. The rolled-up omentum can often be recognised as a thick transverse cord above the umbilicus. The malignant masses or peritoneal adhesions may give rise to obstructive symptoms.

Diagnosis.—The development of new abdominal tumours or ascites in a patient who is known to have cancer of the stomach or other organ is conclusive evidence that the peritoneum is involved. When there is no clear evidence pointing to the presence of a primary malignant or tuberculous focus, it may be difficult to distinguish between tuberculous and malignant peritonitis (see p. 690). When ascites is present and no tumour is palpable, cirrhosis, simple chronic peritonitis or portal thrombosis may be simulated; the abdomen should be tapped, when a tumour often becomes palpable if malignant disease is present.

Prognosis and Treatment.—It is rare for the patient to survive for

more than 6 months after the peritoneum becomes involved. Treatment is purely palliative. Considerable relief may follow paracentesis.

ASCITES

Definition.—Ascites is the accumulation of free fluid in the peritoneal cavity.

Ætiology.—Ascites is a constant symptom of simple, tuberculous and malignant chronic peritonitis. It occurs when there is a rise of pressure in the portal circulation; it is always present in portal thrombosis and when the portal vein is obstructed by a growth or an aneurysm, and portal obstruction is in part responsible for its presence in cirrhosis of the liver. Ascites is very common in heart failure, in which it is almost always associated with œdema of the feet. It is in part due to the same causes as the œdema, but it is also in part caused by portal congestion, and by obstruction to the lymph flow from the thoracic duct owing to the rise of venous pressure. Lastly, ascites accompanies the dropsy of Bright's disease and severe anæmias.

Symptoms.—The abdomen becomes gradually enlarged, at first in an antero-posterior direction, the costal margin being pushed forward, but at a later stage the bulging occurs in the flanks also. The stretching of the abdominal wall gives rises to a tight sensation, which may amount to actual pain if the fluid collects rapidly. It causes the muscles to atrophy and linæ atrophicæ develop in the skin. The umbilicus becomes everted and may form a thin-walled bladder.

The rise in intra-abdominal pressure, caused by the accumulation of ascitic fluid, obstructs the inferior vena cava; œdema of the legs may occur, and the obstruction to the renal circulation may cause albumin to appear in the urine, the quantity of which is reduced owing to the loss of water in the ascitic fluid. Compensatory dilatation of other venous channels results: the dilatation of the veins passing between the abdominal wall and those in the falciform ligament is manifested by the development of large and prominent subcutaneous veins around and above the umbilicus; others pass from the superficial and deep epigastric veins in the middle of the groin towards the costal arch, where they join the superficial epigastric and long thoracic veins. When paracentesis is performed, the dilated veins disappear if they have developed as a result of pressure on the inferior vena cava, but not if obstruction of portal veins is the primary condition.

The diaphragm is pushed up; its excursions on respiration are reduced, and dyspnoea may result. The impulse of the heart may be felt in the third intercostal space; the twisting of the heart may temporarily produce a pulmonary systolic murmur. Cardiac irregularity, palpitation, and attacks of faintness may result. The upper border of hepatic dullness may reach the fourth, third or even second intercostal space in front: the right base is dull behind, owing to the liver being pushed up and the lung compressed. Bronchitis tends to develop, and the engorgement of the lung may in rare cases give rise to hæmoptysis. A pleural effusion may be suspected, but the upper limit of dullness is altered on taking a deep breath if it is due to the liver being pushed up, and the increased dullness diminishes or disappears when the patient lies on his face; in pleural effusion the dullness is higher

in the axilla than behind, but this is not the case if it is due to an abnormally high position of the liver.

The pelvis and renal regions hold a considerable amount of fluid, so that no accumulation occurs in the flanks until at least a litre is present in the abdomen. An area of dullness is, however, found in the most dependent part of the abdomen if the knee-elbow position is assumed. As more fluid collects the resonant note in the flanks is replaced by dullness, but the change may be delayed if there is much gas in the colon. The level of dullness now gradually rises and spreads over the pubes towards the umbilicus. On turning from one side to the other the most dependent part remains dull. This is not, however, pathognomonic of ascites, as similar movable dullness occurs in chronic obstruction of the small intestines.

In chronic peritonitis the mesentery may be so shortened that the intestines are unable to float up on the fluid; the fluid then accumulates in front of the intestines, and the highest part of the abdomen is dull.

A characteristic fluid thrill is felt when one side of the abdomen is sharply flicked by the fingers of one hand, whilst the other hand is placed flat upon the opposite side of the abdomen. When the patient is very fat, or the abdominal wall is cedematous, a similar but less marked sensation may be produced; in doubtful cases the hand of an assistant should, therefore, be pressed perpendicularly over the middle line of the abdomen, as this prevents the transmission of the impulse through the abdominal wall, but not through the fluid contents of the abdomen.

When the liver or spleen is enlarged and hard, or when an abdominal tumour is present, the sensation produced by dipping the tips of the fingers suddenly through the fluid on to the solid organ, which may jump away from them, is most characteristic.

Diagnosis of Ascites.—Confusion has often occurred between ascites and a large ovarian tumour. The history of the development of the abdominal swelling may help the diagnosis. In many cases the outline of an ovarian tumour can be definitely felt, and its pelvic attachments can be recognised by vaginal examination. The antero-posterior enlargement is greater than the lateral bulging, whereas the reverse is the case in ascites; the maximal girth is below the umbilicus instead of at the umbilicus or above; the umbilicus, which is normally and in ascites an inch nearer the pubes than the ensiform cartilage, is proportionately farther from the pubes; and the distension on one side is often greater than the other instead of being uniform.

Diagnosis of Cause of Ascites.—Chronic peritonitis and perihepatitis are generally associated with adherent pericardium or granular kidney and atheroma. The presence of these conditions would point against cirrhosis as the cause of ascites. On the other hand, an enlarged spleen or the occurrence of hæmatemesis would be in favour of cirrhosis. A patient with ascites due to cirrhosis alone rarely survives the performance of paracentesis more than two or three times, as his general health has already greatly deteriorated; if tapping is frequently performed, chronic peritonitis is therefore probably present, even if other evidence indicates that the patient is also suffering from cirrhosis. In cirrhosis the fluid collects rapidly, and the patient is obviously ill; in chronic peritonitis the accumulation on the first occasion is generally very gradual, and the patient may be otherwise well. Tuberculous peritonitis is rare in adults, except as a complication of cirrhosis of

the liver and when secondary to tuberculous Fallopian tubes. In children, ascites due to cirrhosis is very likely to be mistaken for tuberculous peritonitis. Evidence of tuberculous disease in other parts of the body, solid masses palpable in the abdomen or on rectal examination, pain and tenderness in the abdomen, except over the liver, and induration and redness of the umbilicus point to tuberculous peritonitis. The fluid is generally turbid, the specific gravity is above instead of below 1015, and lymphocytes are present. No tubercle bacilli are found by ordinary methods; but injection of the fluid into a guinea-pig causes it to become tuberculous.

In malignant peritonitis there is generally evidence of the primary disease in some other organ, and nodules may be felt in the abdomen, in the neighbourhood of the umbilicus, or in the middle line above it, and enlarged glands may be present. The spleen is not enlarged, emaciation is generally greater than in cirrhosis, and, except when the primary disease is in the stomach, there is no hæmatemesis. A rectal and vaginal examination are particularly important, as ascites, which may recur very frequently, sometimes results from ovarian tumours. In a doubtful case the diagnosis may become clear after paracentesis, when the large hard liver and spleen may be felt in cirrhosis and an irregular enlargement of the liver, but no splenomegaly, in cancer of the liver. In malignant disease the fluid may contain cancer cells; it is more often hæmorrhagic than in tuberculous peritonitis or cirrhosis.

Rapid development of ascites, with enlargement of the spleen and sometimes hæmatemesis, suggests portal thrombosis; if symptoms pointing to cirrhosis are already present, it is probably secondary to this, and even when none are present, it may be secondary to latent cirrhosis, as the majority of cases are due to cirrhosis.

An examination of the circulatory system and the urine should prevent confusion between ascites due to cirrhosis and that due to heart failure or kidney disease; but these conditions may be associated together.

Treatment.—A salt-free diet should be given, as ascitic fluid never contains less than 8 grammes of sodium chloride in each litre; if the quantity of salt taken in the day is reduced to 0·8 gramme, less than 100 c.c. of ascitic fluid can collect during the same period, as the urine always contains some salt, and the percentage in the body fluids never falls greatly below the normal. The quantity of salt and water retained can be still further reduced by giving 2 drachms of calcium chloride 3 times a day for 10 to 12 days, and then injecting 1 c.c. naptal or other similar mercurial preparation in order to stimulate the kidneys to excrete salt. With this treatment, which can be repeated periodically, the ascites generally disappears.

The bowels should be kept well open; but severe purging weakens the patient and is likely to aggravate the catarrh of the alimentary canal, which is often already present. Repeated small doses of calomel, which also acts as a diuretic, and saline aperients or compound jalap powder are the most suitable drugs.

Diuretics are much more valuable as preventatives, when the fluid first appears, or after it has been removed, than as curatives when a large quantity is present, as the pressure on the renal veins makes the kidneys less active, and an enormous quantity of fluid has to be excreted by them before the accumulation can disappear, whereas comparatively little urine need be

passed to prevent its re-accumulation after tapping. Addison's pill of 1 grain each of powdered digitalis leaves, powdered squill root and blue pill, may be given for 2 days before paracentesis is performed, so that its action can come into play at once, and not be delayed until the fluid has already begun to collect again, as the accumulation of fluid is most rapid immediately after paracentesis. This treatment is, however, now rarely required since the introduction of the combined salt-free diet, calcium chloride and mercurial injection treatment of Blum described above.

Attempts have been made to increase the collateral circulation between the portal and the general venous systems by operative means on the assumption that ascites is a result of portal obstruction. The peritoneum over the liver and diaphragm is scraped and the omentum introduced between them, the abdomen being drained and the patient kept in the sitting position so that no fluid can intervene between the roughened peritoneum and prevent adhesions from forming. Great improvement occurs in a small proportion of cases, but in the majority little or no benefit results, and death shortly after the operation is not infrequent. The unsatisfactory results of operation are hardly surprising, as portal obstruction is rarely the sole cause of ascites. Moreover, there is a distinct danger of increasing toxæmia by allowing an increased proportion of intestinal poisons to enter the general circulation without passing through the liver, which retains some of its antitoxic powers to the end.

Paracentesis should be performed at an early stage, as soon as the accumulation of fluid causes discomfort or seriously interferes with the digestion, circulation or respiration. When dullness or râles appear over the bases of the lungs owing to their compression, or the secretion of urine is diminished, the abdomen should be tapped. Hæmatemesis is a further indication, as paracentesis reduces venous engorgement.

The trocar should be inserted in the middle line between the umbilicus and pubes, or in the flank. Care must be taken to avoid the liver and spleen. A trocar and tube of moderate bore should be used, as the very fine Southey's tube formerly employed tends to become blocked, and the discomfort caused by the paracentesis is needlessly prolonged.

ARTHUR F. HURST.

SECTION IX

DISEASES OF THE LYMPHATIC SYSTEM

AFFECTIONS OF THE LYMPHATIC VESSELS AND GLANDS

AFFECTIONS of these structures are as a rule secondary to disease in the other tissues of the body.

1. AFFECTIONS OF THE THORACIC DUCT.—The chief sign of a lesion of the thoracic duct is the occurrence of a milky effusion into the peritoneal or pleural cavity, or more rarely of chyluria. Such effusions are not all of the same chemical constitution. They are divided into chylous and pseudo-chylous effusions; the causes determining the difference being quite unknown. The lesions associated with these effusions are varied, but the chief place is held by carcinomatous or sarcomatous growths pressing upon or infiltrating the duct. Thrombosis of the left subclavian vein, trauma, lymphadenoma, tuberculosis and cirrhosis of the liver are also recorded.

2. AFFECTIONS OF THE SMALLER LYMPHATIC VESSELS.—(a) *Lymphangitis*.—Acute inflammation of the lymphatic vessels is the result of infective processes in the area drained. It is evidenced by the appearance of red lines in the skin leading from the focus to the adjacent lymphatic glands. In the more chronic inflammations such as tuberculosis, and in malignant disease, the lymphatic vessels which drain the affected area become infiltrated and can often be felt as hard cords, e.g. the enlargement of the spermatic cord in tuberculosis of the testicle.

(b) *Lymphangiectasis* is the name given to a diffuse dilatation of lymphatic vessels; circumscribed dilatations forming tumours chiefly composed of dilated lymph-spaces are called lymphangiomata. These may be either congenital or acquired. Instances of the congenital variety are met with about the lips and tongue and floor of the mouth; *macrocheilia*; *macro-glossia*; *lymphangioma of the neck*. The acquired condition is due to obstruction injury, e.g. severe scarring after burns; and blocking of the channels by the parasite *Filaria bancrofti* producing elephantiasis of the scrotum and chyluria.

3. AFFECTIONS OF THE LYMPHATIC GLANDS.—(a) Acute lymphadenitis resembles lymphangitis in being the result of an acute infection in the area drained. The glands in relation to the fauces are those most often affected. The lymphatic glands are also enlarged in many of the acute infectious fevers.

(b) Chronic lymphadenitis is, similarly, most often due to infection. *Pyogenic infections* are common, but both from its frequency and its results *tuberculous infection of the glands* is the most serious. Any gland in the

body may be implicated, but involvement of the cervical group is certainly the commonest. The axillary, inguinal, mesenteric and thoracic groups are also often infected. Tuberculosis of the superficial glands usually comes under the notice of the surgeon and is dealt with in surgical text-books. Tuberculosis of the mesenteric and thoracic groups will be found treated of in the sections on diseases of the peritoneum and the lungs respectively.

In rare instances there occur cases of a generalized tuberculosis of the glands of the whole body. It is an acute infection seen in children and much more rarely in adults, and has to be diagnosed from an acute lymphadenoma, leukæmia or sarcomatosis. This can only be accurately done by the excision and microscopic examination of a gland. The disease is not invariably fatal.

(c) Malignant disease of the lymphatic glands is generally secondary to carcinoma. When the growth is primary in the glands the character of the new tissue is sarcomatous or more rarely endotheliomatous. The last is as a rule slowly progressive, and only locally malignant.

Diagnosis.—Where there is a glandular tumour the physician is usually obliged to take into consideration the distinctions between tuberculosis, new growth, leukæmia, lymphadenoma and syphilis; and in some cases the distinction can hardly be made on clinical grounds. It is then necessary to excise the tissue and examine it microscopically. It is often in cases of obscure illness an aid in diagnosis to be fully aware of the position of the groups of glands which are in relation to affected organs, *e.g.* in carcinoma of the stomach it is not uncommon to find an early involvement of the group which lies above the left clavicle.

LYMPHATISM

Synonym.—Status Lymphaticus.

Definition.—In the absence of any knowledge of what constitutes this condition, the definition is of necessity based upon the appearance found in the bodies of those who have died with a peculiar train of symptoms. There are three classes of cases which must be considered under this heading:

1. The sudden deaths of infants for no apparent reason.
2. The deaths under anæsthetics of older children and occasionally of adults without obvious cause.
3. The occurrence in infants of attacks of dyspnoea and cyanosis due to the presence, it is alleged, of an enlarged thymus gland (Kopp's or Millar's asthma).

In all three cases, the thymus gland is found enlarged, sometimes of an enormous size, and, in addition, the lymphatic structures of the body generally, spleen, tonsils, Peyer's patches and solitary follicles of the intestines, and the glands everywhere, are hypertrophied.

Symptoms.—In the first two classes the condition is usually unsuspected during life. Anæmia, enlargement of the tonsils and of the superficial lymphatic glands are common from other causes, and it is often the sudden failure of vitality either under an anæsthetic or in a child apparently in good health, which first indicates the existence of the condition. The cause of death is not as a rule respiratory, but cardiac, failure; death takes place

abruptly without a struggle or a cry, from sudden cessation of the heart-beat. At the autopsy, the thymus gland is found to be enlarged, and the other lymphatic structures hypertrophied. The thymus gland is thick and fleshy, and weighs two, three or four times its normal weight in children, of 10 to 12 grammes.

In the third class, there is more to attract the attention. An infant in the first weeks of life develops respiratory stridor with attacks of cyanosis and dyspnoea, due apparently to compression of the trachea. By some authorities this compression is held to be caused by the mere enlargement of the thymus gland; but in many instances it is certain that the underlying cause both of the increase of the gland and of the dyspnoea is the existence of an inflammatory lesion in the cervical tissues. Thus, in some typical instances suppuration in the lymphatic glands has been found, and in others, the existence of an unsuspected retro-pharyngeal abscess, and the writer has yet to see an uncomplicated case of "thymic asthma."

Diagnosis.—The diagnosis of enlargement of the thymus gland during life is not easy. The discovery of an abnormal dullness to percussion over the manubrium sterni, extending a little to either side, should lead to an examination by means of the X-ray, when the shadow of the gland or of an abscess may be obvious, and lead to the discovery of an unsuspected lesion in the tissues of the neck or pharynx. In children rather older, who are unduly pale and flabby, whose complexion is muddy, or in whom there is a history of attacks of dyspnoea, the condition may be suspected, and in a few of these careful examination will reveal abnormal dullness and an X-ray shadow apparently representing an enlarged thymus gland. X-ray appearances, however, are apt to be misleading, and a diagnosis based principally on the presence of such a shadow has often proved erroneous.

Treatment.—When the condition is suspected the first consideration should be to avoid the administration of an anæsthetic, and when this is inevitable Buxton recommends a low-strength chloroform vapour with oxygen. Generally, treatment must be directed to the improvement of anæmia by means of iron, dieting, open air, and of muscular tone by massage. In cases of "thymic asthma" operation with removal of a great part of the thymus gland has been practised, occasionally with good result. In some cases the surgeon has found unsuspected suppuration.

LYMPHADENOMA

Synonyms.—Pseudo-leukæmia; Hodgkin's Disease; Malignant Lymphoma; Lympho-granulomatosis.

Definition.—A disease characterized by swelling of the lymph glands in various parts of the body, associated with hyperplasia of the lymphadenoid tissue in the liver, spleen and other organs. It is progressive, and in its later stages accompanied by a severe type of anæmia.

Ætiology.—In many instances the disease seems to follow one or other of the acute infective diseases, but often there does not appear to be any predisposing cause: it is not hereditary, nor is there any evidence of a family character; it is met with in all civilized countries; and is probably more often found in the town-dweller than in the countryman. It occurs at all

ages, but more frequently in the first three decades than later, though no age is immune.

The exciting cause is unknown. Bacteriology has so far failed to discover an organism which can be incriminated, though Fraenkel and Much claim to have demonstrated an acid-fast bacillus which they believe to be causal.

Relation to tuberculosis and the "lymphomata."—It has been maintained that lymphadenoma is a specialized form of tuberculous infection, but the bulk of evidence, alike clinical, bacteriological and pathological, is against this assumption. A patient may suffer at the same time from both diseases, and it is certain that association is fairly common, but the lesions of the two are easily distinguishable from one another under the microscope, and no experimental work has yet succeeded in producing the typical lesions of lymphadenoma.

The exact relation of Hodgkin's disease to the "lymphomata" is still uncertain, and must wait for definition on greater knowledge of the histology of such tumours. But with our present knowledge it is already doubtful whether there are any other diseases than lymphadenoma, tuberculosis, leukaemia, new growths and chronic inflammatory conditions, which can give rise to a large and persistent tumour of the lymphatic glands.

Pathology.—The disease affects the lymphatic glands, the spleen, the liver and the lungs in the order named, and, in addition, the lymph tissue in the other organs, notably in the intestines and in the stomach, is frequently hyperplastic. The glands are smooth, white on section, or pinkish-grey and homogeneous; in cases of long standing they are often more fibrous than normal. Suppuration or caseation is uncommon, and when found should suggest the likelihood of simultaneous tuberculous infection. Microscopically, the gland structure is obscured by the overgrowth of endothelial elements and fibrous tissue. Many of the endothelial cells are multinucleate. Eosinophil cells are said to be present in great abundance, but this is not a constant feature. The same remark applies to the presence of plasma cells. The chief microscopic characters of the spleen are similar; in the liver the accumulations of the morbid cells are found mostly in the lymph structures of the portal canals and the same perivascular concentration is true of the other affected organs. Occasionally hyaline degeneration of the glands occurs, an uncommon feature in any other disease.

The chief features of the affection are the large smooth masses of the glands in the neck, in the axillæ, in the groins, mesentery, and in the retro-peritoneal region. On section these are found to retain the divisions between the individual glands, and seldom to invade the limiting tissues. The spleen is characteristic; it is studded with firm white nodules of different shapes and sizes, giving the organ the appearance of the almond-studded cake, known by the name of "hardbake." These nodules are sometimes yellowish in colour, and occasionally occur as a single large tumour occupying a considerable portion of the organ. The spleen is always of considerable size, and may weigh several pounds. The liver is enlarged, and in a typical case marked by small white nodules which represent the lymphadenomatous infiltration of the portal canals. The lymphatic tissue of the stomach and the intestines is hyperplastic, and in the case of the first-named organ the

overgrowth occasionally presents a striking resemblance to carcinoma. There is, however, no ulceration. In the intestine the overgrowth is confined to the Peyer's patches and the solitary glands.

Symptoms.—The first symptom to attract attention is nearly always an enlargement of the cervical, though in rare cases the glands of the other groups may be first affected. In a few cases, the first complaint is of swelling of the abdomen, jaundice, shortness of breath or general weakness; but never of anæmia, which is a later symptom. In this early stage there is as a rule nothing else to discover. The patients are not anæmic or seriously ill. The swollen glands are soft, discrete, not attached to the skin or the deeper tissues, painless and of slow growth. Most often the swelling appears in the superficial cervical group, and the submaxillary glands are involved later. Even at this stage, however, the spleen is often palpable, and careful examination may find some enlargement of other glandular groups. This swelling may be present for some considerable time before any further trouble is apparent, but sooner or later other enlargements make their appearance, and the general health begins to suffer; the patients complain of weakness and of shortness of breath on exertion, and become anæmic. By the time the disease is fully established anæmia is often marked, with masses of glands on both sides of the neck and beneath the chin; with enlargement of the axillary and inguinal groups; with swelling of the abdomen, due partially to the size of the liver and spleen and partially to the presence of free fluid in the cavity. There may be great respiratory distress as a result of pressure of the mediastinal glands on the trachea, and in some cases tracheotomy becomes necessary. At this stage the spleen is always enlarged to a marked degree, though seldom reaching the size which is attained in leucocythæmia. It is firm, not tender, and occasionally the nodules of the lymphadenomatous hyperplasia give the surface a rough feeling to the palpating fingers.

The red corpuscles are diminished, the hæmoglobin much reduced and there is often a moderate leucocytosis, due to increase in the number of the polymorphonuclear cells. The eosinophil cells are sometimes increased in number, though this is not a frequent occurrence. In rare instances the lymphocytes show a marked increase before death, and the disease takes on the clinical features of an acute leukaemia.

Besides the symptoms of pressure on the trachea, paraplegia from pressure on the spinal cord has been known to occur.

Fever is often a marked feature of the affection. It assumes three types: (1) **Continuous**: considered in association with the large spleen and the swollen abdomen such a fever produces a strong resemblance to typhoid fever; (2) **Intermittent**; (3) **Remittent**. The intermittent is often periodic, the fever lasting a week or 10 days, followed by an apyrexial interval of variable length, again succeeded by a wave of pyrexia. Such a chart is extremely characteristic of the disease ("Pel-Ebstein type"). This type of fever is said to be more common in cases in which the mesenteric and retroperitoneal glands are the chief seat of the disease.

Other symptoms of more or less frequent occurrence are a moderate degree of albuminuria; œdema of the legs, scrotum and back, pleural or less commonly peritoneal effusions, and rarely the deposition of lymphadenomatous nodules in the skin. These nodules are seldom of large size and tend to

appear and disappear, and at times to become purple in colour owing to extravasation of blood. Pigmentation of the skin is most commonly due to the employment of arsenic as a therapeutic measure, but there are cases on record in which true bronzing has been observed.

Course.—The first manifestation of the disease is usually the appearance of a mass of glands in the cervical region. Should these be excised there is sometimes an interval during which there is no further manifestation; but sooner or later the glands again swell either in the same region or in some other group. At the same time the general condition becomes worse, and on examination the spleen and liver are found to be enlarged. From this period of general dissemination of the disease there may be from time to time remissions, but as a rule there is no further period at which any hope of permanent relief is permissible. The disease makes slow and steady progress, and death occurs either from the pressure symptoms or from gradual exhaustion.

Diagnosis.—In the early stages, the most usual mistake is to confuse the enlargement of the glands with that of tuberculous disease. This mistake is the more easy because there are not seldom caseous deposits in these glands in addition to the lymphadenomatous disease. Even in the later stages when there is fever with generalized enlargement of the lymph glands and the spleen, the diagnosis of general tuberculosis has been made. Microscopical examination of an excised gland will as a rule establish the diagnosis. *Sarcoma*, *endothelioma* and *leukæmia* may also be confused with *Hodgkin's disease*, and in rare instances the diagnosis of typhoid fever has been made in error.

Prognosis.—From time to time there are records of cases of lymphadenoma which recover. These, however, are so rare that it is permissible to doubt the accuracy of the diagnosis. The more acute cases usually terminate in 3 to 4 months; but where progress is slower the patients may survive for 2 to 3 years, with occasional remissions in which they appear to recover a considerable measure of health. In rare instances the fatal termination may be delayed for a longer period, up to 7 years; in such instances the condition is usually that of living death.

Treatment.—No form of treatment has hitherto proved able to cure the disease. Surgery can deal with the accessible masses; and X-ray can certainly arrest the growth both of the accessible and of the inaccessible intrathoracic masses, and thus spare the patient the sufferings formerly entailed by the pressure on the trachea and bronchi. But neither surgery nor X-rays can reach the hidden foci of the disease embedded in the viscera. Lately, the use of "Radon seeds" has proved successful in causing the disappearance of inoperable gland masses, but it is too early to speak as yet of "cure." Our knowledge of the wide spread of the lesions renders it unlikely that any local treatment will prove efficacious. The localized manifestations of the disease can be held in check by these means, and the physician can second these methods by the free employment of arsenic. There is no doubt that large and continuous doses of this drug tend to delay the spread of the disease, but there is no evidence that it will cure it. It may be given by the mouth or intravenously. Care must be taken to intermit the dosage in order to avoid the danger of arsenical poisoning; but lymphadenomatous patients appear to tolerate the drug extremely well.

Vaccines made from some of the more abnormal organisms of the intestinal tract have been stated to produce remarkable improvement.

MIKULICZ'S SYNDROME

In the year 1888 Mikulicz published the description of an affection the peculiar characters of which constituted, in his judgment, a clinical type of disease till then unknown. The chief features of the affection were the chronic symmetrical enlargement of the lachrymal and salivary glands, without disturbance of the general health. Since that date a considerable literature has accumulated, dealing with the type originally described by Mikulicz and with allied conditions, differing in various points from the classical type. From this material it is possible to arrange a classification of the varying conditions in which the chief feature of Mikulicz's original description, the symmetrical enlargement of the lachrymal and salivary glands, still stands out, though associated with symptoms which were not present in the original case.

(1) Mikulicz's disease in the strict sense is characterized by a chronic symmetrical enlargement of the lachrymal and salivary glands, without other disturbance of the health. The only disability arising from such an affection is the disfigurement, and the restriction of the fields of vision by the steady encroachment of the lachrymal glands at the outer side of either orbit. Removal of the glands is not followed by recurrence, and in some instances has resulted in the slow disappearance of the salivary enlargement. Examination of the tissues shows only evidence of chronic inflammation, without indication of the cause. The lachrymal are usually involved before the salivary glands; in some instances the enlargement affects the lachrymal, in others the salivary glands alone, though always symmetrical. (2) In the second group, the symmetrical enlargement of the lachrymal and salivary glands is associated with swelling of the lymphatic glands in various parts of the body, especially the neck, and occasionally with enlargement of the spleen. This type undoubtedly exists, though it is difficult to separate it from such diseases as leukæmia and lymphadenoma (Hodgkin's disease) in which the syndrome appears as a complication. When these can be excluded, there emerges a type of disease, sometimes slowly fatal, at other times merely disfiguring. The cause of the enlargement remains obscure. (3) The third type is that in which the swellings are caused by infiltration with malignant growth, usually of the lympho-sarcoma character. Sometimes there is reason to suppose that the growth is primary in the lymphatic glands of the neck: at others it seems that the enlargement is secondary to disease elsewhere, *e.g.* in the bones or in the retro-peritoneal glands. In one such case the swelling was intermittent, recurring at intervals, while the original growth in the pelvis steadily increased. (4) A type in which the symmetrical painless swellings are undoubtedly the result of tuberculous infiltration. In more than one such case tubercles and bacilli have been demonstrated. (5) A type in which the inflammation is due to syphilitic infection; a rare, but established, phenomenon.

There are met with occasionally cases which, while not agreeing with any of the above types in particular signs, yet probably belong to the same

general type ; for example, instances of symmetrical swelling of the salivary glands alone in young children, which persists for months, with some deterioration of the general health, but without any indication of cause. There is also stated to be an hereditary affection which disfigures individuals of the same family through several generations.

Pathology.—Apart from the ascertained causes, leukæmia, malignant growth, tuberculosis and syphilis, we may agree with Mikulicz that the affection is the expression of an unknown infection. This opinion is reinforced by the fact that chronic infection of the naso-pharyngeal tract is often a precursor of the swellings.

Diagnosis and Treatment.—When it is recognized that the syndrome may be the earliest evidence of a serious condition, malignant disease, leukæmia, lymphadenoma or a manifestation of tubercle or syphilis, the residue of cases presenting the peculiar symmetrical enlargements is small. Such patients will more often consult the doctor because of the disfigurement than for any failure of health. Thus, it has happened that a considerable number of the recorded cases have received benefit from the skill of an ophthalmic surgeon ; the removal of the lachrymal glands being followed by the disappearance of the salivary tumours. Besides operative treatment, or, in appropriate instances, specific treatment, attention should be paid to the condition of the tonsils, ears, and sinuses. The use of potassium iodide, to promote a free flow of saliva, appears to be beneficial in some instances.

HUGH THURSFIELD.

SECTION X

DISEASES OF THE BLOOD

CONSTITUENT ELEMENTS OF THE BLOOD

THE blood consists of—(1) Red blood corpuscles ; (2) white blood corpuscles ; (3) blood platelets ; (4) blood plasma.

1. The red blood corpuscles or erythrocytes number 5,000,000 per c.mm. in the male adult, and rather less in the female. The actual counts vary somewhat according to the source from which the blood is obtained, whether from artery, vein or capillary. The figures given are those found by the ordinary methods of examination of the capillary blood. Residence at high altitudes above sea-level increases the average count. The red blood corpuscles are examined for their size (anisocytosis), shape (poikilocytosis) and staining reactions (polychromatophilia) ; and the amount of colouring matter (hæmoglobin) which they contain is estimated by various methods in percentages of the normal. The ratio of the percentage of hæmoglobin to the percentage of the corpuscles is termed the *colour index*. Nucleated red blood corpuscles are only found in normal conditions in the infant—and then usually only for a short time after birth ; they occur frequently in disease, especially in the more severe types of anæmia, and are called *microblasts*, *normoblasts* and *megablasts* according to their shape and size.

The red blood corpuscles are also examined from the point of view of their *fragility* in solutions of sodium chloride. Normally they retain their hæmoglobin in solutions stronger than 0.47 per cent., but in certain diseases their fragility is more or less pronounced.

2. The white blood corpuscles are usually from 8000 to 10,000 per c.mm. ; but their number bears no relation to, and varies independently of, the red corpuscles. The precise nature and characters of the different forms of leucocyte are a matter of dispute, but five varieties are usually recognized—(1) The polymorphonuclear cell ; (2) the lymphocyte ; (3) the large mononuclear or hyaline cell ; (4) the eosinophil cell ; (5) the basophil cell.

In addition to these five varieties another type of cell described as “transitional” is often present ; and in disease “myelocytes,” which are normally found only in the red bone-marrow, appear in the peripheral blood and organs.

An increase of the numbers of the white cells in the capillary blood constitutes a *leucocytosis* ; a decrease a *leucopenia*. In strict usage a leucocytosis may be due to an increase in any one or in all of the five varieties mentioned—in common practice a leucocytosis means an increase of the polymorphonuclear variety ; when otherwise used the proper qualification is added,

e.g. eosinophil-leucocytosis. A physiological leucocytosis occurs during digestion, after exercise, and during pregnancy. It is seldom likely to cause confusion with that due to disease.

3. The blood platelets number from 200,000 to 300,000 per c.mm. They are much reduced in number in certain diseases—especially idiopathic purpura, and increased after hæmorrhage and in some of the severer forms of anæmia.

4. The blood plasma is obviously of the greatest importance both in health and disease; it has been principally studied in connection with agglutinins, precipitins and opsonins; and is known to carry in solution many other bodies of vital significance.

Clinical methods have been devised for the estimation of the coagulability of the blood, the bleeding-time, the viscosity, specific gravity, and total volume of the blood. These methods have as yet entered but little into general use, but the coagulation-time and the bleeding-time have assumed considerable importance both in the diagnosis and in the pathogeny of the diseases of the "hæmorrhagic diathesis."

CLASSIFICATION OF DISEASES OF THE BLOOD

Knowledge of the essential causes of these diseases is still scanty, so that any classification must be tentative, and that here employed is no less arbitrary than another. It is based partly upon clinical facts, partly upon the results of microscopic methods.

1. Those diseases in which anæmia is secondary to disease elsewhere in the body: Secondary anæmia.

2. Those diseases in which the alteration in the blood appears to be the essential factor in the illness: Primary anæmia.

3. Those diseases in which the alteration in the blood appears to be an essential, but not the dominating factor: Leukæmia, splenic anæmia and similar conditions.

4. Those diseases characterized by an increase in the number of the corpuscular elements of the blood: Polycythæmia,

5. Those diseases characterized by the occurrence of hæmorrhages in the skin and from the mucous membranes, which are due to deep-seated abnormalities of the hæmopoietic system; the diseases of the "hæmorrhagic diathesis."

POLYCYTHÆMIA

Synonyms.—Splenomegalic Polycythæmia; Myelopathic Polycythæmia; Vaquez' Disease; Osler's Disease.

Definition.—A condition characterized by the presence of more than 5,000,000 red corpuscles in the c.mm. of blood.

Ætiology.—Polycythæmia may be (1) relative, or (2) absolute.

1. Relative polycythæmia is due to the concentration of the blood, as in severe diarrhœa or excessive loss of fluid from the body. It can occur locally in a congested or cyanotic area.

2. Absolute polycythæmia is (a) secondary, or (b) primary. The former

is due to the effort of the hæmopoietic system to compensate for the defective oxygenation of the blood. Such a condition is observed in congenital stenosis of the pulmonary orifice, where counts as high as 11,000,000 erythrocytes have been made; in the cyanosis of acute and chronic bronchitis, and of a failing circulation; and in persons who live for some time at high altitudes. It has also been recorded in some cases of chronic tuberculosis and syphilis, and in cases of thrombosis of the portal vein or its main tributaries. Secondary absolute polycythæmia is termed *erythrocytosis*. (b) Primary absolute polycythæmia or *erythræmia* is a disease in which it is believed the cause of the polycythæmia is a primary hyperplastic activity of the hæmopoietic system. It is almost invariably associated with splenomegaly.

The disease affects persons of both sexes, usually in the middle period of life, 35 to 55 years of age; but it has been described in younger and in older individuals. Of the exciting cause nothing is known. It does not appear to be related to any of the known infective organisms.

Symptoms.—The earliest complaint is usually of headache, migraine or giddiness, a sensation of “bursting” in the head, pains in the splenic region, epistaxis or bleeding from the mucous membrane of the nose or mouth. At this stage the cyanosis is often not marked, or only becomes evident on exertion; it is most obvious in the lips, ears and finger-tips. The general appearance is bluish-red rather than the dark blue of pulmonary cyanosis. The vascular engorgement can be best observed in the tongue, fauces, conjunctivæ and retina.

The spleen is usually enlarged and hard, but does not often reach any great size, seldom being palpable below the level of the umbilicus. It is not tender to palpation, though there is often some pain in this region.

The urine often contains a moderate amount of albumin, and a few hyaline or granular casts, and has several times been observed highly coloured with urobilin.

The blood-pressure is usually, but not always, above the normal; though in some cases it has been found very high, above 200 mm. of Hg. Hence some authors have used the name polycythæmia hypertonica.

Examination of the blood shows from 7,000,000 to 12,000,000 red corpuscles, which are stated to be often slightly below the normal in diameter. They are well formed and stain well. There is nearly always a leucocytosis even as high as 40,000, due to the increase in the polymorphonuclear cells. Once or twice a leucopenia has been recorded. Normoblasts are nearly always present, and megaloblasts and myelocytes very frequently. The hæmoglobin is usually above 100 per cent., and may reach as high as 200 per cent., but the colour index is seldom above 1. Other changes, e.g. in viscosity, coagulability, specific gravity and total volume have been noted, but at present in too few instances to justify a definite statement. Enlargement of the liver is common, and muscular and mental weakness constant.

Course.—In many instances the disease is apparently non-progressive, in others there appear to be intermissions alternating with exacerbations.

Complications.—Jaundice, hæmorrhage from the mucous membranes, erythromelalgia, pigmentation of the skin, and gradual failure of the heart are the complications most frequently observed. Death occurs from cerebral or meningeal hæmorrhage, with a sudden increase in the cyanosis, or from intercurrent disease.

Treatment is entirely symptomatic. The cyanosis and high blood-pressure may be relieved, temporarily at least, by venesection. Splenectomy has failed. X-ray applications have occasionally appeared to do good. Light diet, abstinence from alcohol, freedom from mental worry, avoidance of sudden exertion, and careful regulation of the bowels appear to be the best means of keeping the patient in comfort. More recently the administration of phenylhydrazine, in doses of 2 to 3 grs., has been recommended.

ANÆMIA

(A) SECONDARY ANÆMIA

Definition.—A secondary anæmia is a condition which can be traced to an ascertainable cause, the removal of which leads to restoration of the normal state.

The above definition is obviously defective, but it will be made more intelligible by what follows.

Ætiology.—(a) The most obvious cause of a secondary anæmia is the occurrence of hæmorrhage. From whatever source this may arise the effect upon the circulation is immediate and proportionate to the amount of the loss. Apart from trauma, the most common causes of severe loss of blood are hæmorrhages from the stomach and intestinal tract. Profound anæmia may also occur from hæmorrhage from the urinary organs.

(b) Anæmia due to the action of poisons, either mineral, chemical or bacteriological. Among the mineral poisons lead takes the first place; other metals are not prominent. Of purely chemical poisons the members of the nitro-benzene group have in the past given rise to some severe cases, even before the Great War; but the poisons of the infective diseases are the most frequent cause of anæmia of this type. All the infectious fevers, the poisons of syphilis and malaria, and probably the toxins of various intestinal infections produce a greater or lesser degree of anæmia. A chronic infective process in the dental alveoli, in the tonsils, and other lymphatic structures of the naso-pharynx is a frequent cause of anæmia. It is of course difficult to separate the different factors in this connection. For example, the anæmia of congenital syphilis is often striking, but the fact that many cases of the disease do not show any anæmia at all, renders it doubtful whether in any given case there are not other factors at work. This is almost certainly the case in chronic tuberculosis, which does not appear, in the absence of complications, to be the cause of any alteration in the blood.

In the case of the parasitic worms there is a twofold possibility. The anæmia may be due to the actual loss of blood as, for example, in the case of infection with the Ankylostoma duodenale, or the worms may produce a toxæmia which leads to the destruction of the hæmoglobin and the corpuscles.

(c) Anæmias due to defective nutrition are a large and varied group. They include not only the anæmias directly to be traced to an insufficiency of food, or to the absence of some essential element, such as a vitamin, but also those which may be broadly called the anæmias of cachexia. Malignant disease, chronic nephritis, chronic suppuration and chronic indigestion may any of them produce a marked anæmia, which may no doubt often be partially

toxic; but it is also probably partly the result of defective assimilation of food. The extreme instance is a carcinoma of the oesophagus or of the stomach which absolutely prevents the ingestion of sufficient nourishment.

Symptoms.—The recognition of an anæmia due to hæmorrhage is as a rule easy. The patient is restless, thirsty, with a small pulse, and obviously blanched. In severe hæmorrhage the red blood corpuscles may be reduced to a half or even a quarter of the normal; the hæmoglobin suffers to a greater degree. It is possible to lose several pints of blood without a fatal issue. If the hæmorrhage be arrested, regeneration begins with great rapidity; and this is especially true of the corpuscular elements, while the hæmoglobin is reconstituted more slowly. Thus, after a severe hæmatemesis, the number of erythrocytes may be normal in 3 to 4 weeks, but the hæmoglobin will not recover its standard for some weeks later. In the stage of recovery the greatest attention should be paid to the condition of the heart-muscle; dilatation and the consequent breathlessness frequently persist for some weeks or even months after the onset.

In all these secondary anæmias the alteration in the blood is approximately the same. There is a diminution in the number of erythrocytes, with a still greater diminution in the amount of hæmoglobin, so that the colour index is below the normal, and does not usually rise above 0·6 or 0·7. The number of leucocytes is, on the other hand, not as a rule markedly abnormal; in special cases, as, *e.g.*, after hæmorrhage, polymorphonuclear leucocytosis is frequent for a few days and nucleated red corpuscles are noticeable; and as is well known in typhoid fever there is a leucopenia, but generally the secondary anæmias are not characterized by abnormalities in this direction.

Diagnosis.—In many instances the origin of a secondary anæmia is easily discerned, and with the removal of the cause the anæmia usually quickly disappears. In other instances, though the blood-picture constantly presents the above features characteristic of a secondary anæmia, the cause eludes the acumen of the physician. It was, for example, many years after the clinical recognition of "miners' anæmia" that the infection with ankylostoma was recognized as the cause.

Treatment.—~~With~~ The detection of the cause, and its appropriate treatment, the anæmia does not as a rule persist. Tonics such as iron and arsenic help recovery, and convalescence is often made more rapid by removal to a bracing and invigorating climate. It is only rarely that any more strenuous treatment is required. Good hygiene and careful feeding are necessary.

(B) PRIMARY ANÆMIA

PERNICIOUS ANÆMIA

Synonyms.—Addison's Anæmia; Idiopathic Anæmia.

Definition.—A severe progressive anæmia of unknown causation, characterized by destruction of the red corpuscles, a high colour index, and a leucopenia. It is of course not a primary anæmia in the strict sense of the word, since it is obviously a disease of much besides the blood, but until further knowledge of its essential nature is obtained it is convenient to keep the conventional term of classification.

Ætiology.—Addison was the first to describe an idiopathic anæmia of severe type progressing to a fatal termination. Since his time the existence of such an entity has been called in question, and some types of severe anæmia have been successfully differentiated; but there remains a group which has certain well-defined characteristics, for which it has been found impossible to assign a cause, and which as a rule progresses steadily, through remissions, to a fatal issue. The disease is found in all civilized countries. There is reason to believe in a family predisposition, manifested in several members of one or more generations. The disease is met with in all classes. It is chiefly one of middle life; indeed, it is doubtful whether the grave anæmias of children belong to the same category. Males are much more commonly affected than females, in the proportion of two to one. It is found alike in those who have suffered a variety of illnesses and in those who have enjoyed robust health. There is no known cause of the disease. Hunter has emphasized that oral sepsis is the cause of the anæmia, but in our opinion the latter is too frequent a phenomenon to permit us to regard the former as more than a contributory cause. Achlorhydria is a constant phenomenon. It is maintained by some authorities that it is the essential underlying cause both of the anæmia and of the combined degeneration of the cord, and that the family predisposition to these diseases, noted above, is due to the existence of a familial achylia gastrica. The recent work of Minot and Murphy on the therapeutic benefits of non-protein, iron-free extracts of mammalian liver suggests that these have a specific action on the production and maturation of erythroblasts in the bone-marrow, and would appear to indicate that the disordered hæmopoiesis is of the nature of a "deficiency disease."

Pathology.—The morbid anatomy is for the most part unilluminating. The body is not as a rule wasted to a marked degree; all the internal organs are bloodless, but in other respects are normal to the naked eye. There are often a few petechial hæmorrhages in the serous membranes, and there is a marked degree of fatty degeneration of the heart muscle ("tabby cat" striation). The striking feature of all cases of idiopathic anæmia is the deposit of free iron in the tissues of the body; the liver and kidneys show this phenomenon best, but it is often present in the heart-muscle, in the suprarenal bodies, in the mucosa of the intestine, in the spleen, and in the bone-marrow. This "Prussian-blue" reaction is so characteristic of the true pernicious anæmia that where it fails the diagnosis must be held doubtful. The bone-marrow is usually of a deep red colour, due to erythroblastic activity. The cells present are for the most part large nucleated red cells, which are greatly in excess of those formed in normal marrow; but general activity of all varieties of cell is marked. Besides these changes there is generally little or nothing to attract attention. The lymphatic glands are seldom enlarged.

Symptoms.—The onset of the disease is slow and insidious; the patient can rarely assign an exact date to the first beginnings; he has only slowly become conscious of failing strength, or of breathlessness on exertion, or that his friends have commented on his appearance, which at once suggests the nature of the disease. The complexion is waxy, with a faint lemon-yellow tint, sometimes most apparent in the sclerotics. The lips and gums are bloodless, and there are often slight hæmorrhages from the mucous

membrane of the mouth. On examination small petechial hæmorrhages may be found in the skin, and in the majority of cases in the retina, and sometimes in the conjunctiva. Epistaxis is not uncommon; but other hæmorrhages are rare. Oedema of the feet and ankles is often present. The muscular weakness is extreme, and the mental condition dull. Physical examination does not add much to these signs. A relatively good state of nutrition, combined with pallor, is very characteristic. Cardiac murmurs are often present, and the heart may show some slight degree of dilatation. The spleen is palpable in about a third of all cases, but rarely reaches any considerable size. Fever is generally present at some time during the course of the illness, but is seldom high; it is often of an intermittent type. Sore tongue is common. Diarrhœa is a frequent feature, and is sometimes intractable. The urine is of a deep colour due to the presence of urobilin. In about half the cases there is, especially late in the disease, evidence of the existence of a combined lateral and posterior degeneration of the spinal cord, revealed by sensory disturbances of the lower limbs, and by paralysis and ataxia, often associated with spasticity. The nervous phenomena may precede the development of the anæmia.

The blood of such a patient shows striking characters. The number of the red corpuscles is always low, often less than 1,000,000 per c.mm., the shapes and sizes of the cells are varied, but increase of cells above the normal size is very characteristic; the staining reactions abnormal; and there are always present nucleated red corpuscles, both normoblasts and megaloblasts. A certain number of reticulocytes may sometimes be present, especially associated with periods of remission and also after the commencement of liver treatment. The hæmoglobin is diminished but usually in much less proportion than the corpuscles, so that the colour index is high; nearly always above 1, and sometimes reaching as much as 2, or even higher. The white cells are diminished, the diminution being due chiefly to the decrease in the number of the polymorphonuclear cells; a common figure is from 2000 to 4000 per c.mm. The blood-platelets are generally diminished in number, but the coagulability and the bleeding-time are usually normal.

A feature of the disease is that the gravity of the case does not correspond to the severity of the blood disorder. It not infrequently happens that the patient may feel better and even fairly well, less breathless and able to walk, or even to do a little light work, with at the same time a blood-picture characteristic of the disease. Vice versa the condition of the blood may be improving steadily towards a normal state while the patient is obviously going fast downhill.

Another curious phenomenon is the occurrence of blood-crises, in which the peripheral circulation is flooded with nucleated red corpuscles for a few days, and the numbers of the corpuscles and the ratio of the hæmoglobin take an upward bound.

Diagnosis.—The accurate diagnosis of this disease is difficult without the frequent aid of skilled laboratory assistance. There are several anæmias of a severe type which a careful examination of the blood can alone differentiate from idiopathic anæmia. Certain cases of infective endocarditis, of septicæmia, of gastric cancer, or of parasitic intestinal disease show symptoms which offer a close resemblance to those of idiopathic anæmia. On the other hand, from time to time there occur cases in which the blood-picture is that

of idiopathic anæmia, but the general symptoms and the course differ widely. To sum up : any severe anæmia which presents the blood-picture characteristic of pernicious anæmia, without any discoverable reason, should be considered to belong to this category, and the prognosis and treatment adjusted to the diagnosis.

Prognosis.—While the course and duration of a typical pernicious anæmia are on the whole progressive and short, there is no doubt that patients suffering from this disease have remissions, during which they not only are able to resume their ordinary life, but their blood often returns almost to a normal condition. Such remissions are usually brief, and a duration of two years is about the usual limit. Death generally occurs as a result of the increasing exhaustion ; and the last stages are frequently those of coma. Recovery is exceptional, but does occur with some frequency. It is, of course, always open to the objection that the patient who recovers was not really suffering from Addisonian anæmia, but in late years the careful diagnosis of these cases has lessened the value of this criticism. In a disease in which remissions and relapses are so common it is difficult to estimate the proportion of true recoveries, but it is certainly as high as 10 per cent. and may be as much as 20 per cent.

The foregoing paragraph, written some three years ago, must now be considerably modified in view of the remarkable results of the treatment with liver and extracts of liver. It can be stated with confidence that a patient suffering from pernicious anæmia, if he is able to assimilate liver or liver extract, can expect a rapid return to a fairly normal life, so long as he continues the treatment. The beneficial effects of the treatment are generally established at once, and within a period of two months the red blood-corpuscle count will have reached from 4 to 5 millions per c.mm., with a cessation of other symptoms and a restoration of muscular and mental power. An exception must apparently be made in the case of patients who at the beginning of the treatment have already shown signs of involvement of the nervous system. Subacute combined degeneration of the cord is probably not influenced by the treatment.

Treatment.—Attention should, of course, be paid to all possible sources of sepsis, such as in the mouth, the tongue and the fauces ; but in severe cases it is better to delay any operative procedure until the condition has begun to improve.

The treatment of pernicious anæmia has been revolutionized by the discovery of the remarkable effect of a diet of mammalian liver. The quantity required appears to vary with individuals, but it is best to aim at the absorption of half a pound of liver daily. It may be administered by any method, raw or cooked, palatable to the patient. According to Minot and Murphy, however, it should not be subjected to prolonged boiling. Liver extracts have now been prepared by several of the well-known chemical houses, and have been proved equally efficacious with the raw liver. They are more easily administered, as they are in the form of a deliquescent powder, soluble in hot water. The resulting liquid can be flavoured to the patient's taste. The dose of these extracts is stated in terms of the quantity of raw liver from which they have been prepared, and should be the equivalent of at least half a pound daily. The chief difficulty encountered is to secure that the patients shall take and assimilate the required amounts. In some cases

it is necessary to begin with less than the desired amount and to increase the dosage gradually. The progress can be best estimated by an enumeration of the reticulocytes, which increase in number by leaps and bounds; but in most cases a sufficient indication can be secured by frequent estimations of the numbers of the erythrocytes. The liver treatment should be continued after restoration to apparent health, since it is probable that, though it so favourably affects the anæmia, it does not attack the unknown underlying cause. Patients in the convalescent stage should take the liver extract three days in each week; and in most cases will require to do so permanently. As regards other items of the diet, so soon as the general condition allows, the patient should receive a generous allowance of fresh meat, fresh fruit and vegetables.

The achlorhydria, which is a common feature of the disease, is best treated by dilute hydrochloric acid, 1 to 2 dr. in water three times a day (*vide* p. 527). Some authorities consider this drug as an essential part of the treatment, to be continued indefinitely. Transfusion with whole citrated or defibrinated blood is a valuable method of treatment in most critical cases. It seems to be better to give two or three transfusions of moderate amounts, 150 to 250 c.cm., rather than larger single quantities. Some physicians have found splenectomy to be effective in rescuing patients in the last stages of exhaustion. It is most successful in patients in whom the spleen is definitely enlarged. In view of the results of liver treatment, this method of treatment will, however, probably disappear.

ANÆMIA GRAVIS OF CHILDREN

The type of pernicious anæmia described above occurs in children with extreme rarity; so rarely that a critical examination of the records reveals less than a dozen cases which could be so classified with any degree of confidence. Anæmia, however, of a similarly severe and usually fatal type is not uncommon below the age of puberty, and possibly may be the same disease. It is often recorded under the title of "Aplastic Anæmia," but since this is an appellation which is suitable to, and has been employed for, a variety of widely different conditions, it is preferable to speak of it as "Anæmia Gravis."

Pathology.—Regarding pathogenesis, there is nothing to add to what has been said in the preceding section, except that the phenomena of spinal cord degeneration have not been observed in the child. The morbid anatomy of the fatal cases is similar to that of the pernicious anæmia of adults; the striking difference is in the condition of the bone-marrow; instead of the reddish tint there is a complete absence of colour, the usual red marrow being replaced by yellowish fat throughout the length of the bone.

Symptoms.—Like pernicious anæmia, the onset is insidious, with lassitude, breathlessness and steadily increasing pallor; there is the same "lemon-yellow" tint of the skin and sclerotics; the same marked diminution in the number of the red corpuscles; and the same leucopenia. On the other hand, the hæmoglobin is destroyed more rapidly, so that there is a low rather than a high colour index; and the nucleated erythrocytes, which are so striking a feature of the blood-picture of pernicious anæmia, are in the child almost

entirely absent. The tendency to submucous and subcutaneous hæmorrhage is in both pronounced; retinal hæmorrhages are common; but hæmorrhages, other than epistaxis, of any degree of severity, are as uncommon as in the adult disease. As in pernicious anæmia, fever is present at some period in the course of the illness, but it is a less striking feature; rarely there is an intermittent pyrexia, with comparatively high peaks of 103 to 104. The teeth, tongue, gums and fauces do not generally present the inflammatory lesions which are common in the adult; but, as in pernicious anæmia, the spleen usually is moderately enlarged. Diarrhœa is not seen, and the urine does not, as a rule, show the urobilin which is common in the adult.

Course.—The course of the disease is similar to that of pernicious anæmia, the difference being that the remissions which are not uncommon in the adult are rare in the child, in whom steady deterioration to a fatal issue is the rule. But just as there are cases of typical pernicious anæmia which after a period of severe cachexia ultimately recover completely, so in children a condition, which in many respects resembles the severest type of the disease, after some months progresses to health.

Treatment.—This is the same as in adults, but so far liver treatment has not seemed to give the remarkable results obtained in the adult form of the disease.

SICKLE-CELLED ANÆMIA

Definition.—A severe anæmia, characterized by the appearance in the blood of a number of red blood corpuscles of a peculiar sickle shape.

Ætiology and Pathology.—Up to the present time the disease has been observed only in the negro. It is hereditary and familial. In the affected families some members who have sickle cells in their blood do not suffer from anæmia. The disease usually dates from infancy. Of its essential cause, nothing is known. The post-mortem appearances do not throw any light upon the pathology.

Symptoms.—The patients are obviously anæmic, and the sclerotics exhibit a greenish-yellow tinge. The liver is bulky, but the spleen is not enlarged. The disease is characterized by intermittent paroxysms of fever, up to 103 or 104 degrees, with severe stabbing pains in the muscles and joints, which last for two or three weeks. In the intervals, the patients suffer but little, though they are listless and depressed. The red blood corpuscles in the intervals reach to a number of about 3,000,000 per c.mm., but during the paroxysms they rapidly fall to less than half that number. The white cells are usually about 15,000 per c.mm., but may rise to as much as 40,000. The sickle-shaped corpuscles are in varying numbers. They appear to increase in number on a warm slide. The coagulation-time, the bleeding-time, the fragility of the corpuscles, and the numbers of platelets are all within normal limits.

Course and Prognosis.—The course of the disease is slow but progressive, and death usually occurs before the age of thirty.

Treatment.—Up to the present time, no treatment has appeared materially to influence the progress of the disease.

CHLOROSIS

Synonym.—Green Sickness.

Definition.—A disease, peculiar to young women, characterized by an anæmia due essentially to a diminution in the amount of hæmoglobin.

Ætiology.—It is a disorder of girls at or near the age of puberty, and of young women. It is said to occur in boys also, but this is extremely doubtful. It is a disease of civilized races, and is more common in the town than in the country. Heredity and family influences play no part in its production. It is most common in the ill-fed and overworked factory hand, who has to spend long hours in close rooms at a period when her growth and development are making the greatest demands on her strength; but these are not essential conditions, as is evidenced by its occurrence among the girls of wealthy families living under the best conditions. Many other causes have been alleged, such as tight-lacing, neglect of the teeth, improper food, habitual constipation, and emotional disturbances, for instance the pangs of unrequited love; but when all is said, the real cause remains undiscovered. What is certain is that, whatever be the reason, the disorder is much less common in the last ten years than it was previously. The age at which it usually makes its appearance is between the fifteenth and the twentieth year of life.

Pathology.—The hypotheses published on the pathology of chlorosis are as numerous and as ill-supported by good evidence as are the guesses at its causation. About the only remark which can safely be made on this head is that measures directed to the cure of the anæmia usually result quickly in the disappearance of all the symptoms of the disorder; in the present state of knowledge it remains a primary anæmia.

Symptoms.—The chlorotic girl is usually well-developed, even fat. Her pallor is striking both in its degree and in its peculiar greenish tint, from which the disorder derives its name. The mucous membranes have scarcely a tinge of colour; the sclerotics are bluish; and there is often a slight œdema of the skin of the face, giving it a puffy appearance. The patients complain of breathlessness, of swelling of the feet and ankles, of fainting attacks, of irritability of temper, and of low spirits. Headache, pain after food, and constipation are often present; and there is nearly always disturbance of the menstrual functions, either amenorrhœa, or less commonly menorrhagia; there is usually also exaggeration of the symptoms at the menstrual periods. Epistaxis sometimes occurs, but as a rule there is no other tendency to hæmorrhage. The appetite is variable and there is often caprice for unusual forms of food or drink. The patients may take large quantities of acid liquids; or eat indigestible materials such as chalk or earth. Pain in the stomach, eructations and vomiting are common. The hydrochloric acid of the gastric juice is commonly increased.

The blood is pale and watery, its total volume increased by an abnormal amount of plasma; the red corpuscles usually somewhat decreased in number to 4,000,000 or less, the hæmoglobin 50 per cent. or less of the normal; and the leucocytes remain in normal or in slightly increased number, the increase if present being due to the polymorphonuclear cells. Under the microscope, the red corpuscles are of various shapes and sizes, and take

stains capriciously (polychromatophilia). Nucleated red corpuscles are uncommon, and abnormal forms of leucocytes are very rare.

The heart is usually dilated to a moderate degree; and palpitation and præcordial pain are common. Pressure over the apex of the heart is often very painful. On auscultation a systolic murmur is frequently present—often at the apex but nearly always at the base of the heart—the so-called hæmic murmur. Over the jugular vein at the root of the neck a loud, harsh, continuous murmur, the *bruit de diable*, is heard. This murmur, though most often found in chlorotic patients, is not peculiar to this disease, for it is found in other forms of severe anæmia.

Chlorosis is an afebrile disorder, but in exceptional instances there is a slight rise of temperature, easily controlled by rest.

Complications.—The only complication met with in chlorosis is thrombosis of veins, and this is rare. The vein most frequently involved is the femoral; but there are records of thrombosis of the longitudinal sinus and even of the veins of the retina. Whenever a large vein such as the femoral is thrombosed there is a possible risk of pulmonary embolism.

Diagnosis.—Usually the condition can be recognized at a glance, and the only error at all likely is to mistake the early anæmia of tuberculosis or of Bright's disease for the simple anæmia. The failure of treatment quickly corrects this mistake.

Prognosis.—There is no disease which is more amenable to treatment than chlorosis, and though in a few cases recovery may be delayed for some weeks it is usually complete and permanent. Recurrences are not very common.

Treatment.—It is almost permissible to speak of iron as a specific drug in the treatment of chlorosis. It may be given in any easily assimilable form: reduced iron, citrate of iron and ammonium, Bland's pill, or one of the ferruginous waters. Arsenic is also of value. Apart from iron, the physician must pay attention to the relief of the constipation, and for this there is no better remedy than aloes. To these remedies it is only necessary to add rest in bed for a severe case, and fresh air and moderate exercise for the convalescent. The diet should be simple and such as does not lead to the symptoms of indigestion. It is not necessary to give any cardiac tonics, and in fact it is wise to avoid any mention of dilatation; the chlorotic girl is only too ready to diagnose heart disease for herself.

LEUKÆMIA

Definition.—A disease characterized by increase of one or more of the leucocytic elements of the blood.

Ætiology.—The predisposing and exciting causes of the affection are equally unknown. It is recognized in all civilized countries, and in them affects all races; there is no evidence that it is inherited—indeed, healthy children have been born of mothers suffering from the disease—nor is it a family affection. It occurs at all ages from infancy to old age: at least three-quarters of the lymphocytic type occur in children under 10 years of age, whereas the myelocytic form is found predominantly in adults; the two sexes are affected about equally.

A possible conception is that the hæmopoietic system is liable to attack by a variety of toxins having affinity for different portions of the system, manufactured within the body in morbid conditions whether these are of bacterial origin or not.

As to the exciting cause of the disease we are ignorant. If the acute form be studied alone it is difficult to resist the conception of an acute infection. However, in spite of the occasional discovery of streptococcal infection, it is agreed that there is no positive evidence; and at present no other parasite has found acceptance. Moreover, however plausible such an explanation may be for the acute form, it leaves us without an adequate hypothesis for the more chronic type, and in our view no explanation which would separate the two groups can be satisfactory.

TYPES OF THE DISEASE.—The disease is met with principally in two forms, distinguished from each other by the usual course of the illness as well as by the characteristic alteration of the blood. These two types are called—(a) the myelocytic type, and (b) the lymphocytic type. These will be described separately, but it is necessary to mention briefly some other varieties about which there has been and there still is considerable diversity of opinion.

Mixed leukæmias.—This term is frequently employed to indicate those cases of the affection in which neither the myelocytic nor the lymphocytic type appears to predominate. It is, however, a mistake to make use of a term which merely serves to confuse further a subject already presenting much difficulty in classification, and it is best to adopt Cabot's rule that where there is a large proportion of granular cells, polymorphonuclear, eosinophil, basophil or myelocytic, the designation should be "myelocytic leukæmia," even though the percentage of non-granular forms is high.

A-leukæmic leukæmia.—This cumbersome and contradictory title is given to cases of the disease which run their course without any increase in the total number of leucocytes circulating in the blood. Such cases are uncommon, and it is more usual to find the initial fall in the numbers is only temporary and there is a steadily increasing preponderance of myelocytes or of lymphocytes. The clue to the right appreciation is given by a close study of the forms of leucocytes which are present. Thus in a boy with only 6300 leucocytes a differential count showed that 85 per cent. of these were lymphocytes. In some few of these cases the diagnosis remains uncertain until death, when the leucocytic infiltration of the organs usually gives the required information. Instead of the title used above it is preferable to speak of leukæmia without leucocytosis.

Aplastic anæmia.—This is another term which has been unfortunately employed to denote the absence of leucocytosis in a disease which otherwise has most of the features of leukæmia. The conception which underlies the name is that the hæmopoietic system has been so paralysed that it has entirely ceased to produce the elements of the blood. This condition, however, is not confined to leukæmia, but occurs in other forms of anæmia. The majority of cases which have been published with this title are probably instances of leukæmia without leucocytosis, but they also include unusual types of pernicious anæmia, and possibly some few cases of the most severe type of purpura hæmorrhagica. It is a disputable point whether there is any form of severe rapidly fatal anæmia other than these three diseases, but

the more closely the records of the cases are scrutinized the less reason there appears for the introduction of a new type.

The term "leukanæmia" has also been employed to describe cases of this type: and "pseudo-leukanæmia," specially on the Continent, denotes the same group.

There is a small group of cases in which the changes in the blood are those of leukæmia, myelocytic or lymphocytic, but the nature and growth of the glandular swellings resemble those of a neoplasm. They fall into two divisions—(a) chloroma; (b) sarcomata originating in the lymphoid tissues of one or other of the glandular organs of the body. These growths are rare and should in the present state of our knowledge be separated from leukæmia.

Pathology.—The view adopted here is that leukæmia is one disease, affecting the whole hæmopoietic system, marrow, glands, spleen and lymphoid tissues of the viscera, with special incidence on one or other of these structures in different cases. The more closely the different types are studied the more clearly does the essential similarity appear. The older conception of two sharply differentiated types, myelogenous and lymphogenous, arising respectively in the bone marrow and the lymphoid tissues, was urged by Ehrlich and his pupils, but it is now generally agreed that both types are myelogenous, and that the various types of cell probably originate from one primitive marrow-cell.

The hypothesis that leukæmia is of the nature of a malignant new growth of the system does not appear to be tenable, if only because it fails to offer any explanation of the cases of fulminating leukæmia, in which death occurs in a very few days.

The changes which are found in the body are almost confined to the hæmopoietic system, and to the lymphoid tissues of the organs. The bone-marrow is unusually red in colour, and in the myelocytic type verges on a purple tint. Microscopically, there is an abundance of mononuclear non-granular cells in all types, and in the myelocytic variety a large number of fully-differentiated granular cells. There is also a marked increase in the number of nucleated erythrocytes.

The blood is often of a greyish colour, due to the preponderance of leucocytes, and the serum opaquely milky. The spleen is always enlarged and in the myelocytic type is often larger than in any other disease, and not infrequently contains large pale infarcts consisting of agglomerations of leucocytes; or of degenerated tissue, partly caseous, partly hyaline.

The liver is large, firm and of a pale yellow tint, or mottled with small whitish areas. Microscopically, the periportal and capillary spaces are thronged with leucocytes, myelocytes in the one form and lymphocytes in the other. In the more acute cases these deposits are more scattered, and considerable search will be necessary to find them.

The kidneys are large and sometimes mottled with hæmorrhages. Under the microscope the interstitial tissue is so crowded with the myelocytic or lymphocytic cells as occasionally to obscure the structure of the organs.

The lungs also show the same microscopic characters, especially under the pleuræ, and the heart muscle, besides the fatty degeneration which accompanies any form of severe anæmia, shows similar patches of infiltration.

Petechiæ are often found in the pericardial and pleural membranes, and

occasionally in the mucous membranes of the intestine, but extensive hæmorrhages are unusual. A special type of hæmorrhage is occasionally seen in the retina, constituting "leukæmic retinitis."

Onset.—Clinically there are two types of onset—the acute and the chronic. The rule, though with exceptions, is that the more acute the onset the more likely is the disease to assume the lymphocytic form, and the chronic cases are for the most part of the myelocytic variety. There are, however, acute cases of the myelocytic type, and even more frequent, especially in older patients, are the chronic cases of the lymphocytic variety. It is also true, that the classification of the chronic cases usually presents little difficulty, and that the "atypical" cases are of acute onset and course. The terms "acute" and "chronic" are arbitrary, and their use is determined by (a) the mode of onset, and (b) by the duration of the illness, which in the acute form rarely exceeds 3 months.

A. MYELOCYTIC FORM.—Symptoms.—The patient seeks medical advice either for the increasing lassitude and breathlessness, or for the enlargement of the abdomen, due to the increasing size of the spleen. The anæmia at this stage is not marked; indeed, the appearance is not seldom one of good health. Pain is sometimes felt in the left side and would appear to be due to the dragging weight of the enlarged spleen. The only other symptom at all common is some degree of discomfort after meals.

On examination the striking feature is the size of the spleen. It occupies the greater part of the left side of the abdomen, often reaching the iliac crest and the middle line at the umbilicus. It forms a hard, smooth tumour with rounded edges, not tender to palpation, and easily recognized by the characteristic notches in the anterior margin. The size tends to vary in the course of the disease; sudden enlargement is due to hæmorrhage or infarction; and marked diminution nearly always occurs with the approach of death. The liver is always larger than normal, but usually the enlargement is moderate. The lymphatic glands are usually palpable in the neck, axilla and groins, but rarely form any considerable masses.

Fever is commonly slight and there are often long periods of normal temperature, interrupted now and then by small rises of short duration to 101° to 103° F.

The blood.—The principal characteristics are progressive loss of hæmoglobin and of red corpuscles, and increase, frequently enormous, of the leucocytes. A large part of this increase is due to the presence of myelocytes, though all the other varieties of leucocytes share in it. A typical blood count is the following: Red corpuscles, 3,240,000 per c.mm.; white corpuscles, 452,000 per c.mm.; hæmoglobin, 50 per cent.; colour index, 0.7.

Differential count of leucocytes.—Polymorphonuclear cells, 171,700; lymphocytes, 45,200; large mononuclear leucocytes, 6100; eosinophil leucocytes, 8000; basophil leucocytes, 7000; myelocytes, 214,000.

In this instance there were also present a large number of nucleated red corpuscles, both normoblasts and megaloblasts—a common but not invariable feature. There are numerous minor changes in shape, size and staining reactions of the cells.

Although the above count is typical, there is a wide variation in the actual figures. In the later stages, there is much more anæmia, and often very great and sudden alterations in the number of the leucocytes. These may sink

almost to normal, or may exceed the numbers of red corpuscles, reaching a total figure of 1,500,000, or even more. The characteristic cell, the myelocyte, however, almost always forms a large proportion of the leucocytes present.

In the acute cases there is a greater tendency to hæmorrhage, and the blood count shows a greater degree of anæmia, and a smaller number of leucocytes, but with the characteristic cell predominating. The spleen is often very little enlarged, and until the blood is examined the picture is rather of an acute anæmia of the pernicious type than of a leukaemia.

Course and Prognosis.—It is not unusual for the disease to reach a stage in which there is little or no progress, and for months or even for years the patients suffer little inconvenience from their affection. The writer knows of one instance where the pause was prolonged for nearly 7 years, and the patient earned his living as a tram-driver without hindrance, although the spleen remained large and the blood showed the characteristic changes. In a few cases the improvement goes further, and a complete remission occurs with disappearance of the spleen beneath the ribs, and return of the blood to normal conditions. As a rule, however, these remissions are not of long duration, and the patient becomes weaker and more anæmic, and dies either from exhaustion or from some intercurrent infection. A few instances are on record of death from intestinal or gastric hæmorrhage. The average duration of a large number of cases is 3 to 4 years, but some patients survive for 10, 12 or even 15 years.

The duration of the acute cases is as a rule much shorter; the patients go rapidly downhill and die within a few weeks of the onset. Even in such cases, however, remissions occur, and life may be prolonged for several months.

B. LYMPHOCYTIC FORM.—Symptoms.—In the majority of instances of lymphocytic leukaemia the onset is acute, with bleeding from the gums and the nose, and with petechiæ in the skin. This is accompanied by a rapidly increasing anæmia, and often quick enlargement of the lymphatic glands of the neck, or less frequently of one of the other groups of glands. In the chronic form, more frequent in adults, the onset is more often signaled by enlargement of the glands than by anæmia and hæmorrhages, which with the other symptoms are often late in appearing. The widespread involvement of the lymphatic glands often affords a striking contrast to the comparative absence of enlargement in the myelocytic form of the disease.

The hæmorrhages occur in any of the mucous membranes, but those of the mouth and nose are most common, together with the profuse petechiæ scattered all over the body. Retinal hæmorrhage is common; and hæmorrhage from the urinary tract frequent though seldom severe. Hæmorrhage into the meninges is not rare towards the end. Hæmorrhage into the semi-circular canals has been known to produce Ménière's symptoms.

The glands at the angle of the jaw are enlarged, soft, not adherent to the skin, and tend to vary much in size. The axillary and inguinal groups are usually unduly palpable, though seldom forming masses; and during life it is uncommon to be able to detect any enlargement of the abdominal groups though post-mortem these are always of considerable size, and often hæmorrhagic.

The liver is always enlarged, sometimes to a considerable size, but the spleen is often small, though it can always be recognized. In exceptional cases it may even reach the level of the umbilicus.

Fever is always present, and sometimes remains throughout at a high level, but is more often intermittent in type. The patient is restless, breathless, often in a "typhoid" state, unconscious and suffering from a profuse diarrhœa.

An occasional remarkable symptom is the development of lymphoid deposits in the skin, similar to those found in lymphadenoma; and a bi-lateral enlargement of the parotid and lachrymal glands occurs. ("Mikulicz's Syndrome.")

The principal characteristics of the blood are the steady fall in the total number of the red corpuscles and of the hæmoglobin, and the extraordinarily high proportion of lymphocytes in the increased number of white cells. The total numbers of these latter seldom reach the figure common in myelocytic leukæmia. Counts below 50,000 per c.mm. are usual, and those above 200,000 are rare. Often, and especially in children, the total white count is actually below normal, 6000 per c.mm. or less. It is the differential count, however, which marks the distinction; instead of the granular myelocyte, which in the myelocytic form occupies the chief place, the non-granular "lymphocyte" here forms from 70 per cent. to 99 per cent. of the leucocytes present. The precise nature of the "lymphocyte" of acute leukæmia is uncertain; it is not the lymphocyte of the normal blood, and is probably (Cabot) "a marrow rather than a lymph-gland cell," termed by some "myeloblast." Some authorities speak of "large" and "small" lymphocytes, and have attempted to correlate their predominance with special types of the disease; but all that can be said with certainty is that the greater the predominance of the "large" form the more acute is the leukæmia.

Diagnosis.—The recognition of leukæmia is not as a rule difficult. In the commonest type of the disease, the splenic tumour can hardly be mistaken. Both kidney tumours and tumours of the intestines are quite unlike it, both in general shape, outline and in position, and in any case of doubt the most cursory examination of the blood will at once give the proper clue. The only disease which in the least resembles chronic myelocytic leukæmia is *anæmia pseudo-leukæmica infantum*, and here the age of the patient and the result of a careful examination of the blood are sufficient distinctions. Nor is it easy to mistake acute lymphocytic leukæmia, provided the blood be examined, though here there are certain sources of error. In *pertussis* there is a marked lymphocytosis, occasionally reaching figures of 100,000 or more. In some few cases of *sepsis* instead of the expected polymorphonuclear leucocytosis there is a lymphocytosis; and in a few cases of *generalized sarcomatosis* there is an excess of lymphocytes in the circulating blood. The real difficulty occurs with the atypical forms, and in a few of these it may be impossible during life to make an accurate diagnosis. The characteristic microscopical changes in the organs and the bone-marrow found post mortem are nearly always decisive. The most acute cases of *purpura hæmorrhagica* are distinguished by the absence of the abnormal types of leucocytes, and by the diminution or absence of the blood platelets. Briefly it may be laid down wherever there is, even in the absence of a leucocytosis, a predominance of abnormal cells, whether these be myelocytes or "lymphocytes," to the extent of 25 per cent. or over, of the total, the disease is leukæmia.

Course and Prognosis. The more acute the onset, the shorter is likely to be the duration. Some cases are fulminating, the passage from health

to death occupying less than a week. The majority of patients die within 3 months, of hæmorrhage, weakness and intercurrent infection.

The total duration of the chronic type is usually under a year, but occasionally life may be prolonged for several years. Remissions of the kind met with in myelocytic leukæmia occur but rarely, and recovery is probably unknown.

Treatment.—The treatment of leukæmia is empirical, and the reported successes to a considerable extent invalidated by the fact of the natural “remissions.” In the acute forms as a general rule the end comes swiftly, and no therapeutic measure hitherto employed has seemed to do more than defer the fatal issue. On the hypothesis that the disease is a toxæmia, the most benefit might be expected from the use of remedies of the antiseptic and antimicrobic order. Naphthalene tetrachloride in doses of 30 grains a day appeared to be efficacious in one desperate case, but has failed in others. Arsenic, iodides, iron, extracts of various organs, and various sera all seem to be useless. The use of human blood serum in doses of 10 or 15 c.c. intravenously each day undoubtedly helped, but did not save a patient of the writer's.

In the chronic myelocytic form there is more hope. There is now no doubt by the application of X-rays to the region of the spleen, and also possibly to the long bones, a considerable degree of benefit can be secured. The spleen diminishes in size, the anæmia is relieved, and the numbers of leucocytes in the circulating blood sink rapidly. In one patient, treatment of this kind, prolonged over a period of 9 months, reduced the number of leucocytes to less than 9000 per c.mm. with only an occasional myelocyte, and with marked improvement in strength and general health. The improvement was maintained for more than a year, but then relapse occurred, and the end came quickly. Other patients have derived even greater benefit, and it is certainly possible in the majority of cases to secure by this means a considerable prolongation of life, though there is no good evidence of a permanent cure. As regards drugs, arsenic is certainly useful, and should be used in large doses either intravenously or by the mouth. Excision of the spleen in this disease is a dangerous operation, but of late years has been performed with success in several cases, without, however, benefiting the patient otherwise than by the removal of a cumbrous tumour.

CHLOROMA

Definition.—A sarcomatous growth of marrow-like tissue with a green tint, invading the bones, especially of the skull, accompanied by changes in the blood resembling those of leukæmia.

Pathology.—The tumours show a vivid green tint which rapidly fades. They are found principally in connection with the bones of the orbit, the temporal and frontal bones, the vertebræ, ribs and sternum. Metastases have been found in the viscera and in the glands, and these do not always exhibit the typical green tint.

Symptoms.—It is a rare disease of insidious onset, the early signs being simply pallor and listlessness, and headache. The headache is due to the pressure of the tumours in the skull, which later produce deformity of the

temporal and frontal bones, exophthalmos, papilloedema, and swelling of the veins of the head, neck and face. Hæmorrhages occur from the mucous membranes. The lymphatic glands of the neck and axillæ are enlarged, and the spleen usually is palpable. Fever is usual, and rapid wasting occurs.

The blood shows the changes characteristic of leukæmia, usually of the lymphocytic type; but a few cases have been described where the predominant cell was myelocytic.

Diagnosis.—The only affection which can cause confusion is suprarenal sarcoma, which gives rise to similar tumours of the skull. The distinction is made by a blood examination.

Prognosis and Treatment are hopeless.

ATYPICAL CHLOROMATA.—In addition to the more classical type of chloroma, there sometimes occur cases of multiple tumours of bone which excite in the hæmopoietic tissues a "leukæmia" reaction. The reaction may be lymphocytic, myelocytic, or myeloblastic. The tumours are of the general type of sarcomata, and appear to originate in the bone-marrow. They may or may not show the green tint characteristic of true chloroma. It is remarkable that myelomata in general do not appear to possess the power of exciting this "leukæmic" reaction.

ANÆMIA PSEUDO-LEUKÆMICA INFANTUM (VON JAKSCH)

Synonym.—Splenic Anæmia of Infants.

Definition.—A disease of infants characterized by great enlargement of the spleen, a high degree of anæmia, and the constant presence of myelocytes.

Ætiology.—The affection is confined to the first 3 years of life, and the larger proportion falls within the first 2 years. The average age at which the patients come under observation is 18 months. It affects the sexes equally, and does not distinguish races, though Jews are said by some authors to be more liable. Heredity plays no part in the causation, but there is some evidence of family tendency. No predisposing cause is recognised. Rickets, congenital syphilis and marasmic conditions may be present, but do not appear to be determining factors. It is a disease of the poorer classes of the town population, and never, or rarely, affects the children of the well-to-do.

By some authorities it is held that any anæmia in an infant may pass into the present disease.

Relationship to other diseases.—The constant presence of myelocytes and the size of the spleen suggest an affinity to myelocytic leukæmia; but the whole course of the disease is so unlike that of leukæmia that it is clear it is a different disorder. However, in exceptional instances, the terminal stages have been signalized by an influx of lymphocytes into the circulating blood, producing the picture seen in acute lymphocytic leukæmia. Taken as a whole, the features of the affection seem to present the picture of an independent entity.

Symptoms.—The onset of the disease is always insidious, and by the time that the increasing pallor or enlargement of the abdomen has excited alarm the disease is fully established. Occasionally epistaxis or the appearance

of a petechial eruption is the earliest symptom. The pallor, often of a waxy kind, is always extreme. Emaciation is seldom marked; indeed the patients are not seldom fat. They are always listless and apathetic; the muscles are soft and flabby; and there is often some œdema of the feet and ankles. The trunk and limbs are spotted with petechiæ, which also are sometimes seen in the mucous membrane of the mouth. The abdomen is protuberant owing to the size of the spleen, which often reaches the iliac crest and the middle line of the belly. The organ is hard, smooth and free from tenderness. The liver is seldom much enlarged. The lymphatic glands do not often appear enlarged during life, though the superficial cervical or axillary glands are sometimes palpable; but after death it is usual to find the mesenteric group considerably larger than normal.

Besides the epistaxis and the petechiæ already mentioned, hæmorrhage is rare, but slight hæmaturia, traces of blood in the motions, and slight oozing from the gums have been observed. Fever, rarely above 102° F., of an irregular type, is usual, but is not a constant feature, and is of short duration. A fever which lasts more than two days is due to some complication, usually broncho-pneumonia. Diarrhœa occurs in about half the cases, and is intermittent and not often severe. But of the fatal cases the majority die either of broncho-pneumonia or of uncontrollable diarrhœa.

Blood.—The erythrocytes are diminished to 2,500,000 or 3,000,000 per c.mm., and show some slight alteration in shape and size. Nucleated cells are always present—sometimes in large numbers. The hæmoglobin shows a decrease to 20 per cent. to 40 per cent. of normal, so that the colour index is low, from 0.5 to 0.7. There is nearly always a leucocytosis at some time during the course of the disease, but it is moderate, rarely reaching above 30,000, and sometimes the number may sink as low as 5000. The feature of the blood film is the constant presence of myelocytes, which occur in numbers greatly above those found in any other disease except leukæmia, though seldom in numbers sufficient to suggest that disease.

Course and Prognosis.—The course of the disease is slow, but on the whole tends to recovery in 65 per cent. to 70 per cent. of cases. A fatal issue is usually the result of an acute diarrhœa or broncho-pneumonia, and apart from these complications recovery is the rule and is complete, the children regaining health and strength and rapidly returning to a normal growth and development. The duration is from 6 to 9 months. Recovery is accompanied by so great a diminution in the size of the spleen that it often can no longer be palpated in the middle of the third year of life, though in a few cases it may remain palpable for several years.

Treatment.—During the more severe and chronic stages of the affection all the usual measures to combat anæmia seem to be without result. The patients do best with abundance of fresh air and light, and should be nursed, if possible, in the open air. Careful dieting, with the use of intestinal disinfectants, such as salol in doses of 2 to 6 grains per diem, is indicated. Splenectomy has been performed with good results, but hardly seems necessary, since the majority of patients recover. It is probably a wise procedure in view of the great loss of hæmoglobin to give iron, although no immediate result should be expected. Pulv. ferri redacti grs. i-iiij per diem is a suitable preparation.

PURPURA

Definition.—Purpura is the name applied to spontaneous extravasations of blood in and beneath the skin and mucous membranes, of unknown causation, more particularly to denote a disease in which extravasations are the chief symptom.

Classification.—It is convenient to divide the cases into classes :

(1) The secondary purpuras, those in which the purpura is a manifestation of a recognisable disease, and (2) primary or idiopathic purpura, where no other recognisable disease is present.

SECONDARY PURPURA.—In this group it is possible to recognize five subdivisions — (1) Infective, (2) cachectic, (3) toxic, (4) nervous, (5) mechanical.

1. *Infective purpura.*—In this subdivision must be placed, firstly, the hæmorrhagic types of the infectious fevers, hæmorrhagic small-pox, hæmorrhagic measles, and the like ; secondly, those fevers almost always accompanied by purpuric eruptions, for example, epidemic cerebro-spinal fever and typhus ; and thirdly, the symptomatic purpura which accompanies the pyogenic infections, for example, streptococcal endocarditis and other septicæmias ; and the hæmorrhages of severe jaundice.

It is probably correct to place in this section also “ peliosis rheumatica ” (Schönlein's disease), which is discussed later.

2. *Cachectic purpura.*—Purpuric eruptions are frequently met with in the cachexias of chronic Bright's disease, of carcinoma, and of the later stages of tuberculosis, and in children, in the cachexia of marasmus, and other chronic wasting diseases of nutrition. The purpuric spots found in scurvy, in leukæmia, in lymphadenoma, and the like may also be placed in this category.

3. *Toxic purpura.*—The iodides, bromides, antipyrine, and antitoxic sera occasionally produce purpuric eruptions.

4. *Nervous purpura.*—Purpuric spots and subcutaneous hæmorrhages sometimes appear in the course of certain diseases of the nervous system, for example in syringomyelia, and, it is said, in hysteria ; and perhaps it is correct to place the local asphyxias and gangrene of Raynaud's disease under this heading.

5. *Mechanical purpura.*—In old age slight injuries, in the ordinary way quite incapable of producing extravasation of blood, often produce blotches and spots beneath the skin of the hands and legs, and it is possible to consider the purpura of dropsical tissues and the hæmorrhages which occur in the conjunctivæ in pertussis as examples of mechanical purpura.

It is obvious that these divisions are arbitrary, and there is no hard-and-fast line separating them.

PRIMARY OR IDIOPATHIC PURPURA.—When the symptomatic purpuras have been put on one side there remains a large and important class in which no extraneous disease can be recognized, but which has as its principal symptom the occurrence of hæmorrhages in the skin and from the mucous membranes. The nature and course of the illness also serve to set it apart from the secondary purpuras. Till recent years it has been customary to divide idiopathic purpura into four classes, distinguished from each other by

the symptoms which are most prominent and by the course of the disease :
 (1) purpura simplex ; (2) purpura hæmorrhagica ; (3) purpura arthritica or rheumatica ; and (4) Henoch's purpura or purpura abdominalis. Admittedly this division is purely arbitrary and it is often difficult to assign with certainty an individual case to any one group.

It has long been known that in purpura hæmorrhagica the blood-platelets are, at any rate in the more hæmorrhagic stages of the illness, notably diminished, and even absent ; whereas in the other types here under consideration these bodies, though sometimes diminished in numbers, seldom reach so low an ebb as in purpura hæmorrhagica. Hence there has arisen the conception of an essential thrombocytopenic purpura, corresponding to the morbus maculosus of Werlhof, or purpura hæmorrhagica, distinct from the simple purpura, arthritic purpura and Henoch's purpura, which are grouped together under the name of "anaphylactoid" purpuras. The distinguishing marks of an essential thrombocytopenic purpura are held to be : (1) the marked diminution in the number of the blood-platelets ; (2) an absence of the retraction of the clot ; (3) an increase in the bleeding-time, with a normal or but slightly prolonged coagulation-time ; and (4) a marked tendency to recurrence. These signs are said to be absent in the anaphylactoid purpuras, which on the other hand are closely allied to the urticarias and angio-neurotic cedema, so much so that a single patient may at the same or at different times suffer from urticaria, angio-neurotic cedema, painful effusion into joints, and a definite purpuric eruption.

This conception of the relationship of the different types of purpura is probably too precise, and there are clinical and experimental facts which make it difficult to accept. There are, in the first place, cases which would be accepted by all physicians as examples of hæmorrhagic purpura, which yet have not the alleged characteristic absence of thrombocytes. There are cases in which the thrombocytes are markedly deficient, and yet there is little or no bleeding. Further, there are cases which apparently pass from one group to another at different times ; and there is apt to be just as frequent recurrence in the anaphylactoid as in the thrombocytopenic purpuras. In spite of these objections, however, the conception has been of considerable value, for it was the supposed malignant influence of the spleen upon the production or maturation of the platelets which led Kaznelson and others to recommend and practise splenectomy for recurrent purpura—a remedy which, though it has but little permanent influence on the numbers of the platelets, yet has apparently the power to abolish the tendency to bleed.

Pathology.—From what has been said it will be clear that there is as yet no accepted pathology of idiopathic purpura. That the platelets are concerned in the tendency to bleed is certain, not only from clinical but also from experimental observations (Bedson and others). But that their diminution alone is capable of inducing the hæmorrhages is known both clinically and experimentally to be an insufficient explanation. Experimentally they may be completely absent without any appearance of purpura. It would appear that we must still retain the older hypothesis of a lesion of the capillary wall, which allows of the escape, now of serum only (urticaria), now of hæmorrhagic serum, and now of the whole blood.

The following description of the disease as a whole, and of its main manifestations, has accordingly been retained, since it appears to agree more

with the observed facts than the newer conception of widely separated entities.

Symptoms.—The one symptom which all forms of the disease have in common is the occurrence of hæmorrhages in and beneath the skin. They usually occur early in the illness, but are sometimes preceded by general malaise, pains in the limbs and abdomen, and cedema of the feet or legs, and in the milder cases are confined to the lower limbs; but when more widespread there is no portion of the surface which escapes—the trunk, the face, the scalp and the neck are covered with the eruption. The latter usually bears some relation to the severity of the illness, but not always, for in some instances of serious or even fatal issue it is comparatively limited, and in some examples of widespread eruption the illness is short and not accompanied by any symptoms of grave import. The hæmorrhages are usually small, round spots, not elevated above the surface, and change their colour, which does not fade on pressure, from the bright red of their first appearance to purple or brown as they fade. Frequently successive eruptions present all shades of colour from bright red to a dingy brown in the same patient. The absence of elevation above the surface is the rule; but occasionally, as mentioned previously, the hæmorrhages occur in the form of papules or weals. The smaller spots are called "petechiæ"; the lines and streaks "vibices"; and the larger irregular patches "ecchymoses." These larger patches in rare instances become gangrenous and slough. Such gangrene occurs in the type known as "purpura fulminans."

The hæmorrhages occur with great suddenness and recur in crops, often for several days, or even weeks. Many patients are subject to recurrences every year, or the attacks may recur at shorter intervals, with intermediate good health. In the milder cases petechial spots in the mucous membrane of the gums, mouth or palate are not common, but in the more severe attacks they can nearly always be seen.

This cutaneous and subcutaneous eruption is the only sign which is common to all forms of the disease, though even in the mildest forms there is usually some degree of derangement of the general health; constipation, slight fever or complaint of pains fleeting over the body and limbs.

The blood is but little altered, even in the most severe cases. There is, of course, anæmia with severe or repeated hæmorrhage, but recovery is as a rule rapid. In the ordinary case the number of red corpuscles is a little lower than normal, the hæmoglobin likewise proportionately diminished, and the white corpuscles normal or slightly increased in number, as a result of a polymorphonuclear leucocytosis. There are no abnormal cells. The blood platelets are diminished in number, and in the severe types absent.

It is claimed that certain cases of gastrostaxis, or "essential hæmaturia," and of bleeding from the uterus, without further evidence of purpura, belong to this chapter of disease, and are benefited by splenectomy. In the opinion of the writer, however, the claim is not as yet substantiated.

PURPURA SIMPLEX.—This is the most common form of the disease.

Ætiology.—It is seen most frequently in children between the ages of 4 and 10 years, but is also found in both sexes and at all ages.

Symptoms.—Besides the eruption there is often very little to observe. Fever may occur at the onset, seldom above 100° F., slight malaise with possibly some indication of intestinal disturbance, constipation or diarrhœa.

The eruption is often confined to the lower limbs, and recurs with slight œdema each time the patient is allowed to rise from his bed. The duration of the attack is from 1 to 3 weeks; but it is this form which is so apt to recur.

PURPURA HÆMORRHAGICA.—Symptoms.—In the cases which fall into this category all the above symptoms occur with the addition of hæmorrhages of greater or less severity from the various mucous membranes. The fever is often more prolonged, but seldom above 101° F., and the general signs of illness more marked. There is often vomiting at the onset, with slight hæmatemesia. The eruption is more widespread, covering the trunk and often the face and neck. Any of the mucous membranes may bleed, but the bleeding is not usually severe, rather a continued oozing than a free hæmorrhage. Epistaxis and oozing from the gums and mucous membranes of the mouth and throat are the most common; but the urinary and intestinal tracts may bleed as well. In the most severe cases the patient is in a pitiable condition, blood escaping freely from each orifice of the body, and the skin covered with large purple extravasations. Menorrhagia in the adult is frequent, and a dangerous symptom. Even in such cases, however, the prognosis is not hopeless, for, when improvement begins, recovery is as a rule rapid. There is often effusion, which is not bloodstained, into the joints, though this is not frequent in the severest type; it seems to occur most often in association with intestinal and kidney bleeding. In some instances, without hæmorrhage from the kidneys, there is evidence, in the albuminuria and in the presence of casts, of a nephritis; but this is exceptional, and generally is unaccompanied by œdema or deficiency of urinary excretion, and disappears with the termination of the illness.

PURPURA ARTHRITICA.—It is common to assume that there is a purpura intimately associated with rheumatic fever. That there are patients who in the course of rheumatism develop purpura is certain; but that there is a purpuric disease which has as its basis rheumatic infection is much less clear. Schönlein described "peliosis rheumatica": a purpuric disease due, he thought, to rheumatism, with hæmorrhages as a complication. Apart from the occasional case of rheumatic fever which develops a purpuric eruption, usually as a symptom of severe infection, or of cachexia, there is but little evidence that purpura and rheumatism are allied with each other. Few of the cases of purpura show endocarditis, and the general course of the affection is quite unlike that of rheumatism. The similarity is confined to the fact that both diseases are associated with effusion into the joints. Further, this effusion may occur in any of the varieties of purpura, and is by no means confined to those cases which have evidence of rheumatic infection. Lastly, the undoubted relationship of purpura with other exudative lesions, such as urticaria and angio-neurotic œdema, points to the fact that in its essence purpura is an exudative phenomenon, and an effusion into the joint-cavities is not therefore unexpected.

HENOCH'S PURPURA.—Ætiology.—This variety of purpura is more common in children and young adults than in older people, and is apt to recur at intervals.

Symptoms.—The form of disease thus called is distinguished from the other varieties merely by the severe crises of abdominal pain, often accompanied by vomiting, diarrhoea with bloody stools, and prostration. Sometimes there is also an effusion into the joints as in the other types. The

eruption and the mucous hæmorrhages are similar to those already described. Clearly the division is artificial, and there must be border-line cases. Yet purpura with severe abdominal pain forms a distinct type of the disease. The crises of pain occur often before the appearance of the purpura, or may come on after the illness is already established. These attacks sometimes cause considerable difficulty in diagnosis, and operation has been performed for the relief of supposed intestinal obstruction, or intussusception.

The duration of the attacks varies from a few days to several weeks. Fatal results are rare; but death has been reported from intestinal bleeding and from cerebral hæmorrhage.

Diagnosis.—The diagnosis of purpura is not as a rule difficult. The secondary forms occur in conditions which as a rule are easily recognized. When these are excluded, the only difficulty likely to arise is that of distinguishing the abdominal pain of Henoch's type from other conditions which cause similar crises. In young children the diagnosis from intussusception may be impossible without an exploratory laparotomy, and in at least one instance purpura has been complicated by intussusception.

Prognosis.—There are three points to consider: the probable issue, duration, and the effect on the future health. With regard to the issue the prognosis, except in the fulminating hæmorrhagic cases, is good. Even severe hæmorrhagic cases get quite well. In any large series of cases the actual mortality is very small. As to duration it is difficult to prophesy, because of the marked tendency towards recurrence. Usually health is completely restored in a few months even after a severe attack. Recurrences may, however, go on for several months, usually in a milder form. The only legacy which idiopathic purpura is likely to leave is nephritis, and as already stated this as a rule passes away with the disappearance of the disease.

Treatment.—In the secondary purpuras, the treatment must be directed to the disease of which the purpura is a symptom; and since in many of these cases the occurrence of purpura is the herald of the later stages of a serious infective process, there is often but little that the physician can hope to accomplish.

In the milder cases of idiopathic purpura, rest in bed, with careful dieting and the administration of iron and arsenic, is usually all that is required, though the frequency of recurrences seems to demand more active interference. In the hope of influencing this tendency to recurrence, innumerable drugs have been employed, but on the whole without any appreciable effect. The newer conception of an "anaphylactoid" purpura has naturally led to attempts at "desensitization," but so far without striking results. The injection beneath the skin, or into the muscles, of normal serum is probably the most efficacious method of controlling these recurrences.

In the more hæmorrhagic types, local measures of checking bleeding may be employed wherever the source of the hæmorrhage can be reached. The older styptics are generally useless, but solutions of adrenalin sprayed into the mouth or nose are certainly beneficial. Most of the more modern styptics, hæmoplastin and the like, are disappointing; and calcium salts are apparently useless, either locally or given by the mouth or intravenously. There are three methods whereby the tendency to bleed can be arrested. Normal serum injected either intravenously, or intramuscularly, in a number of instances has stopped the hæmorrhage and is always worth a trial. The

amount to be administered is from 10 to 30 c.cm. diluted with warm salt solution. It should be given on two or three days in succession. The danger of anaphylactic shock is practically negligible, unless when a period of ten days or more is allowed to elapse between the first and subsequent doses. The second method of proved value is blood-transfusion. Here again repeated small doses of 30 to 50 c.cm. appear to be more efficacious than single larger amounts; but in any case the amount must be measured by the condition of the recipient: if he is blanched from loss of blood, it should be from 300 to 600 c.cm.

Kaznelson and others, basing their proposals on the pathological conception of a deleterious action of the spleen on the blood-platelets, have shown that splenectomy exercises a remarkable influence on purpura; and undoubtedly wherever the disease is either severe or shows a marked tendency to disabling recurrences, the spleen should be removed. The effect in stopping the hæmorrhage is probably not due to the quite temporary increase in the number of the platelets which follows the operation, as it is now known that a reduction to a very low count often recurs in a few days without any fresh bleeding. Further, the success of splenectomy in the treatment of purpura is not confined to the thrombocytopenic group, but has been observed in the anaphylactoid group, e.g. Henoch's purpura, where the blood-platelets are present in normal or but slightly diminished numbers. At present, therefore, in any case of severe hæmorrhagic purpura, of whatever type, or in face of recurring attacks of a milder type, whether the spleen is or is not clinically enlarged, splenectomy should be considered as the most effective form of treatment.

OTHER HÆMORRHAGIC DISEASES

Besides purpura and hæmophilia there are a few other conditions in which spontaneous hæmorrhage occurs either into the skin or from the mucous membranes. These are chiefly met with in infants.

(a) *Hæmorrhage due to congenital syphilis*.—This is a rare occurrence. In the cases described the bleeding began about the third day of life, from the mucous membranes, from the navel, or into the skin. The bleeding was usually fatal, and visceral hæmorrhages were found after death.

(b) *Melæna neonatorum*.—Bleeding in this type usually begins about the third day of life, and is, as the name implies, usually from the bowel. Blood also may ooze from the mouth, nose, urinary tract, or may be extravasated into the viscera, or into the cavities of the body. It is not very uncommon; but the origin is quite unknown. In some cases acute gastric and duodenal ulcers have been found at autopsy, but it is more probable that these represent necrosed areas resulting from submucous hæmorrhages than that they are the origin of the hæmorrhage. Recently the subcutaneous injection of normal horse serum has completely altered the prognosis. If from 10 to 15 c.c. of serum be given subcutaneously each day the bleeding stops quickly and the infant makes a good recovery. Until this treatment was adopted the mortality was very high.

(c) *Epidemic hæmoglobinuria (Winckel's disease)*.—A very fatal epidemic disease usually occurring among the new-born babies in lying-in institutions.

The onset about the third or fourth day, the fever, hæmorrhages and post-mortem appearances all make it probable this is a severe type of sepsis, though so far no organism has been incriminated.

(d) *Buhl's disease* is similar in its occurrence to the last. It is characterized by œdema, anæmia, hæmorrhages into the skin and from the mucous membranes, and death after an illness of a week or 10 days. Post-mortem examination reveals an advanced state of fatty degeneration of all the organs.

(e) *Hæmorrhage into the suprarenal capsules*.—In patients under 1 year of age such a condition is characterized by sudden onset, fever, vomiting and petechiæ in the skin; convulsions rapidly occur, and end fatally. Post-mortem examination shows, as the only prominent feature, bilateral hæmorrhage into the suprarenal bodies, which are dark purple and much enlarged. It is probably an infection though no organism has been demonstrated. The cases are uncommon and tend to occur in groups.

HÆMOPHILIA

Definition.—Hæmophilia is an hereditary disease of males, characterized by a tendency to uncontrollable hæmorrhage, either spontaneous or arising from wounds which in the normal person hardly bleed at all.

Ætiology.—In the majority of cases of hæmophilia the “bleeder” is one of a family in which other males have been affected, though there are on record isolated instances. More usually the family tendency is well known, and the diagnosis is made without the aid of a doctor. The main peculiarity of the disease lies in the mode of inheritance. The males of the family are alone attacked, and the transmission is exclusively by the females. To this rule there are according to some authorities exceptions; but the more closely these are studied the less authentic do they appear. Hence the diagnosis of hæmophilia in a female is not, according to the present view, permissible. Not all the males of a “bleeder” family suffer, nor do all the females transmit. The inheritance can be explained in terms of Mendel's laws, as a recessive characteristic.

The disease is one of the temperate zone, and nearly all the reported cases are of English, American or German origin. The Latin races are, it appears, rarely affected, though the French author Weil holds that it is not uncommon.

The phenomena make their appearance early, and persist throughout life.

The number of hæmophilic patients living is not apparently large at any time, and it is obvious, with the rule of transmission stated above, that there is a tendency for the disease to disappear from a family and to appear in some other hitherto unaffected. Family records are seldom reliable for many generations except in the direct male line, but there is one family in which the affection has been traced back for nearly 200 years. The Appleton family, which was the first adequately recorded, is apparently extinct.

Pathology.—Hæmophilic blood clots with greater difficulty than that of normal individuals, but the bleeding-time is not prolonged, as it is in purpura hæmorrhagica. While these facts are acknowledged, their explanation is unknown. The blood-platelets are present in normal number.

Symptoms.—The greater number of individuals who suffer from hæmophilia manifest the tendency early in life. In 60 per cent. to 70 per cent. of the recorded cases the presence of the disease was recognized before the second year. The hæmorrhage establishing the diagnosis is sometimes spontaneous, but more usually follows upon some slight injury. The newborn infant of a hæmophilic family rarely suffers. Circumcision has, however, often led to a recognition of the disease, and has occasionally proved fatal. In a few instances the onset of puberty has put a term to the tendency to bleed, but as a general rule once manifested it persists throughout life.

The special characteristic of hæmophilic bleeding is not so much its severity as its persistence; hence it is rare for the hæmophilic to die of a sudden profuse hæmorrhage; he rather fades out of life owing to the inability to stop the slow continued loss of blood.

Spontaneous hæmorrhage is not nearly so common as traumatic. Indeed it is doubtful whether genuine spontaneous hæmorrhage ever occurs. In some individuals there are prodromal symptoms of giddiness, palpitation, sweating or dyspnœa before the actual hæmorrhage, and visceral hæmorrhages are occasionally met with in men who are known to be hæmophiles.

The great majority of hæmorrhages occur either from the skin, or from the mucous membrane of the mouth and nose. Those in the skin are chiefly in the form of bruises or ecchymoses, rarely appearing as petechiæ. Oozing of blood from the unbroken skin of the finger-tips has been recorded. Generally the bleeding is preceded by some scratch or slight wound which has broken the skin. Epistaxis is the most frequent form of hæmorrhage from the mucous membranes, and next in order bleeding from the gums. Some patients cannot use a tooth-brush for this reason. Hæmorrhage from the internal organs is uncommon, either from the lungs, intestines, stomach or the urinary tract. Hæmorrhage into the subcutaneous tissue or into the muscles sometimes occurs, and forms a hæmatoma which has been mistaken for an abscess and incised.

The most remarkable form of hæmorrhage, and one which is common, is into the cavities of the joints. The joints which suffer most often are the knees and elbows; but any joint may be affected. The swelling and effusion take place with great rapidity, and with a great deal of pain. The joint is hot, tender, reddened, and the surrounding tissues swollen. The temperature is raised to 101° or 102° F. The effusion is almost pure blood, but as absorption proceeds it becomes a dirty brown colour which stains the synovial membrane and the cartilages of the joint. It is sometimes absorbed rapidly, and the joint restored to complete mobility. When absorption is slow or effusions repeated contraction and ankylosis may cripple the patient permanently. In a joint often affected there is always considerable destruction of the cartilages and of the ligaments, with the result that the bones are exposed and undergo changes resembling those of osteo-arthritis. Osteophyte formation is however rare, and so is bony ankylosis. Fibrous ankylosis is, on the other hand, common.

The other symptoms noted for the most part depend on the hæmorrhages. Wright states that these are often periodic, and more likely to occur by night than by day. It has also been noted that hæmophiles often have depraved appetites, and are ready to eat dirt and grit of all kinds.

Diagnosis.—A diagnosis of hæmophilia must rest in large degree on a

knowledge of the family history. In the absence of a "bleeder" in the family tree the diagnosis is suspect. It must be remembered there are other causes of hæmorrhage than hæmophilia: purpura, for instance, is sometimes accompanied by effusion into a joint. In purpura, however, the effusion is serous, not bloody, as in hæmophilia. The real difficulty occurs in the known hæmophilic family when one of the boys has had an epistaxis, some urinary hæmorrhage, or possibly some effusion into a joint, and the doctor is asked to determine whether the phenomenon is a mere accident or a manifestation of the inherited tendency. Such a question it may be impossible to answer without observation of the individual extending over several years.

Prognosis.—As regards life the outlook is bad. It has been stated that less than 12 per cent. of known "bleeders" survive to puberty. This would seem to be an exaggerated estimate, and is probably based on the figures of the recorded "bleeder" families. It has already been stated that puberty sometimes terminates the manifestations. In those patients who survive there is likely to be serious interference both with education and pursuit of a trade or profession, but with the lapse of years the danger to life seems to become distinctly lessened.

Treatment.—*Prophylaxis.*—The females in a known "bleeder" family should be advised not to marry. If this advice is disregarded and they have sons, the children must be considered as potential "bleeders," and consequently any operation, such as circumcision, the extraction of teeth, or tonsillectomy, should be undertaken only after careful preparation and also with all the means at hand for the control of hæmorrhage. The preparation for operation should include a subcutaneous or intramuscular injection of fresh normal serum (20 to 30 c.cm.).

Treatment of Hæmorrhage.—Local treatment of actual hæmorrhage is comparatively easy when the bleeding point is accessible to pressure. Pressure with tampons soaked in serum or in fresh normal blood, quickly brings the oozing under control. In bleeding from cavities, such as the mouth and nose, where pressure is difficult or impossible, the employment of heat is said to be efficacious. It is applied by the use of sprays of water as hot as the patient can tolerate. The raising of the patient's temperature by radiant heat, or hot baths, or vapour baths, is also of assistance, since it has been shown that the time of coagulation is appreciably shortened with a rise in temperature. In serious cases, or when these simpler methods have not succeeded, no time should be lost in transfusing with the whole blood, defibrinated or citrated, of a normal healthy person. It is said that the blood of the other members of a "bleeder" family, provided they are of an appropriate blood-group, is not contra-indicated. While the preparations for transfusion are being made, the subcutaneous or intramuscular injection of 20 to 30 c.cm. of normal horse serum is advantageous. The joints should be immobilized in the acute phase of the effusion, but passive movements should be begun as soon as possible, in order to avoid the occurrence of ankylosis. Where the effusion is considerable, it is quite safe to puncture the joint and remove as much as possible of the blood. A needle puncture hardly ever bleeds in a hæmophilic patient.

Attempts have been made to find some method of altering *permanently* the time of coagulation. Weil claims that the subcutaneous or intra-

muscular injection of normal serum (20 to 30 c.cm.) every two months has in his hands not only kept hæmophilic patients free from manifestations for several years, but has resulted in a definite lowering of the prolonged coagulation-time to periods within normal limits. No other author, however, has been able to confirm Weil's results. Recently, the induction of protein shock by intravenous injection of a foreign protein (t.a.b. vaccine) has apparently given good results.

SECTION XI

DISEASES OF THE SPLEEN

ENLARGEMENTS OF THE SPLEEN

THE spleen, more than other organ of the body, is liable to enlargement in disease. It is affected in many, if not all, of the acute specific fevers; in the general pyogenic infections; and in a long list of chronic diseases. On the other hand, it is seldom the seat of carcinoma or sarcoma, whether primary or secondary, and hydatid and other cysts are rather pathological curiosities than clinical phenomena.

Diagnosis.—The diagnosis of a splenic tumour is seldom doubtful. The situation, the extension upwards of the splenic dullness, normally situated at the level of the ninth rib in the mid-axillary line, the recognition of the notches in the anterior border, and the abrupt margin of the tumour in the loin are usually sufficient to prevent a mistake. There is, however, occasionally a difficulty in distinguishing between a splenic and a renal tumour, or between a splenic and an intestinal or mesenteric mass; and a movable spleen may cause some confusion by presenting itself as a tumour in parts of the abdominal cavity remote from its normal site. The relationship of the descending colon to the tumour is important; it lies in front of a renal, but internal to a splenic, tumour.

The conditions in which enlargement of the spleen occurs may be classified as follows: (1) Enlargement due to acute general infections—typhoid fever, other specific fevers, infective endocarditis, pyogenic septicæmia, Mediterranean fever and acute catarrhal jaundice. (2) Enlargement due to chronic infective processes—tuberculosis, syphilis and lymphadenoma. (3) Enlargement due to protozoal infections—malaria, kala-azar and possibly some others, e.g. Egyptian splenomegaly. (4) Enlargement due to mechanical obstruction—hepatic portal cirrhosis, thrombosis of the splenic vein, decompensated cardiac disease and movable spleen. (5) Enlargement due to new formations—cysts (parasitic and non-parasitic), malignant growths, and amyloid degeneration. (6) Enlargement associated with disorders of the blood—idiopathic pernicious anæmia, the leukæmias and acholuric jaundice (congenital or acquired). (7) Primary enlargement—splenic anæmia, splenic anæmia with hepatic cirrhosis (Banti's disease) and splenomegalic cirrhosis.

The clinical characters of the splenic enlargement in the greater number of the conditions mentioned are fully considered elsewhere. Here it will be sufficient to point out that the chief difficulties are found in the differential

diagnosis of chronic enlargements due to tuberculosis, syphilis, lymphadenoma and splenic anæmia; and it will often be necessary to employ not only accurate blood examinations and the Wassermann test, but even to resort to splenic puncture, or the histological examination of tissue, *e.g.* from a lymphatic gland, in order to arrive at a correct judgment.

TUBERCULOSIS OF THE SPLEEN

In general tuberculosis the spleen is often considerably enlarged, but seldom reaches more than an inch or so below the costal margin. Its enlargement is due to the inflammation which accompanies the development of miliary tubercles in the organ.

A much more pronounced enlargement is occasionally met with as a result of the formation of caseous masses in the organ. It may then be mistaken for the spleen of Banti's disease, or lead to a diagnosis of lymphadenoma. In this condition it is sometimes difficult, even when the organ is seen after death, to be assured of the character of the numerous yellowish deposits, which give it a marked resemblance to the spleen of Hodgkin's disease. During life the diagnosis of these rare cases is dependent on the existence of tuberculous lesions elsewhere in the body. Splenectomy has been practised with success in some such cases.

SYPHILIS OF THE SPLEEN

The spleen is enlarged in the syphilis of infants, especially in the period of the more acute manifestations during the first 3 months of life. Its detection at this period is often of considerable service in diagnosis. At a later period of childhood the spleen is enlarged, together with the development of a syphilitic cirrhosis of the liver. The later manifestations of syphilis cause enlargement of the spleen in two ways, either (1) by the development of gummatous deposits in the organ, when it may occasionally reach a great size; or (2) by the development of lardaceous disease. Syphilitic enlargement of the spleen only gives rise to difficulties in diagnosis when it is accompanied by severe anæmia, and this appears to be rather the exception than the rule in gummatous disease, except after severe hæmatemesis. On the contrary, the existence of large gummatous deposits, or of large tuberculous caseous deposits in the spleen, is often accompanied by an unduly high red blood corpuscle count, and a fairly high percentage of hemoglobin.

SPLENIC ANÆMIA

Synonyms.—Banti's Disease; Primitive Splenomegaly.

Definition.—A disease characterized by anæmia of a definite type, accompanied by enlargement of the spleen.

The terminology of the group of diseases included under this name is at present in a very confused state. Banti considers that the disease begins as an anæmia with enlargement of the spleen, and steadily progresses through a long period of years to a terminal stage of hepatic cirrhosis with ascites. It is, however, certain there are cases where the stage of cirrhosis is never

reached, and therefore it is better to regard the condition as a single disease of which the termination may be either a fatal anæmia or an equally fatal cirrhosis. There are, in addition, other conditions in which the combination of splenomegaly with anæmia are present, but their other features enable them to be separated from the disease under consideration; for example, syphilitic splenomegaly, Gaucher's type of splenomegaly; and splenomegaly associated with acholuric jaundice, whether congenital or acquired. The disease therefore which is here discussed is characterized by the following features:

1. A primitive, chronic, cryptogenetic (Banti) splenomegaly.
2. Anæmia, with (a) diminution in the number of erythrocytes, and absence of erythroblasts; (b) diminution in the hæmoglobin, proportionate with or greater than that of the erythrocytes, i.e. a colour-index below 1; (c) diminution in the number of leucocytes with absence of myelocytes; (d) diminished or normal fragility of the erythrocytes. The anæmia is a constant feature of the disease, even when there has been no hæmatemesis. Its usual disappearance after splenectomy suggests that it is due to some abnormal influence of the disordered splenic functions.
3. Absence of enlargement of the lymphatic glands.

Ætiology.—The disease is most commonly met with in the third and fourth decades; but occurs at all ages outside infancy. It is slightly more common in males than in females. It is found in all civilised countries and in all races.

Pathology.—Its causation is unknown. Various organisms, including a streptothrix, have been described; but at present no good evidence is extant for their causal connection with the disease. The morbid anatomy likewise gives no characteristic change, beyond the enlargement of the spleen due to the increase of fibrous tissue and the dilatation of the blood sinuses. Infarcts of any size are rare, but perisplenitis is common. Dilatation of the œsophageal veins is often seen, and is the source of the hæmatemesis. In the later stages the liver is always the seat of a periportal cirrhosis.

Symptoms.—The patient complains of increasing weakness, of anæmia, of hæmatemesis, or of the presence of a tumour in the abdomen. Physical examination shows an enlargement of the spleen which is usually already extreme by the time the patient applies for advice. It commonly reaches the umbilicus in the mid-line, and the iliac crest in the flank. It is firm, not tender, and as a rule the splenic notches can be readily felt. Occasionally accessory splenic nodules can be discerned. The lymphatic glands are not enlarged.

The anæmia is obvious at a glance. An examination of the blood shows a diminution, generally not extreme, of the erythrocytes, e.g. between three and four millions; a diminution of the hæmoglobin usually to 50 per cent. or under; with consequently a colour-index below 1, i.e. 0·6 or 0·7; and a leucopenia due principally to a loss in the number of the polymorphonuclear leucocytes. The fragility of the erythrocytes is normal, or more commonly slightly less than normal. The blood-platelets are not diminished.

In addition to these physical signs there is, as a rule, nothing else remarkable; the heart may be moderately dilated, and there may be a hæmic murmur.

Some of the patients, a large proportion according to Banti, develop an

hepatic cirrhosis with marked ascites, and after being relieved by tapping soon relapse and die of progressive weakness. The degree of emaciation varies, but is seldom extreme. Pigmentation of the skin also occurs on occasion; but the more usual complexion of the patient is sallow, without anything which could be called real pigmentation.

Course.—The duration of the disease is variable; it cannot be called acute in any case, for nearly always it is 2 to 3 years before the more fatal signs make their appearance. The pre-cirrhotic state of the disease may last for 12 years, and there are on record cases in which the disease has been recognized by competent observers 15 or 20 years before death.

Such a patient has reached a condition in which he may remain for a number of years without further progress, at times being able to resume active life to a moderate degree, but always subject to increase in his anæmia, and likely at any time to suffer from a severe hæmatemesis. This accident is in fact a frequent termination of the disease.

Diagnosis.—The recognition of splenic anæmia is by no means easy. There are a number of other conditions accompanied by enlargement of the spleen and anæmia, and even when these are recognized there remain cases which it is very difficult to classify. The conditions which have most frequently led to confusion in the past are the anæmias with splenomegaly of syphilitic origin; the splenomegaly of hepatic cirrhosis; the rare cases of large tuberculous spleens; the congenital and acquired acholuric jaundices; and rarely abnormal cases of pernicious anæmia and of lymphadenoma. Careful examination of the blood, and of the fragility of the erythrocytes, and observation of the course of the disease usually serve to establish a conclusion. If the patient has already reached the stage of cirrhosis of the liver with ascites, it becomes almost impossible, without most careful investigation of the history and of the symptoms, to separate the condition from that of cirrhosis of the liver with secondary enlargement of the spleen. The distinction, however, is of great importance, for in the latter case splenectomy, which is of undoubted value in splenic anæmia, has a high operative mortality. In tropical and semi-tropical countries there are conditions which with our present knowledge cannot be differentiated from the type which we are considering. Such a disease is Egyptian splenomegaly, which differs in the accesses of fever and the seasonal variation from splenic anæmia. Kala-azar also has points of resemblance. The enlarged spleen of chronic malaria, with its attendant severe degree of anæmia, also deserves mention. Lastly, there is the rare condition of Gaucher's type of splenomegaly.

Treatment.—The ultimate outlook in this disease is so uniformly bad that it is probably the duty of the physician, so soon as he has established the diagnosis beyond doubt, to advise splenectomy. The results of such a proceeding have been in some instances remarkable, the patient being enabled to resume a normal life, and even in one case within the writer's knowledge to perform heavy manual labour. The mortality from the operation cannot at present be placed lower than 10 per cent., and in a fair number of cases the results, while leading to improvement, have not cured the condition. A successful splenectomy saves the patient, at least for a time, from the dangers of death from hæmatemesis, and certainly defers, if it does not abolish, the progress of the illness. The anæmia usually disappears completely within a brief period of the operation.

Apart from this remedy the physician is confined to the treatment of the anæmia with ordinary remedies, or to the employment of X-rays. These have now been used in a considerable number of cases, and while there is no doubt the spleen tends to grow smaller with their application there is no improvement in the anæmia, and the progress of the disease is not apparently checked.

GAUCHER'S TYPE OF SPLENOMEGALY

The distinctive features of this type of disease are: (1) its incidence in childhood; (2) its frequent presence in other members of the family; (3) the progressive enlargement of the spleen to an enormous size without materially interfering with the normal health and comfort of its possessor; (4) the later and equally enormous enlargement of the liver; and lastly and most important, (5) the presence in spleen, liver, lymphatic glands and bone-marrow of large mononuclear cells of an endothelial type.

The disease is being increasingly recognized. Its pathology seems to place it among the inborn errors of metabolism; the error leads to the infiltration of the cells of the reticulo-endothelium throughout the body with a lipoid substance—kerasin (Pick). A similar, but chemically different, infiltration has been described in children by Niemann. None of Niemann's cases, which were all in infants, survived beyond the second year. There is often a definite anæmia, which, however, preserves the characters of a secondary anæmia, without the appearance of abnormal cells. Some patients have shown a tendency to bleed from the gums, and in them there has been found a diminution of the blood-platelets. The infiltration of the bone-marrow has led to spontaneous fractures of the long bones, and in one instance to a spinal curvature simulating spinal caries, and in another patient, under the writer's observation, there were severe attacks of hæmorrhagic periostitis, resembling acute osteo-myelitis.

The diagnosis of the disease can be made with some certainty by the method of splenic puncture, the tissue removed by the needle showing the typical "Gaucher cells." It is now known that the course of the disease is not so benign as was originally supposed.

Treatment is entirely symptomatic. Splenectomy has now been done in some 20 to 30 cases, chiefly where life has been threatened or made miserable by hæmorrhages. It has been completely successful in causing the cessation of the bleeding, but there is at present no evidence that it alters or controls the course of the disease otherwise.

HUGH THURSFIELD.

SECTION XII

DISEASES OF THE CIRCULATORY SYSTEM

DISEASES OF THE HEART AND PERICARDIUM

It is generally recognised that within recent years there has been a great advance in our knowledge of cardiac disorders, and this advance has been of so practical a character, and of such vital importance in the diagnosis, prognosis and treatment of these diseases that it is the duty of every clinician to make himself acquainted with its nature and scope. This progress has been mainly due to the introduction of what are called graphic methods in the examination of the cardiac mechanism. By means of the electro-cardiograph and the clinical polygraph we are now able to analyse the cardiac action in a manner which was never possible before. The work of elucidation having been accomplished, it is, however, not now necessary to employ either of these instruments in the great majority of cases, the use of a sphygmograph being sufficient, and in a large proportion palpation and auscultation suffice. This is of great practical importance to the general practitioner.

As the electro-cardiograph cannot be regarded as an instrument available to the general practitioner, I have included clinical electro-cardiography at the end of the section.

PHYSIOLOGICAL CONSIDERATIONS

THE APEX-BEAT.—In normal circumstances it is the left ventricle which gives rise to the clinical apex-beat, and the apex-beat is then a definite forward thrust, lasting about $\frac{1}{3}$ rd second, and occurring about $\frac{1}{16}$ th second before the carotid, and $\frac{1}{8}$ th second before the radial pulse. It consists of three phases, namely: (a) a sudden and short shock, representing the pre-sphygmic period; (b) bulging of the heart into the intercostal space, the apex pressing against the chest-wall, corresponding with the sphygmic period; and (c) a backward movement or falling away from the intercostal space, corresponding with the post-sphygmic interval. When the right ventricle is much enlarged, however, that chamber may displace the left ventricle backwards, so that the apex-beat is formed by the right, instead of the left, ventricle: in this event, there may be a more diffuse systolic recession over the lower part of the præcordium, the out-thrust being diastolic in time.

SINO-AURICULAR NODE.—The sino-auricular node is a node of specialised tissue, discovered by Keith and Flack, at the junction of the superior vena cava with the auricle, immediately beneath the epicardium. In it are

nerve-fibres and ganglion cells, which are connected with the vagus and sympathetic nerves.

AURICULO-VENTRICULAR NODE AND BUNDLE.—The auriculo-ventricular node is a small node of specialised tissue which is situated in the septal wall of the right auricle, near to the coronary sinus, immediately above the insertion of the median cusp of the tricuspid valve. The auriculo-ventricular bundle of Stanley Kent and His is a bundle of tissue connecting the auricles and ventricles. It arises from the auriculo-ventricular node, passes forwards in the interauricular septum, then turns downwards, and at the upper margin of the interventricular septum divides into two branches, the right and left septal divisions, one of which goes to the right and the other to the left ventricle, each ending in the ventricular musculature by widespread sub-endothelial arborizations—the Purkinje fibres. Nerve-fibres and ganglion cells are present in the auriculo-ventricular bundle, and its blood supply is mainly derived from a special branch of the right coronary artery.

In the adult mammalian heart the primitive cardiac tube has become modified, and has ceased to exist as a tube. The sinus venosus, instead of remaining as a separate structure, has become incorporated in the auricle, its area being bounded by the orifices of the two venæ cavæ, the coronary sinus, and the interauricular septum. The sino-auricular node is believed to represent part of the sinus venosus, and there is reason to believe further that the auriculo-ventricular node and bundle are also remains of the primitive cardiac tube. The remains of the primitive cardiac tube are more excitable than the auricular or ventricular tissue, and the remains of the sinus venosus at the orifices of the great veins are the most excitable part. The stimulus for contraction, therefore, arises normally at this point, and there is reason to believe that it begins in the sino-auricular node; for this reason the node has been called by Erlanger the "pace-maker" of the heart; the rhythm of the sinus governs the rhythm of the remaining segments of the heart, the impulse travelling as a wave of contraction which spreads peristaltically over the other portions of the heart at rates of speed which vary in different parts. From the sino-auricular node the stimulus spreads rapidly over the auricles, and auricular systole takes place. It then travels through the auriculo-ventricular node, along the auriculo-ventricular bundle, its two main branches and their subendothelial arborisations, and is so distributed to the ventricles. Normally, therefore, stimulation and contraction of the sinus, the auricles, and the ventricles occur in the order named, the ventricle contracting only in response to stimuli received from the auricle through the auriculo-ventricular bundle. It is scarcely necessary to point out that relaxation proceeds in the same order as contraction. As will be noted later, by means of a specialised function, called conductivity, the cardiac muscle has the power of conveying the stimulus for contraction from fibre to fibre. The stimulus travels so rapidly that the contraction of the ventricle commences almost immediately after the completion of the auricular systole. But while normally the stimulus for contraction arises in the sinus part of the auricle, if any other portion of the remains of the primitive cardiac tube becomes more excitable the stimulus for contraction arises at that point; for this reason the different parts of the heart are capable of starting an independent contraction.

The auriculo-ventricular junctional tissues—either the auriculo-ventricular

node, or the auriculo-ventricular bundle above its division into two branches—and also the ventricle below the division of the auriculo-ventricular bundle, possess the power of originating the stimulus for contraction. In what is termed “nodal rhythm” the stimulus for contraction arises in some part of the auriculo-ventricular junctional tissues, giving rise to a simultaneous contraction of both auricle and ventricle. When the ventricles beat independently of the auricles, the independent rhythm of the ventricles is called “idio-ventricular rhythm.” What is known as “reversed rhythm” may occur when, owing to the fact that the ventricle below the division of the auriculo-ventricular bundle is the most excitable part of the heart, the stimulus for contraction arises there, proceeding thence to the auricle, so that each contraction of the auricle follows, instead of precedes, ventricular systole.

FUNDAMENTAL FUNCTIONS OF THE HEART MUSCLE-FIBRES.—Gaskell has described five fundamental functions of the fibres of the heart muscle, namely, stimulus production, excitability, conductivity, contractility and tonicity—contractility being the most important. Mackenzie has defined these functions as follows: By stimulus production is meant the power which the muscle-fibres possess of originating a stimulus which can excite the heart to contract; by excitability is meant the power to receive a stimulus; by contractility is meant the power of contracting when stimulated; by conductivity is meant the power of conveying a stimulus from fibre to fibre; and by tonicity is meant that function of the heart muscle which keeps the heart during diastole in a state of slight tonic contraction.

The functions of stimulus production and excitability are most highly developed at the sinus part of the auricle. The rate of the heart depends upon these functions, an increase of their activity resulting in an increase of the frequency of the cardiac action. The activity of the function of stimulus production varies a good deal, as, for instance, the slight acceleration of the heart-rate during inspiration, and the corresponding slowing which occurs during expiration, in the young. When excitability is increased, the heart has also a greater tendency to respond to abnormal or irregular stimuli; hence extra-systoles are more likely to occur. While diminished excitability may lessen the heart-rate, it should be remembered that slowing of the ventricular rate may be due to other causes, such as depressed conductivity. When stimulus production and excitability are equal, the rhythm of the heart is regular. The pulsus alternans is probably an indication of depressed contractility of the heart. The rate at which the wave of contraction travels from fibre to fibre varies in different parts of the heart. Thus, the impulse spreads in the auricles and ventricles more quickly than it does from auricle to ventricle. In this connection it may be noted that conductivity is observed by estimating the time between the systole of the auricles and ventricles. A lowered state of tonicity results in dilatation of the heart and of the auriculo-ventricular orifices.

Immediately after the muscle-fibres of the heart have contracted, they cannot again be stimulated; in other words, excitability has for the moment disappeared. This is called the refractory stage. Restoration of excitability, however, at once recommences, and steadily increases during diastole. When stimulated, the cardiac muscle either does not contract at all, or it contracts to the fullest possible extent at the time, whether the stimulus

be weak or strong. There is, therefore, no relation between the strength of the stimulus and the strength of the contraction; it is a case of "all or none."

The longer the time that has elapsed since the previous contraction, the weaker is the stimulus required to bring about a further contraction. Further, the greater the degree of excitability of the muscle-fibres, the weaker is the stimulus required, and the earlier in the refractory period will the heart contract. The contractility of the muscle-fibres is measured by the degree of contraction. The amount of contraction does not depend upon the strength of the stimulus employed, but varies according to the time at which the stimuli are applied. When a contraction occurs early in diastole, the contraction in the succeeding cardiac cycle is weaker than that preceding it. Within certain limits, the degree of contractility depends upon the length of the preceding diastole; the greater the period of rest, the more perfect and full is the recovery. It can, therefore, be readily understood that the greater the heart-rate the greater is the possibility of cardiac failure. The circulation is carried on most efficiently when the cardiac rate is exactly that which allows the myocardium to recover its full contractility, a rate over or under this being a disadvantage. Similar laws apply to each of the other special functions of the heart muscle. In the case of conductivity, for example; when conduction occurs, this function has been exercised to the fullest extent possible at the time of stimulation. The refractory period follows immediately after the conduction of a stimulus, and during this brief period the muscle-fibres cannot again conduct a stimulus, conductivity being completely exhausted. Restoration, however, quickly commences, and ultimately the function is restored. The extent of the relaxation between the contractions depends upon the degree of tone present, and upon the rate of the heart-beat. With a slower rate, there is, of course, more time for full relaxation. There should be a sufficient period of rest after each function has been exercised. Within certain limits, the greater the period of rest the more perfect and full is the recovery of each special function. In heart failure one or more of these special functions are at fault, and, if this occur to two or more simultaneously, the different functions are not necessarily equally affected. From what has been said, the value of rest in heart failure can be readily understood.

The heart has the power of rhythmically contracting and dilating, due to an inherent power possessed by the cardiac musculature, independent of any extrinsic nervous influence. Nevertheless, the activity of the various functions of the muscle-fibres is under nervous control. Both the inhibitory fibres of the vagus and the accelerator fibres of the sympathetic are normally in a state of tonic activity, and the cardiac centres are in a state of continuous slight excitation.

There are reasons for believing that, besides decreasing the rate of the heart, the vagus nerve depresses the functions of excitability, contractility, conductivity—either by acting on the auriculo-ventricular bundle, or by diminishing the irritability of the ventricle itself—and tonicity; and that the accelerator nerve, besides increasing the rate of the heart, increases the force of contraction and conductivity. Stimulation of the central part of the divided vagus nerve is followed by a fall of blood-pressure, and simultaneously by a retardation of the beats of the heart. Inhibition of the heart is due

to stimulation of the vagus as a diastolic effect; acceleration is due to stimulation of the sympathetic as a systolic effect.

THE CARDIAC CYCLE.—Stated briefly, in the cardiac cycle there occur in rapid succession auricular systole, ventricular systole, and ventricular diastole. The auricular diastole commences during the ventricular systole, and the ventricular diastole continues during auricular systole. The diastole of the auricles coincides with the commencement of the ventricular systole, the diastole of the ventricles with the commencement of the pause. The two active phases (systole and diastole) are followed by the state of rest.

There are three phases in the systole of the ventricles, namely: (a) ~~The period during which all four valves are closed~~; this is called the pre-sphygmie period. The pressure within the ventricles has caused the auriculo-ventricular valves to close, but it is not yet greater than that in the aorta and pulmonary artery, so that the semilunar valves remain closed. (b) ~~The period during which the semilunar valves are open~~; this is called the sphygmie or pulse-period. The pressure within the ventricle having risen above that in the aorta and pulmonary artery, the semilunar valves are forced open and the blood flows from the ventricles into these vessels. (c) The period between the closure of the semilunar valves and the opening of the auriculo-ventricular valves; this is called the post-sphygmie period. It should be noted that the sphygmie or pulse-period in a tracing of the cardiac apex, carotid pulse or radial pulse, does not refer to the actual time of occurrence of ventricular systole, but to a period in the tracing; and, on account of the distance from the heart, the sphygmie or pulse-period will necessarily be later in a radial tracing than the same period in a tracing taken at the cardiac apex or over the carotid. The periods of time which elapse between the apex-beat and the carotid pulse, and between the carotid and radial pulses, have each been found to be $\frac{1}{10}$ th of a second; the pulse-period, therefore, in a radial tracing commences about $\frac{1}{10}$ th of a second behind the same period in a tracing of the carotid, and about $\frac{1}{4}$ th of a second behind that in a cardiogram.

Assuming that in normal health the human heart beats about 72 times per minute, each cardiac cycle, therefore, is completed in about $\frac{5}{6}$ ths of a second, this time being divided up in the following manner: Systole of auricle, $\frac{1}{10}$ th of a second; systole of ventricle, $\frac{3}{10}$ ths of a second; diastole, $\frac{1}{6}$ ths of a second. The most stable part of the cardiac cycle is the ventricular systole, and the most variable is the diastole. The rate of the heart-beat mainly depends upon the duration of the diastole. When the heart beats unusually quickly, the duration of the diastole is shortened by a greater degree than that of the systole; in other words, when the period of the cardiac cycle decreases it is the long pause which is particularly shortened.

THE CLINICAL POLYGRAPH: POLYGRAPHIC RECORDS

By means of the clinical polygraph we are able to obtain records of the movements of both the auricles and ventricles, to measure the function of conductivity of the auriculo-ventricular bundle above its division into two branches, and to make out the time-relations of the contraction of the auricles and ventricles. It often affords—directly, or by inference—valuable information regarding the state of the myocardium. It is possible to take a simul-

taneous tracing on the same recording surface of any two of the following : the radial pulse, the apex-beat, the carotid pulse, the jugular pulse, the liver pulse and the respiratory curve ; further, a time-marker registers $\frac{1}{4}$ th second on the same recording surface. The usual plan is to take simultaneous tracings of the arterial and venous pulses. With regard to the former, the radial artery is usually chosen, although the carotid is sometimes employed. As a rule a tracing of the radial or carotid artery is more reliable than that of the apex-beat, because, in contrast with the latter, it is possible to determine with certainty the systolic and diastolic portions. Sometimes, however, as, for example, when it is difficult or impossible to obtain a satisfactory tracing of the radial artery, it is advisable to take a tracing of the apex-beat instead. With regard to the venous pulse, the jugular vein is almost always employed ; very rarely the liver.

A tracing of the arterial pulse is called a sphygmogram, a tracing of the apex-beat is called a cardiogram, and a tracing of the venous pulse is called a

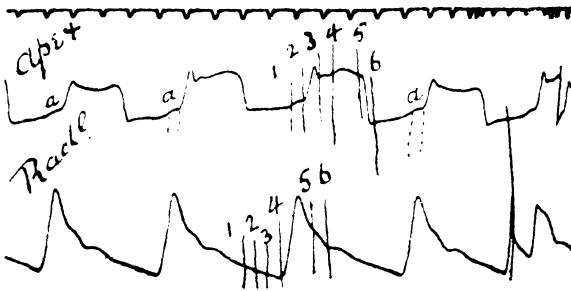

FIG. 22. Simultaneous tracings of the apex-beat and of the radial pulse showing a positive cardiogram. At 1, the commencement of auricular systole ; at 2, the commencement of ventricular systole ; at 3, the commencement of the carotid pulse ; at 4, the commencement of the radial pulse ; at 5, closure of the semilunar valves ; at 6, opening of the tricuspid valves. The space between 2 and 3 represents the pre-sphygmic period, the space between 3 and 5 the sphygmic period, and the space between 5 and 6 the post-sphygmic period. Note that the radial pulse begins $\frac{1}{4}$ th second after the commencement of ventricular systole.

phlebogram. It is not my intention to deal here with the normal sphygmogram, but it may be noted that the sphygmic or pulse-period commences with the beginning of the percussion wave and ends at the bottom of the diastolic notch.

THE CARDIOGRAM.—If the receiver be placed over the left ventricle the record is called a positive cardiogram, while if the receiver be placed over the right ventricle it is called a negative or inverted cardiogram. It should be remembered that when in enlargement of the right ventricle that chamber displaces the left ventricle, and the clinical apex-beat is formed by the right, instead of the left, ventricle, a cardiogram over the actual apex-beat will be a negative or inverted one ; otherwise, the significance of an inverted cardiogram will be misunderstood.

On analysis, a positive cardiogram is found to consist of the following parts (Fig. 23): (a) **An ascending limb**, representing the pre-sphygmic period. Its commencement is indicated by the vertical stroke 2, and exactly

corresponds with the summit of the *a* wave in a tracing of the jugular vein, and is synchronous with the commencement of the first sound; while its termination, which is usually abrupt, is represented by the vertical stroke 3, and corresponds with the commencement of the carotid pulse. (b) A fairly level line—the systolic plateau; but, instead of this, the line may continue to rise, or it may sometimes rapidly descend, representing the sphygmie or pulse-period. Its commencement is indicated by the vertical stroke 3, and its termination by the vertical stroke 5, the termination practically corresponding with the dicrotic notch of the carotid pulse. (c) A fall, either a slanting or a more vertical descent, representing the post-sphygmie period. Its commencement is represented by the vertical stroke 5, and the lowest point by the vertical stroke 6; the latter coincides with the apex of the *v* wave in the phlebogram. (d) During the period in which the blood flows from the auricles into the ventricles and slowly fills them, the heart may push against the intercostal space, giving rise to a gradual ascent in the cardiogram; or filling of the ventricles may have no effect upon the interspace, in which event the level of the tracing remains much the same until the next ventricular

FIG. 24.—Simultaneous tracings of the clinical apex-beat and of the radial artery, from a case of greatly dilated heart, showing a negative cardiogram.

systole. In some cases a slight abrupt rise is found immediately preceding ventricular systole, due to the contraction of the auricle causing a sudden increase in the contents of the ventricle. The positive wave is called *a*, and its commencement is represented by the vertical stroke 1. Normally it precedes the commencement of the wave due to the ventricular systole by about $\frac{1}{16}$ th second, an increase of this interval being sometimes indicative of a delay in the passage of the stimulus from auricle to ventricle. The *a* wave may be absent even when other indications of auricular systole are present. There is a period of about $\frac{1}{16}$ th of a second each between the vertical strokes 2 and 3, and 3 and 4.

A negative cardiogram is characterised by the following features (Fig. 24): Instead of an ascending limb and a flattened elevation, there is a slight rise, followed by a great depression—the former being due to the shock of the contracting ventricle, and the latter to the ventricles diminishing in size, on account of pouring out their blood as soon as the semilunar valves have opened. The *a* wave may be present.

THE PHLEBOGRAM.—If a tracing of the jugular pulse taken from a normal individual be studied, in each cardiac cycle three main waves are seen

(Fig. 25). They indicate a rise of pressure within the vein. The first wave in point of time is due to the contraction of the auricle, and is called the *a* wave. Its commencement is an indication of the beginning of auricular systole. Following the first wave is a fall, called *x*. The fall *x* is temporarily interrupted by the second wave. It has been already noted that the semilunar valves open at an early stage of ventricular systole. A wave of increased pressure passes along the arterial system, reaching the carotid artery about $\frac{1}{10}$ th second before the radial artery. This wave of increased pressure in the carotid artery is represented by the second wave in the tracing of the jugular vein, and is called the *c* wave, being synchronous with the primary or "percussion" wave of the arterial pulse at the same level of the neck. After the *c* wave the fall *x* is continued until towards the termination of ventricular systole, when the third wave occurs; the onflowing blood experiences an increasing difficulty in entering the auricle, leading to a fullness of the jugular vein, this being indicated by a wave in the venous tracing. The third wave is called the *v* wave. It terminates at about the time of opening of the tricuspid valves, and is then followed by a depression, which is called *y*.

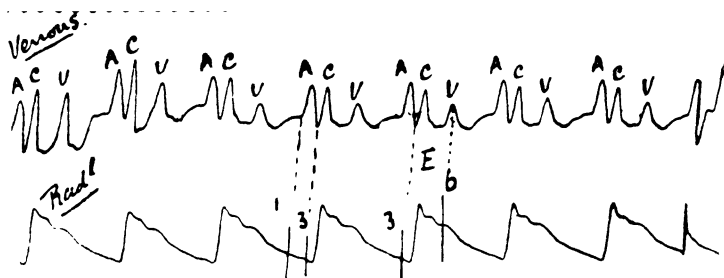

FIG. 25.—Simultaneous tracings of the jugular and radial pulses, showing the auricular form of venous pulse. Note that the *a-c* interval is $\frac{1}{10}$ th second, and that the summit of the *v* wave coincides with the dicrotic notch of the radial pulse.

The pressure within the ventricle falls rapidly during diastole, the blood contained in the auricle passes into the ventricle, and as a result the auricular pressure falls. From the point of time corresponding with the bottom of the *v* wave to the beginning of the next auricular systole, the venous tracing shows a line which is either horizontal, or which slopes upwards to the commencement of the following *a* wave. Sometimes the *c* wave is divided into two component parts, and the *a* wave more rarely so.

The time-distance between the beginning of the *a* wave and the commencement of the *c* wave is called the *a-c* interval. It is of great clinical importance; for it is an index of the *As-Vs* interval, that is, the interval separating the commencement of auricular and ventricular contraction, and is a measure of the function of conductivity of the heart. In normally acting hearts the *a-c* interval is almost constant, and does not measure more than $\frac{1}{10}$ th of a second (Fig. 25), being about 0.15 to 0.20 second in duration. In rapidly acting hearts there is a tendency for it to become shortened. If, therefore, in rapidly acting hearts the *a-c* interval measure $\frac{1}{10}$ th of a second, or, if in hearts acting at the normal or less than the normal rate

it exceed $\frac{1}{5}$ th of a second (Fig. 43)—particularly if there be a change in the *a-c* interval from beat to beat—it may be inferred that there is a prolongation of the *As-Vs* interval, and a delay in the conduction of the stimulus, this indicating that the function of conductivity is depressed; this is called “depressed conductivity,” and probably indicates some affection of the auriculo-ventricular node or of the auriculo-ventricular bundle above its division into two branches. The *a-c* interval is longer than the corresponding *As-Vs* interval in a cardiogram by $\frac{1}{10}$ th of a second.

The time of commencement of the *v* wave varies, this in all probability depending largely upon the degree of engorgement of the right heart; it may begin during the systolic plateau, or towards its termination. The earlier the *v* wave commences in the negative phase *x*, the greater the degree of engorgement of the right side of the heart; when the engorgement is marked, there may be no fall in the tracing during the period *E*. The termination of the *v* wave, on the other hand, does not vary; it never extends beyond the end of systole; when, therefore, the duration of the *v* wave increases, it does so by commencing earlier in the sphygmic period.

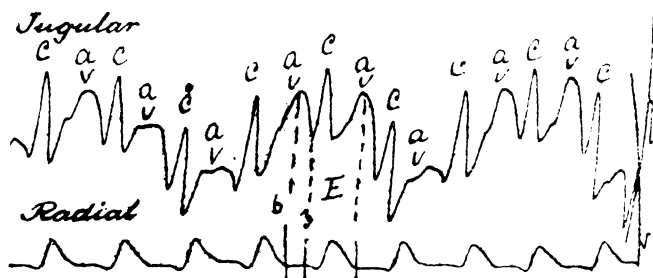

FIG. 26.—Simultaneous tracings of the jugular and radial pulses. The *v* and *a* waves coincide and superimpose.

The summit of the *v* wave is of great importance as a time-mark, being synchronous with the opening of the auriculo-ventricular valves. It corresponds approximately with the bottom of the aortic notch in the radial pulse. Sometimes the *v* wave is divided into two component parts, there being a notch or angle between them, that part which occurs earlier being called *v*¹, and the other *v*². The angle between the two component parts, in other words the beginning of *v*², coincides in point of time with the closure of the semilunar valves, and is represented in tracings by the vertical stroke 5; while the apex of *v*² coincides in point of time with the opening of the auriculo-ventricular valves, and is represented by the vertical stroke 6.

The negative phase *y* begins with the opening of the auriculo-ventricular valves. This phase tends to diminish more and more as diastole becomes shortened with increasing frequency of the cardiac rate; the *v* wave approaches more and more to the following *a* wave, and when the cardiac rate is unusually frequent *v* and *a* may even coincide and superimpose (Fig. 26).

THE *h* OR *b* WAVE.—Occasionally, more especially in relatively slow-acting hearts, there may be small waves due to stasis. Hirschfelder and

A. G. Gibson described a fourth wave, occurring in the diastolic period of each cycle, shortly after the opening of the tricuspid valves, and between the *v* wave and the succeeding *a* wave; it has been called the *h* or *b* wave (Fig. 27). It disappears when the pulse-rate becomes more rapid.

We are now able to note the relation of the different events in the cardiac cycle as recorded in a sphygmogram, cardiogram, tracing of the carotid pulse, and phlebogram:

At 1, commencement of the *a* wave in the phlebogram, and, if present, in the cardiogram.

FIG. 27.— Simultaneous tracings of the jugular and radial pulses, showing the auricular form of venous pulse, with the *h* or *b* wave.

At 2, summit of the *a* wave in the phlebogram, and commencement of the ascending limb in the cardiogram.

At 3, commencement of the carotid pulse, of the *c* wave in the phlebogram, and summit of the ascending limb in the cardiogram.

At 4, commencement of the radial pulse, and summit of the *c* wave in the phlebogram.

At 5, commencement of v^2 —if the wave be divided into two component

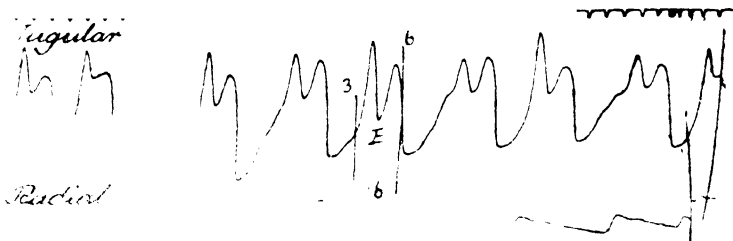

FIG. 28.— Simultaneous tracings of the jugular and radial pulse, showing the ventricular form of venous pulse, from a case of auricular fibrillation.

parts—sudden drop in the cardiogram, and dicrotic notch in the carotid pulse.

At 6, lowest point in the cardiogram, summit of the *v* wave—or of v^2 if the *v* wave be divided into two component parts—in the phlebogram, and in the radial curve the bottom of the aortic notch. There is an interval of about $\frac{1}{10}$ th second each between the vertical strokes 1 and 2, 2 and 3, and 3 and 4.

THE AURICULAR AND VENTRICULAR FORMS OF VENOUS PULSE.—When in a venous pulse the *a* wave is undoubtedly present, the form of pulse is called the auricular or negative form of venous pulse (Fig. 25). In this form of pulse

the *a* wave is present in each cardiac cycle, and its position is constant from cardiac cycle to cardiac cycle. The presence of the *a* wave informs us that the auricle is contracting normally. In what circumstances does the auricular form of venous pulse occur? It is present in two classes—(1) in all normal individuals; (2) in a large proportion of cases of organic heart disease—a point which should be particularly noted.

When in a venous curve there is no sign of the presence of the *a* wave,

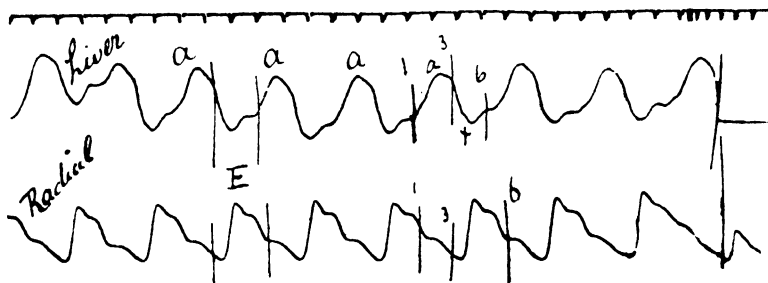

FIG. 29.—Simultaneous tracings of the liver and radial pulses. The liver pulse is of the auricular form.

the type of pulse is called the ventricular or positive form of venous pulse (Fig. 28), in contradistinction to the auricular form of pulse. It signifies that the auricle is not contracting in a normal manner. The vast majority of cases are due to auricular fibrillation; a small proportion are due to a greatly distended right auricle, or to some forms of paroxysmal tachycardia. It will thus be seen that all cases of heart disease, whether valvular

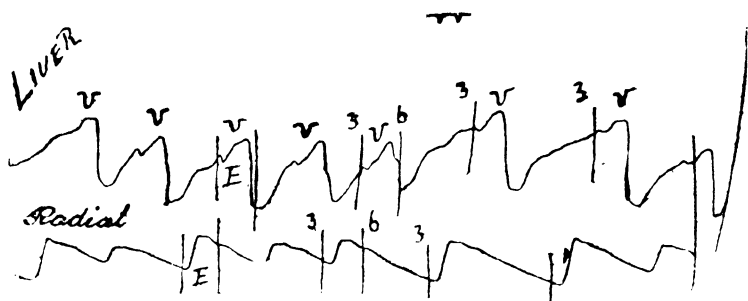

FIG. 30.—Simultaneous tracings of the liver and radial pulses. The liver pulse is of the ventricular form.

or myocardial—and it may be here mentioned whether cardiac failure be present or not—may be divided into two groups—(1) those cases in which the auricular form of venous pulse is present, and (2) those cases in which the ventricular form of venous pulse is present.

LIVER PULSE.—In a tracing obtained from the liver, the *c* wave is, of course, absent. The liver pulse, like the pulse of the jugular vein, may be one of two types—(1) the auricular form, in which the *a* wave is present

(Fig. 29), and (2) the ventricular form, in which the α wave is absent (Fig. 30). When the liver pulse is of the auricular type, according to Mackenzie, we may infer that tricuspid stenosis in all probability exists.

FREDERICK W. PRICE.

HEART FAILURE

In considering heart disease it is of fundamental importance that we should have a true conception of the principles which underlie heart failure. It should be understood that the essential cause of cardiac failure lies in the heart muscle, and is due to changes in the heart muscle which render it unable to maintain an efficient circulation, one or more of its five fundamental functions being impaired. Now, if this view of the causation of heart failure be correct, valvular defects, diseased conditions of the blood vessels, and disturbances of the cardiac mechanism—such as auricular fibrillation—should be regarded from the point of view of the relation which they bear to the myocardium, as well as specific affections in themselves. Let us take the case of a valvular lesion: First of all, it can be readily understood that it is a mechanical impediment to the heart muscle in its work. But it should always be remembered that there are as a rule, along with the valvular lesion, coincident changes in the cardiac musculature, the aorta, or coronary arteries. In all cases of valvular disease, therefore, it is of the utmost importance that we should endeavour to ascertain whether the lesion which has invaded the valve has also affected the myocardium, or blood vessels, or both. These morbid changes of the musculature of the heart may not be limited to one chamber, but may affect all the chambers. They may occur as an acute condition, which later on may become chronic; or as a primary chronic affection. As an example of the former, acute infection of the endocardium of the mitral valve by the rheumatic poison may be cited. It is recognised that this is usually followed by organisation, resulting in the formation of fibrous tissue, which tends to contract as life advances, ultimately giving rise to permanent stenosis, or incompetence, or both. It is also known that in every case of acute endocarditis there is probably always present some degree of myocarditis, and that acute myocarditis may occur independently of acute endocarditis. But it is not sufficiently understood that acute myocarditis is often followed by permanent structural changes in the myocardium, which, as in the case of endocarditis, may not fully declare themselves until some years afterwards, and we should always endeavour to try and ascertain the degree of these permanent structural changes. As an example of a primary chronic affection, may be cited many cases of aortic incompetence which come on insidiously in males during or after middle life. As a rule there are coincident or secondary changes in the cardiac musculature, aorta, or coronary arteries, and it is our duty to endeavour to estimate the degree of these changes.

Another point of great importance is whether the lesion (valvular, myocardial, or vascular) is progressive or not. In this connection, it may be mentioned that degenerative processes show a greater tendency to be progressive than those changes which follow an acute inflammation.

Now, with regard to the investigation as to whether the myocardium is involved, and to what extent, and whether the lesion which is present is

progressive, while the results of physical examination—such as evidence of enlargement of the heart—are important, there are other criteria, which are by no means sufficiently appreciated. Of these, *the most important of all is the question of the functional efficiency of the heart.* Is this impaired, and, if so, to what extent, and is the degree of impairment increasing? Mackenzie emphasised that *the best way to answer these questions is to ascertain how the heart responds to effort; in other words, the amount of physical exertion in which the patient can indulge without experiencing symptoms of cardiac distress.*

In conducting this inquiry, it is essential at the outset that three facts should be borne in mind. The first is that the natural standard of the heart's strength varies in individuals, each individual knowing the kind and amount of exertion in which he can *normally* indulge without producing symptoms of cardiac distress, and being aware when there is a departure from this, and to what extent. Our inquiry should aim at finding out whether the normal standard of a patient has decreased, and, if so, to what extent, and whether it is still decreasing.

The second fact which should be borne in mind is that symptoms of cardiac distress on exertion may be due to causes other than heart disease. Thirdly, the cardiac muscle may be merely temporarily exhausted, and this may occur whether the heart is diseased or otherwise. But, provided extrinsic and temporary causes—such as anæmia, sleeplessness, temporary physical or mental overstrain, deficient tone due to lack of physical exercise—can be excluded, the fact of a departure from the normal standard of an individual, and its degree, may be taken as fairly indicative of the presence and degree of myocardial disease. Further, if the symptoms of cardiac distress on exertion be increasing—in spite of an adequate period of rest and the employment of other remedial measures—and provided again that we can exclude extrinsic and temporary causes to account for this, we may be satisfied that the lesion is progressing, and its rate of progress may be inferred by the rate of increase in the severity of the symptoms.

Symptoms.—In the great majority of cases, the first indications of heart failure are symptoms of cardiac distress on exertion, and it is only afterwards that objective signs—such as increased pulse-rate, dilatation, or dropsy—appear. These symptoms appear as the result of less and less effort, until ultimately some or all of them are present even during rest, and objective signs also become evident.

Some of the symptoms of cardiac failure are of much greater importance than others. The commonest are breathlessness, palpitation, fatigue, and præcordial pain, on exertion.

The evidences of cardiac failure in chronic valvular disease and myocardial degeneration as a rule appear gradually; in rheumatic carditis, acute myocarditis in diphtheria, and the rapid effusion of fluid into the pericardial sac, they are usually rapid in onset: while in the case of rupture of a valve from over-exertion, and the complete and abrupt closure of the lumen of a coronary artery or one of its main branches, they are usually abrupt.

Breathlessness or dyspnœa is one of the earliest, and a very important, symptom of cardiac failure, the amount of exertion which the patient can undergo without experiencing shortness of breath being of great value in estimating the state of integrity of the heart muscle. It should be borne

in mind, however, that dyspnoea on exertion is a symptom common to many affections besides heart disease, such as anæmia, pulmonary affections, and displacement of the contents of the abdominal cavity. The degree of dyspnoea in heart disease may be so slight that the patient himself may only observe it on over-exertion. Later, it is induced by less and less effort, until ultimately—when cardiac failure is marked—severe dyspnoea is brought on by such slight forms of exertion as a change of position in bed; it may be present, indeed, without any effort of any kind. The degree of dyspnoea may amount to orthopnoea; that is, the patient may be unable to lie down. A peculiar form of breathlessness which may occur in heart disease is what is often termed “cardiac asthma.” This condition is characterised by paroxysms of breathlessness, the attack coming on suddenly, with a sense of suffocation—the intensity of which may be extreme—compelling the patient to sit up in bed, and to breathe in a very laboured fashion; wheezing sounds may be present, and the patient may cough up frothy sputum. After a time, it may be a few hours, the attack quickly subsides. These attacks are frequently nocturnal, and the patient is apt to suffer from what are called “night starts”—that is, he starts up with a sensation of suffocation; this is apt to occur when he is falling off to sleep. When a patient suffers from paroxysms of breathlessness, we should always be careful to exclude renal disease, bronchial asthma and hysterical dyspnoea. The syndrome known as Cheyne-Stokes respiration may occur as a symptom in cardiac failure, and is usually of serious import; it should be distinguished from other forms of periodic respiration, such as are occasionally found in children during sleep, and also in meningitis. It may be present for days, or even for some weeks, and yet ultimately disappear. While ordinary dyspnoea on exertion may occur in all forms of heart disease, it is more pronounced in mitral than in aortic disease; in mitral disease, indeed, it is usually the earliest symptom noted by the patient. Cardiac asthma and Cheyne-Stokes respiration are most apt to occur in chronic myocardial disease, especially with supernormal blood-pressure.

Palpitation may be a symptom of cardiac failure; but while this symptom may occur in organic disease of the heart, it should be remembered that it is more frequently met with apart from organic disease. A common symptom of cardiac failure is a sense of exhaustion during or after physical or mental effort; this may even be experienced in slight or very temporary heart failure; in the more serious cases other phenomena also are present.

Pain in the præcordium is a frequent symptom of cardiac failure, being of more common occurrence in aortic disease and in myocardial degeneration than in mitral disease. *The most characteristic feature of pain due to heart disease is that it is brought on by exertion—though it should be noted that the pain may not come on until some hours after the exertion which has induced it.* It may be constant, dull and aching; or recurring and sharp; or may present the characteristic features of angina pectoris. Its severity varies greatly. While pain in the præcordium may occur in organic disease of the heart—and, indeed, is present some time or other during the course of most cases of the severer forms of cardiac disease—it should be remembered that it is also frequently met with apart from organic disease, especially in females. The site of the pain is frequently in the neighbourhood of the apex-beat, but it may be over any part of the præcordial area. The pain of angina

pectoris, on the other hand, is usually over the sternum. Accompanying pain or occurring independently of it, there may be a sense of constriction in the chest, and tenderness in the præcordium may also be associated with it.

Cerebral symptoms, due to a diminished supply of blood to the brain, may depend upon cardiac causes, especially aortic disease and chronic myocardial disease. Among these symptoms are giddiness, syncope or fainting attacks, attacks closely resembling *petit mal*, lack of power of concentration, early fatigue in mental effort, impairment of memory, sleeplessness, disagreeable dreams, nervousness, loss of emotional control, mental irritability, and, in severe cases, delirium, hallucinations, or even insanity. Giddiness may be slight and transient, or severe enough to cause the patient to fall. Syncope or fainting attacks are preceded as a rule by a preliminary sensation of great weakness, giddiness, loss of sight, and, it may be, nausea and vomiting; while during the attack the face becomes of a greenish pallor, the patient breaks out into a clammy sweat, respiration almost or completely ceases, and the pulse at the wrist becomes very feeble or even imperceptible; the return to consciousness is gradual. While giddiness and faintness may, and frequently do, occur in heart disease, they are frequently due to vaso-motor derangement, in which connection it is of fundamental diagnostic importance whether they are more associated with physical exertion or changes of posture. Attacks closely resembling *petit mal* may occur in elderly people, especially in those with arterial disease and chronic myocardial disease, and it is sometimes extremely difficult to distinguish them from fainting attacks. The distinguishing features of the latter have already been described. Adams-Stokes syndrome may occur. This is described on page 797.

In heart disease, especially in affections of the mitral valve, there is often a persistent dusky flush over the cheeks, while later there may be lividity of the lips, ear-tips, and cheeks, and clubbing of the finger-tips may be present in chronic cases. In aortic disease, on the other hand, the face is generally pallid and anxious, though in some cases the colour may be high; while, later, when relative incompetence of the mitral valve has become established, the facies resembles that which is characteristic of mitral cases. An icteric tinge of the skin may also be present.

Loss of flesh may be present in cardiac failure, and, when heart disease occurs in the early years of life, development may be arrested. Digestive disturbances are not uncommon in, and may give early indications of, cardiac failure, being due either to deficient blood supply or chronic venous congestion of the alimentary organs, usually the latter. These may take the form of loss of appetite, a sense of fullness and oppression after meals, pain in the epigastrium and between the shoulder-blades, nausea, vomiting, gastric and intestinal flatulence, and constipation or diarrhœa. Hæmatemesis and melæna are of rare occurrence, and, if severe, are usually due to associated hepatic disease. When tricuspid regurgitation and venous engorgement have become established, there may be tenderness over the liver, which may be palpable, having a sharp edge and smooth surface, and may pulsate. Later, jaundice and ascites may develop. The spleen may be increased in size, though it is generally smaller than normal, unless there is infarction or chronic septicæmia. There may be menorrhagia or metrorrhagia, due to congestion of the uterine mucous membrane.

Œdema is an important manifestation of cardiac failure, and is more liable to occur in mitral than in aortic lesions. It usually commences in the most dependent parts, and generally the patient first notices some puffiness round the ankles in the evening. Even in severe and prolonged cases, the œdema is often confined to the lower extremities; but, occasionally, especially in children, it is first observed in the face, and, when this is the case, renal disease is often suspected. Towards the final stages it may become general, even when the kidneys are unaffected. Œdema may involve the serous membranes, with resultant ascites, hydro-thorax, and occasionally hydro-pericardium. In mitral stenosis, it is not very infrequently limited to the peritoneal cavity. The urine may be scanty, high-coloured, exhibit an excess of urates, and may contain albumin, or even blood.

Affections of the respiratory system, such as bronchitis and broncho-pneumonia, are liable to occur in heart disease, especially in mitral affections. Hæmoptysis is not uncommon; mitral disease, indeed, especially stenosis, is one of the commonest causes of blood-spitting, and the heart should invariably be examined when a patient presents himself with a history of hæmoptysis. Hæmoptysis occurring in chronic valvular disease may be the result of chronic venous congestion or pulmonary infarction. There may be chronic venous congestion and œdema of the lungs, particularly of the bases, and, later, hypostatic pneumonia. More rarely, pulmonary infarction may be present. The existence of pleural effusion should always be borne in mind in cases of dyspnœa, for not infrequently I have seen it completely overlooked; when present, it is generally bilateral. Acute pulmonary œdema is rarely met with; in these cases intense dyspnœa comes on suddenly, and is accompanied by the appearance of frothy mucus which wells out of the mouth and nose in quantities, the patient usually dying within a few hours of the beginning of the attack. Embolism, as well as arterial and venous thrombosis, may be an expression of cardiac failure.

With regard to the pulse, while increased frequency is the rule, bradycardia is occasionally to be noted in cardiac failure. The volume and force of the pulse may become diminished. The arterial pressure varies, and is, therefore, not a reliable indication of cardiac failure; it may be subnormal, but, on the other hand, it may be even supernormal until shortly before death. The apex-beat is usually displaced outwards, may be diffuse, and difficult or even impossible to locate. On percussion, the area of cardiac impairment is generally increased transversely to the right or the left, or both. On auscultation, modifications in the cardiac sounds and the cardiac cycle, as described elsewhere, may be present. Distension and pulsation of the jugular veins and other indications of tricuspid incompetence (to be described later) may be present.

Lastly, sudden death may occur, even without previous indications of cardiac failure.

The indications of failure of the left ventricle are chiefly those of systemic anæmia, the indications of failure of the left auricle are pulmonary in character, while the indications of failure of the right side of the heart are those of tricuspid incompetence. It should be noted that there may at the same time be indications of failure of all the chambers of the heart, with those of one chamber predominating. The symptoms of cardiac failure in mitral disease are principally respiratory in character. The symptoms of cardiac

failure in aortic disease, on the other hand, are at first usually mainly those of systemic anæmia, there being little or no chronic venous congestion; later on, symptoms of relative mitral incompetence are apt to appear. It should be noted that dyspnoea on exertion is perhaps the most frequent symptom of aortic disease, and may be the result of systemic anæmia as well as of some disorder of the respiratory organs. Precordial pain, as well as cerebral symptoms, are of more common occurrence in aortic than in mitral disease; while gastro-intestinal symptoms, dropsy, and embolism are of less frequency.

PROGNOSIS IN CARDIAC AFFECTIONS

Prognosis in cardiac affections is a subject of the utmost importance, and often presents great difficulties. From the nature of the ailment, the reasons for the importance of prognosis are not far to seek. Among these are the fact that the patient and his friends are naturally anxious for, and have the right to, an opinion, based upon a full consideration of all the circumstances of the case, as to the probable duration of life, the ability of the patient to lead within limits a fairly normal existence, and perhaps also his capacity for employment. This is a very natural anxiety, which if unrelieved may have a most injurious effect upon the general health and well-being of the patient. It is a misfortune that in the popular view there is a tendency to group together all classes of cardiac affections as necessarily of serious import, the result being that in a considerable proportion of cases quite needless anxiety may be occasioned.

In trying to form a prognosis in any given case of cardiac disorder, the following points, among others, require consideration: the family history, age, sex, occupation, mode of life, social conditions, the locality, nature, extent and mode of origin of the lesion, its duration, the condition of the myocardium, whether the lesion is stationary or progressive, the degree of cardiac failure, the risk of sudden death, the immediate cause of the present attack, the number, if any, of previous attacks, the state of the patient's general health, the existence or otherwise of complications, and finally the response to treatment.

With regard to the family history, we should particularly note whether the other members of the family have suffered from any form of cardiovascular disease, the average period of longevity, and the constitutional strength of the family. The question of age is one of considerable importance, the prognosis of heart disease being less favourable at the extremes of life. This in early life is owing to the fact that the heart is less able to undergo compensatory changes during the period of active growth, while any form of cardiac affection has a deleterious effect upon the general physical and mental development; moreover, rheumatic endocarditis is not infrequently accompanied by pericarditis, and there is also the risk of recurrence of rheumatic infection of the organ. Sudden death, on the other hand, is of rare occurrence. At the other extreme of life, the capacity of the heart for compensatory changes is much diminished, while degenerative processes, and associated disease in other viscera, are not infrequently present. Taking all cases of cardiac affections into account, the prognosis is better in females than in

males. Among other reasons for this is the fact that the former are less subject to physical and mental strain, in them mitral disease is relatively more common than aortic disease, and myocardial degeneration and coronary disease are relatively of less frequent occurrence. On the other hand, mitral stenosis is much more common, and the strain at puberty is greater in females than in males, and, further, the risks of pregnancy and parturition have to be considered. Any occupation or mode of life involving undue physical or mental strain or exposure, and unhealthy habits, such as over-eating or over-drinking, render the prognosis less favourable. The prognosis is considerably modified for the worse also if the patient be unable, when this is found to be necessary, to change an unfavourable occupation for one more suitable; or if he be compelled to live under unsatisfactory hygienic conditions as to food, fresh air and the opportunity for rest so necessary in those suffering from cardiac affections; or, if after suitable treatment has been instituted, a return has to be made to an unfavourable environment.

There appears to be no doubt that, taking cases as a whole, the prognosis of aortic is less favourable than that of mitral disease, and lesions affecting both valves graver than when one only is involved. It is a matter of no small difficulty to give the order of relative gravity of lesions affecting the different valves, but so far as my observations of four varieties of chronic valvular disease are concerned, I should place in order of gravity, aortic incompetence, mitral stenosis, aortic stenosis, and mitral regurgitation. With regard to aortic stenosis, however, a qualification is necessary; for although when due to a previous attack of acute endocarditis the prognosis is better than that of mitral stenosis, when primary chronic endocarditis is responsible it is not so good. Among the points which may be of assistance in trying to form an estimate of the extent of the lesion are how far the character of the pulse is modified, and the size of the heart. It should be noted that the severity of pain in the præcordium is not necessarily indicative of the nature or severity of the morbid changes present; for the pain may be severe in patients who are the subjects of slight lesions, and, on the other hand, may be of trifling severity in those who suffer from grave lesions.

Taking cardiac cases as a whole, when the lesion is due to a previous attack of acute endocarditis the prognosis is not so serious as when due to a primary chronic affection; because in the latter case the lesion is apt to come on after middle life and to be progressive, and to be associated with myocardial degeneration. It should, however, not be forgotten that when the lesion is due to a previous attack of acute endocarditis the patient is liable to recurrent attacks and consequent further crippling of the valve. If the lesion have existed for a considerable time and the health of the patient be still good, the outlook is correspondingly hopeful.

In any estimate of the prognosis of a case of cardiac disorder, it is of the utmost importance that the condition and degree of the integrity of the myocardium, and also whether the lesion is stationary or progressive, should be determined: both of these subjects have been discussed in the preceding section. The degree of cardiac failure is, of course, of great importance, and in any given case the following points, among others, should be noted: the nature and severity of the subjective symptoms, the rate—both while at rest and after physical exertion, the volume and force of the pulse, the

strength of the apex-beat and of the impulse of the right ventricle, the existence or otherwise of secondary dilatation, the character of the cardiac sounds and of the cardiac cycle, whether murmurs have diminished in intensity, the respiratory rate, the extent of œdema, and the size of the liver. It might be helpful if I indicated what, speaking broadly, may be regarded as clinical manifestations of four degrees of cardiac failure—namely: slight, moderate, severe, and extreme. *Slight*: Shortness of breath, palpitation, exhaustion, and, it may be, præcordial pain, on exertion which the patient formerly could do without experiencing this. *Moderate*: Shortness of breath, palpitation, and, it may be, cyanosis, on moderate exertion, such as walking quickly on the level; puffiness round the ankles in the evening; some degree of increased rapidity of the pulse while at rest; slight enlargement of the liver. *Severe*: Shortness of breath on slight exertion, such as walking at the ordinary rate on the level, or on changing position in bed; cyanosis while at rest; a considerable degree of œdema of the lower extremities in mitral cases, and a moderate degree in uncomplicated aortic cases; a considerable degree of tachycardia while at rest; œdema of the bases; a moderate degree of hepatic enlargement: albuminuria; orthopnoea; cardiac asthma. *Extreme*: Continuous shortness of breath; severe dyspnoea on slight exertion; marked cyanosis while at rest; general anasarca in mitral cases, and a considerable amount of œdema of the lower extremities in uncomplicated aortic cases; œdema of the serous membrane; much hepatic enlargement; pulsus alternans in the absence of a severe grade of tachycardia. A point of the utmost prognostic importance in angina pectoris is the ease with which the pain is provoked, and whether it occurs even when the patient is at rest.

With reference to the risk of the occurrence of sudden death in cardiac affections, a fatal issue in this way is most likely to occur in fatty or fibroid degeneration of the myocardium; it is also of not uncommon occurrence in angina pectoris; while of the valvular diseases it is most frequent in aortic incompetence. Another cause of sudden death is complete and abrupt closure of the lumen of a coronary artery, or of one of its main branches.

With regard to the immediate cause of the present attack, inquiry should be made as to whether this can be attributed to some temporary cause, such as a period of undue physical or mental strain, or some such intercurrent malady as acute bronchitis, or whether the symptoms have gradually appeared without any such cause; in the latter event, the prognosis is less favourable. The prognosis is also influenced by the state of the patient's general health, and the existence or otherwise of complications, among the latter being anæmia, bronchitis, supernormal blood-pressure and renal disease. The bearing upon prognosis of the supervention of auricular fibrillation, auricular flutter, pulsus alternans, intraventricular block, or any other variety of disordered cardiac mechanism, in any case of valvular or myocardial disease, will be considered in dealing with these affections.

Finally, the prognosis in cardiac affections must be considered in the light of ~~response to treatment~~. For example, given a case of auricular fibrillation, with indications of severe cardiac failure, it is impossible to say what the future will be until full doses of digitalis have been administered.

Having now reviewed the various points which may arise in the consideration of the prognosis of most cardiac affections, these need not be again

referred to when the prognosis of individual cardiac affections comes under discussion.

TREATMENT IN CARDIAC AFFECTIONS

IMPORTANCE OF TREATMENT IN CARDIAC AFFECTIONS.—In few departments of medicine is careful and skilful treatment of so great importance as in that of cardiac disorders, and in few is it so well rewarded. For although we cannot rectify the actual lesion in the case of a damaged valve or myocardium, it is none the less true that in a large proportion of cases it is possible by the adoption of proper and adequate therapeutic measures to prolong life for many years, and in most cases to save patients from much suffering. Moreover, the work which has been done in recent years in the realm of cardiac disorders has resulted in a great advance with regard to what can be accomplished in the large class of patients who are the subjects of auricular fibrillation, or of auricular flutter. At the outset, therefore, I would emphasise the fact that the practitioner will be amply rewarded for any time spent and patience exercised in considering and putting into practice suitable therapeutic measures for any given case of heart disease which may come under his care.

It is desirable to devote one section to the consideration of the therapeutic measures which may be applicable to any form of cardiac disorder, in order to save much needless repetition when we come to consider the treatment of the individual cardiac affections.

OBJECTS OF TREATMENT.—If the view previously put forward, that the essential cause of cardiac failure lies in the heart muscle, be borne in mind, certain points of fundamental importance with regard to the management of any case of heart disease can readily be grasped. We should focus our attention on the heart muscle. On the one hand, every factor which has an influence in strengthening it should be taken advantage of, while, on the other hand, everything which may throw an undue strain upon it should be considered carefully and in detail. Our objects should be: (1) To avoid everything which may possibly add to the degree of the already existing morbid affection, or embarrass the heart; (2) to do everything in our power to promote the efficiency of the myocardium; (3) to treat cardiac failure when this be present; and (4) to treat symptoms as they arise.

INSTRUCTIONS REGARDING MODE OF LIFE.—Given a cardio-vascular affection, whether valvular, myocardial, or arterial, one of the most unfortunate of things we have to face is the fact that such a large proportion of patients endeavour, or are compelled, to live beyond the limits of the heart's strength; a constant strain is thus thrown upon the organ. It is of the utmost importance that the patient should acquire the habit of always living within the limits of the heart's strength, and should on no account attempt to go beyond this. On the other hand, care should be taken not to restrict unnecessarily the normal pursuits of a patient; otherwise he is apt to become unduly nervous and introspective. With regard to the amount and kind of physical exertion which a patient suffering from heart disease may undertake without harmful effects, it is impossible to lay down hard-and-fast rules, because the constitution and temperament of different patients differ greatly. It is possible, however, to enunciate a cardinal principle which will be found to be of inestimable

service in these cases. It is, that any exertion which the patient may undergo should not be attended or followed by breathlessness, palpitation, fatigue, a sense of tightness or oppression, or discomfort or pain in any part of the front of the chest, or giddiness or faintness. On the other hand, any exertion short of producing these symptoms is usually not harmful, provided violent and sudden effort be always avoided, and a sufficient amount of exercise is in every way desirable. It is not enough to regulate the amount of physical exertion only; the importance of attending to the amount of mental work in these cases is not sufficiently appreciated. When the cardiac affection is progressive, the amount of effort, physical and mental, should be correspondingly reduced. Every form of excitement, anxiety, worry, and emotional strain should, as far as possible, be avoided.

The question of focal sepsis is an important one and should receive attention. Prophylactic measures should be adopted with regard to the risk of infection by influenza or other intercurrent disease. It is important to guard against rheumatism in chronic valvular disease, especially when of mitral origin, and particularly so in children or in young adults. An attack of bronchitis or other affection of the lungs, influenza or other febrile disease, should be most carefully and energetically treated, and a sufficient amount of rest during convalescence should be enjoined. When exertion is again allowed it should not be such as will produce any symptoms of cardiac distress.

The patient should be instructed to eat slowly and thoroughly masticate the food, and, where necessary, the teeth should receive attention in order to allow of this. In most cases, the daily amount of fluid should be somewhat restricted, our aim being to lessen the work done by the left ventricle, by diminishing its output. The meals should be as dry as the patient will take them, a sufficient amount of fluid being taken between meals. The three meals of the day should be evenly balanced, as a large meal causes too great variation in the vascular system, to which the heart does not readily adjust itself. The food should be nutritious, but at the same time easily assimilable and not likely to cause indigestion. A diet of carbohydrates is bulky, and is apt to cause flatulence and hyperchloxydria, while a diet consisting of highly nitrogenous food increases the resistance in the peripheral circulation and is equally to be avoided; while, therefore, the diet should be a carefully mixed one, the albuminous element should predominate. Articles of food which the patient knows by experience to cause indigestion should, of course, not be taken. Anything which causes flatulent distension of the stomach or bowels should be avoided, since it, by direct pressure, embarrasses the heart, and is one of the commonest causes of palpitation. In the opinion of most, a salt-free diet is of value as an aid in preventing senile changes in the arteries, and in the treatment of supernormal blood-pressure and atheroma. The excessive use of tea, coffee, tobacco, and alcohol should be avoided. It is better for the patient to abstain from alcohol altogether; but if he has been accustomed to alcohol, and its deprivation be a great hardship, a strictly moderate amount of light wine, or well-diluted spirit, taken with meals, may be allowed.

If the patient suffers from an unduly excitable nervous system, this should receive careful attention. The bromides are often extremely useful, but their long-continued use is not to be encouraged. The ammonium salt is less depressant than the potassium salt, and may be given in doses of 10 to

20 grains, three times a day after food. It is difficult to exaggerate the importance of sleep, and enquiry should invariably be made regarding its amount and character, and if any defect be found it should be adequately and skilfully treated on the lines laid down later on. Any existing anæmia in patients suffering from heart disease requires to be effectively treated by a generous supply of red meat, and iron and arsenic. Patients who exhibit a gouty tendency should have their diet regulated, and take an occasional dose of blue pill, followed by a saline aperient. In adults who are the subjects of heart disease, a course of such tonics as iron, arsenic, phosphorus, strychnine, or quinine may be taken from time to time; while in children, cod-liver oil, the syrup of phosphate of iron, or the syrup of iodide of iron is of especial advantage.

REST.—Needless to say, rest is of cardinal importance in the treatment of cardiac failure; it is difficult, indeed, to exaggerate its value. It is not sufficiently appreciated that cardiac rest is the objective of all therapeutic measures. While bodily rest is indicated in all cases of cardiac failure, it is, in my opinion, of greater value in those cases in which auricular fibrillation is not present, than when it is; indeed, in the former group of cases rest easily holds the first place among the therapeutic agencies at our disposal. In determining the degree to which exertion should be curtailed, a cardinal principle, as has already been pointed out, is that the exertion in which the patient indulges should fall short of producing symptoms of cardiac distress. When there are indications of progressive exhaustion of the heart's strength, the amount of effort should be proportionately reduced, and when the symptoms of cardiac failure are pronounced it will be necessary to order the patient to keep to his bed.

SYSTEMATIC EXERCISES.—Systematic and graduated exercises are sometimes useful in cardiac affections, provided they be judiciously and carefully employed, and their effects watched. They are of special value in cases of slight cardiac failure due to the heart muscle being flabby and lacking in tone, as in fatty infiltration; in these cases they may prove a valuable aid to treatment, but it is essential that the myocardium should be fairly sound. Graduated exercises are contra-indicated in acute affections of the heart, in considerable myocardial degeneration, in cases of severe failure—as, for example, when there is severe dyspnoea on exertion, dropsy, enlarged liver, or angina pectoris, and in cases in which the heart failure is progressive. In my opinion, simple movements are, certainly in most cases, better than the resistance exercises as practised at Nauheim, and of the former I am inclined to favour Swedish exercises. Exercises may be indulged in even when the patient is confined to bed, but in all cases should stop short of producing any indications of cardiac distress, or maintained increased frequency of the pulse.

MASSAGE.—Massage is useful in many cases. It may be employed when the patient is confined to bed, but in which absolute rest is not necessary, while, on the other hand, ordinary muscular exercise is not advisable.

BATHS AND SPA TREATMENT.—It is commonly known that immersion of the body in water may exercise a decided influence on the circulation. It is, further, believed by some that certain waters at Nauheim, on account of their ingredients, possess a specific therapeutic value in cardiac affections; but I am very sceptical with regard to this. Patients undoubtedly often derive

very great benefit from a stay at Nauheim and at similar spas; but this appears to be due to the rest, the change of air, the regular mode of life and exercise, the careful dieting, and other factors. Given the same conditions of life, equally good results would be obtainable elsewhere. Spa treatment is particularly serviceable in patients who have indulged in excesses of various kinds.

DRUGS.—It is, unfortunately, true that the reputation of many drugs used in the treatment of cardiac affections does not rest upon trustworthy evidence; by this I mean proof that the drug is a definite causal factor in the improvement of the patient. When a combination of various therapeutic agencies is employed, care should be taken to avoid crediting the administration of a particular drug with results which are in reality due to some other agency, more especially rest, or to the natural course of the malady. A problem which was notoriously a source of difficulty and perplexity to the clinician is the extraordinary difference in the results of the administration of digitalis or one of its allies in persons who are suffering from identically the same lesions, and complaining of precisely the same symptoms. As long as the drug has been in use in the treatment of cardiac affections, it has been known that the results of its administration are astonishingly varied; in some cases of cardiac failure it is of very great value, while in others it is quite ineffective. What is the cause of this variability? Is the drug capricious in its action or uncertain in its strength? Or is it due to some particular preparation being active while another preparation is inert? This has been thought to be the case by some, and for this reason special preparations have been prepared and advertised as being more uniformly certain in their action. These opinions have been proved to be wrong. It is of great importance to the practitioner to realise that this problem of the variability in the results of the administration of digitalis has been to a great extent solved. Put briefly, *those cases of cardiac failure which show wonderfully good results are, in the vast majority of instances, cases of auricular fibrillation, or of auricular flutter, in either case accompanied by a rapid ventricular rate.*

THE DIGITALIS GROUP OF DRUGS.—This includes, among others, digitalis, strophanthus, squills, convallaria majalis, and apocynum. The most suitable preparations for oral administration are tincture of digitalis (B.P., 1918, dose, 5 to 15 minims); the fresh infusion of digitalis; tincture of strophanthus (B.P., 1918, dose, 2 to 5 minims, effective dose, however, being 5 to 10 minims); and tincture of squills (B.P., 1918, dose, 5 to 15 minims, but it should be administered in twice this dose in order to obtain the same effect as the tincture of digitalis). In this connection, it should be remembered that the tincture and the fresh infusion of digitalis contain all the glucosides. There is no evidence that the more recent preparations of digitalis are either pure substances, or are more reliable than the tinctures or the fresh infusion. They should not be administered orally, and strophanthus, in particular when in pure form, has been found to undergo decomposition in the alimentary canal. None of these preparations can be employed hypodermically in an adequate dose, on account of the local irritant action, and the same applies to intramuscular injections of strophanthin. Strophanthin is suitable for intravenous injection, and may be employed in urgent cases, or when the patient cannot

tolerate any of the other preparations of the digitalis series of drugs by the mouth. The results are the same as those following the administration of digitalis or strophanthus by the mouth, but are much more rapid, improvement in the general symptoms commencing within about two hours and becoming very pronounced 6 to 10 hours later. Strophanthin, 0.5 mg. ($\frac{1}{160}$ th gr.), may be injected very slowly into a vein, and digitalis medication by the mouth may be commenced the following day. The injection should not be repeated within 24 hours, and then only in special circumstances (depending on the ventricular rate) and in a smaller dose.

It has been found that samples of digitalis supplied by different firms of chemists proved to be very constant in strength. It is advisable, however, whenever possible, to employ physiologically standardised preparations. The samples of tincture of strophanthus obtained from chemists are not nearly so constant in strength as those of digitalis. The active principles of the tincture of digitalis, strophanthus, and squills not infrequently undergo decomposition when these preparations are freely diluted with water, and this is especially so in the case of strophanthus. For this reason, the tinctures should be dispensed either undiluted, or diluted only with alcoholic preparations, and afterwards taken in water. In some cases, strophanthus and squills seem to have less tendency to induce digestive disturbances, and in a few cases I have found the latter succeed where the administration of digitalis or strophanthus was followed by gastro-intestinal symptoms or headache. On the whole, however, from a therapeutic standpoint, digitalis has proved to be the most reliable of the three drugs, and the others should be regarded as substitutes, which may be tried especially when digitalis appears to induce toxic symptoms.

The special indications which are commonly accepted for the administration of digitalis are increased ventricular rate—say over 80 per minute, weakness of the contractile force of the heart muscle, left- or right-sided cardiac dilatation, anuria due to deficient circulation, and anasarca, the cardinal indication being failure of tonicity. The drug is more generally useful in mitral than in aortic cases, especially with scanty, highly coloured urine, and with dropsy; in all probability, the explanation of this is that auricular fibrillation is much more common in mitral lesions. The drug is often useful when mitral regurgitation has become super-added to aortic disease, and also in many cases of fibroid degeneration of the myocardium, but in the latter group of cases the effects should be carefully watched.

The question is often asked whether digitalis should be given in cases of aortic incompetence. There are divided opinions on this point. A supposed disadvantage of the employment of the drug in aortic incompetence is that slowing of the pulse—if it occur—by prolonging diastole, allows more time for the distension of the left ventricle by the regurgitant current of blood. It should be pointed out, however, that slowing of the pulse may occur independently of the use of digitalis. It is further urged that the drug tends to cause sudden death in this affection. Patients have undoubtedly been known to die during its administration; but it does not necessarily follow that digitalis is responsible for this, for sudden death is apt to occur in aortic disease whether patients are taking the drug or not. In order to prove the contention that sudden death is due to the use of digitalis, there

should be no doubt that a relatively larger proportion of people suffering from aortic disease die when taking the drug than in the case of those in whom it is not being used. I am not convinced on this point. To be on the safe side, however, the drug should be given cautiously in this condition, and the patient should be kept in bed when considerable doses are being administered; while in those cases in which auricular fibrillation is not present, the drug should be stopped as soon as the acute symptoms have disappeared. Some authorities adopt the same precautions in cardiac failure associated with mitral stenosis, or suspected marked fatty degeneration. Others, again, prefer strophanthus to digitalis in aortic disease.

Digitalis is, as a rule, contra-indicated in cases of undue slowness of the pulse; in these cases, if given at all, it should be administered cautiously. The same precautions apply in the presence of a forcible apex-beat and bounding arteries. It is possible to do harm in cases of diminished conductivity, though the drug is not necessarily contra-indicated in these cases. Some writers recommend that prior to the administration of digitalis there should be free purgation. In cases of supernormal blood-pressure, Balfour believed in dilating the arterioles, and those who share this view administer one of the vaso-dilators along with digitalis or strophanthus. I myself am not optimistic with regard to the efficacy of vaso-dilators, except perhaps in cases of slight or moderate supernormal blood-pressure; and, as I have already pointed out, my investigations have shown that there is no risk attending the administration of digitalis in those cases in which there is supernormal blood-pressure, or arterial degeneration.

But, while the special indications for digitalis are increased ventricular rate, weakness of the contractile force of the heart muscle, cardiac dilatation, anuria due to deficient circulation, and dropsy, the results of its administration when these are present are variable. The response to these drugs differs according to the cardiac action and character of the rhythm; those cases of cardiac failure which show wonderfully good results are, in the great majority of instances, cases of auricular fibrillation, or of auricular flutter, in either case accompanied by a rapid ventricular rate—whether the lesion be valvular, or myocardial, particularly when subsequent to acute rheumatism or chorea. In these cases whether dropsy be present or not, the results of the administration of digitalis in the majority of cases are very, and in some cases, extraordinarily good: the administration of the drug is followed by a rapid fall in the ventricular rate (Fig. 31) and a concomitant improvement in the general symptoms. Two exceptions are: (1) Some cases of marked myocardial degeneration, and (2) cases in which there is accompanying pyrexia. In the latter, apparently, the response to digitalis, if present at all, is as a rule very slight, whether auricular fibrillation or auricular flutter be present or not. With regard to dosage: As a rule a certain amount of improvement may be obtained after a time by the administration of small doses of 5 minims of the tincture three times a day; but, on the other hand, the full effects of the drug are produced in a much shorter period by large doses. It would, therefore, appear to be desirable to commence with full doses, and to go on with these until some physiological reaction is obtained: and then, if required, to continue the administration, but to regulate the amount until it is discovered what is the optimum dose in a given case. A good method is to begin with a drachm of the tincture per diem, or

in urgent cases even $1\frac{1}{2}$ or 2 drachms per diem, and to continue until there is anorexia, nausea or vomiting, diarrhoea, headache, an unduly slow pulse, or what is called *pulsus bigeminus* or *coupling of the beats* (Fig. 53).

In some cases the action of digitalis on the heart is manifested before its effect on the stomach; in others, anorexia, nausea, vomiting, headache or diarrhoea occurs first; in others again the effects on the circulatory and digestive systems are coincident. A physiological reaction usually occurs within a week, sometimes in 3 or 4 days; the time, however, varies greatly. In auricular fibrillation, the drug should then be stopped until these symptoms have passed away, which is generally in a few days. In the great majority of cases the patient relapses, and the indication then is to find out what dose suits him best—that is, the dose sufficient to control the action of the heart, without at the same time giving rise to any toxic symptoms; this may require weeks or even months of careful observation, and much perseverance will generally be required. One method is to begin with half the original dose, and this can be increased or diminished according as the rate of the heart increases or diminishes. In this connection help may frequently be obtained from the patient himself, who is often able to say what dose suits him best; in other words, the patient's own sensations are often a good guide, and should be taken into account, as well as the ventricular rate. The dosage necessary in individual cases may exhibit a wide variation; it may be as small as a drachm of the tincture per week, or as large as 45 minims or even more per diem. Having discovered this dose, it will be necessary, in the great majority of cases, for the patient to continue the drug for the remainder of his life. In the course of time variations in the dose may be found to become necessary. The cumulative action of digitalis is apparently not nearly so important as has been believed; at the same time the ventricular rate ought to be watched. *Pulsus bigeminus* is a danger signal, and we should either stop the drug for a few days or diminish the dose.

Digitalis has no effect upon the auricular fibrillation itself; but it diminishes conductivity of the auriculo-ventricular junctional tissues, thereby interfering with the pathway of impulses from auricle to ventricle, and so cutting off some of the too numerous impulses reaching the ventricle, and thus leading to a reduction in the ventricular rate, as a result of which the cardiac contraction becomes stronger, with consequent improvement in the circulation and in the general symptoms. In very rare instances, complete auriculo-ventricular block is induced. In the opinion of Cushny, the diminu-

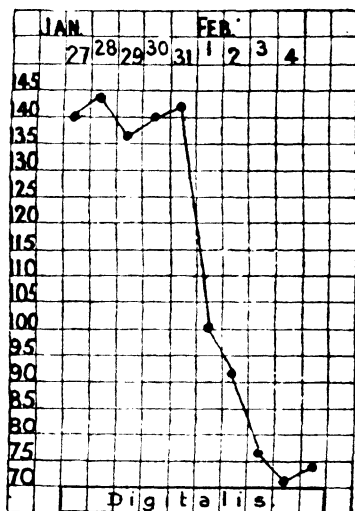

FIG. 31.—Chart showing typical result on the cardiac rate of the administration of digitalis in a case of auricular fibrillation with tachycardia. A drachm of the tincture per diem was commenced on 27th January.

tion of the ventricular rate in auricular fibrillation is due to the direct action of the drug on the heart muscle, and not to stimulation of the inhibitory mechanism, since it is not prevented by atropine. This view is not accepted by others, however, who hold that it is due to stimulation of the inhibitory mechanism.

When auricular fibrillation is not accompanied by a rapid pulse, no marked result usually follows the administration of digitalis; indeed, it is often difficult to be certain how far the improvement may be due to the rest in bed and other measures adopted, apart from the effect of the drug.

In auricular flutter, the administration of full doses of digitalis at first usually induces partial heart-block, or an increase of the degree of block already existing, with a resulting diminution of the ventricular rate. Later on, the drug may induce auricular fibrillation. This may persist, or the physiological rhythm may be restored—either event occurring during the administration of the drug or after it has been discontinued, or the normal rhythm may be interrupted from time to time by paroxysms of flutter, or after the cessation of the drug the flutter may return and continue. The same dosage should be employed as in cases of auricular fibrillation with tachycardia, and should be continued until the full physiological reaction is obtained. After this one of two plans may be adopted: (1) The dosage may be gradually diminished, and afterwards the administration of the smallest dose necessary to control the ventricular rate continued in the hope that the flutter may cease; or (2) large doses may be continued, in the hope of inducing auricular fibrillation, after which the administration of the drug is discontinued for some days, in the hope of a return to the normal rhythm. The first plan is generally to be preferred.

Eggleston, in 1915, introduced the method of the oral administration of massive doses of digitalis, and since then others have advocated this method. A physiological reaction is usually obtained in from 12 to 36 hours. The drug should then be stopped for a time. The employment of massive doses should be restricted to urgent cases of auricular fibrillation or of auricular flutter with a rapid ventricular rate. Only physiologically standardised preparations of digitalis should be used. Three doses of $1\frac{1}{2}$ drachms, 1 drachm, and half a drachm, at intervals of 6 hours, or 1 drachm, or a drachm and a half, 1 drachm, 1 drachm, and 1 drachm, at the same intervals, may be employed.

If the case be not one of auricular fibrillation or of auricular flutter, exceptionally the administration of digitalis induces auricular fibrillation. *Apart from these cases, as a rule, though not always, the beneficial results will be only moderate, almost negligible, or even altogether absent—unless dropsy is present.* The drug appears to act by increasing the strength of contraction and perhaps by augmenting tonicity. In some of these cases, the ventricular rate is diminished—though rarely in so marked a degree as in auricular fibrillation, but this is not an essential factor. In the majority of cases with a normal rhythm, however, the ventricular rate is not diminished more than can be accounted for by the rest in bed and other therapeutic measures. Or, the various grades—even complete—of auriculo-ventricular block, or sinus irregularity, extra-systoles, sino-auricular block, or pulsus alternans, may be induced. The higher grades of heart-block are sometimes induced by full doses of one of the digitalis series of drugs in those exhibiting a slight degree of block who had previously suffered from

a rheumatic infection of the heart. Cushny is of opinion that slowing of the heart, usually auriculo-ventricular and sino-auricular heart-block, and sinus irregularity are due to vagus stimulation; and extra-systoles, and sometimes auriculo-ventricular and sino-auricular block, to the direct action of the drug on the cardiac muscle. My custom in cases of normal rhythm also is to commence with large doses, and to continue until there is anorexia, nausea, vomiting, an unduly slow pulse, or heart-block, extra-systoles, sinus irregularity, or pulsus alternans. In some cases, heart-block or extra-systoles are at first only observed after exertion; after the temporary acceleration produced by the exertion has subsided, the pulse-rate becomes slower than before the exertion, if the individual be under the influence of the drug, and it is during this period of slowing that heart-block or extra-systoles appear. When these symptoms have appeared, the drug should be stopped, or the dosage reduced. If improvement in cases without auricular fibrillation occur, it can usually be maintained without continuing the drug; sometimes, however, it is advisable after stopping the drug for a few days to resume with smaller, but yet sufficiently large, doses. Here again, the patient's own sensations should be taken into account.

Digitalis is contra-indicated in partial heart-block. I have never found it of any value for the irregularity of extra-systoles.

Quinidine: During recent years quinidine has been employed in the treatment of persistent auricular fibrillation and persistent auricular flutter, more especially the former, with the object of arresting either condition—in other words, to restore the normal rhythm; and also in paroxysmal tachycardia, in the intervals between the attacks, to prevent their recurrence. In about half the cases of persistent auricular fibrillation reported, the normal rhythm was restored.

Lewis and his co-workers are of opinion that quinidine has the following effects: (1) It diminishes the sino-auricular rate considerably. (2) It increases the absolute refractory period of the muscle of the auricle. (3) It diminishes the rate of conduction in the auricle, along the auriculo-ventricular junctional tissues, and in the ventricle. The three effects are due to a direct action on the muscle. The drug usually induces paralysis of the vagus—generally partial, rarely complete—both with regard to its action on the sino-auricular rate, and the rate of conduction along the auriculo-ventricular junctional tissues. With regard to the latter, however, exceptionally, vagal stimulation lessens the degree of any existing auriculo-ventricular block. The effects of the administration of quinidine in patients suffering from persistent auricular fibrillation are mainly: (1) A progressive diminution in the auricular rate; (2) a simultaneous increase in the ventricular rate; and (3) a sudden cessation of the auricular fibrillation, with a return to the normal rhythm. The usual sequence of events is coarse fibrillation, impure flutter, pure flutter, a short period of arrest of the whole heart, and the restoration of the normal rhythm. There is a preliminary, and very early and progressive diminution in the auricular rate, even up to 200 per minute, due to (1) a diminution in the rate of conduction in the auricle, and, under certain conditions, (2) an increase in the length of the refractory period, causing the circulating wave to choose a longer path. If the auricular rate falls to about 200 or under, there is a danger of the ventricle suddenly taking on the same rate as the auricle. Rarely a slight rise in the auricular rate results in a long arrest of

the whole heart. Whether the normal rhythm is finally restored or not, an increased ventricular rate, to 120 per minute or more, which may cause attacks of palpitation, is common during the first two days of the administration of the drug. The increased ventricular rate may be controlled by a preliminary course of digitalis medication, in full doses, which almost always causes the oscillations of the fibrillating auricle to become more frequent, and also diminishes conductivity of the auriculo-ventricular junctional tissues. Extra-systoles may be observed after the auricular fibrillation has ceased, and may give rise to palpitation. They may appear isolated, or at irregular intervals, or a single extra-systole may occur regularly after each normal beat—resulting in coupling of the beats, or the extra-systoles may occur in short or long runs—in the latter event lasting even for some hours. The occurrence of extra-systoles is to be noted as a general rule only when the auricular rate has diminished considerably, generally to 250–300 per minute. Their appearance is an indication of poisoning.

In persistent auricular flutter, the administration of quinidine may restore the normal rhythm.

General toxic symptoms, cardiac failure, and embolism may occur during the administration of quinidine. Among general toxic symptoms are headache, giddiness, tinnitus, transitory visual disturbance, nausea, vomiting, abdominal pains, palpitation, tachycardia, præcordial discomfort or pain, sweating, scarlatiniform or morbilliform rashes, urticaria, a mild degree of pyrexia, fainting attacks, and mental symptoms. Among the manifestations of cardiac failure are sudden collapse, sudden cessation of respiration, severe dyspnoea, cyanosis, and disappearance of the pulse—due to ventricular standstill during the transition stages. Naturally these effects are more likely to follow when there is a considerable degree of cardiac failure and of cardiac enlargement, notwithstanding the fact that a course of rest and digitalis medication has been tried. The risk of embolism occurs at the time when the auricle first commences to contract again after the restoration of the normal rhythm. Thrombi are expelled from the auricular cavity into the systemic or pulmonary circulation, and death may result. Embolism is more likely to occur when the patient is the subject of mitral stenosis, when the auricular fibrillation or the auricular flutter is of long standing, and there is a previous history of embolism. Death during the administration of the drug may be due to cardiac failure or to embolism.

In persistent auricular fibrillation or persistent auricular flutter quinidine is most likely to be successful in those cases in which there is either a complete absence, or at the most only a moderate degree, of valvular or myocardial disease, of cardiac enlargement, and of cardiac failure; in those in which the abnormal rhythm is the result of antecedent rheumatism or chorea rather than when due to degenerative changes; in cases in which there is an absence of acute endocarditis, or acute myocarditis; when the onset of the condition has occurred during an acute infection—such as influenza; when the abnormal rhythm has followed paroxysmal attacks, and, in the opinion of some, when of recent origin; and in the case of the young. The majority of successful cases follow the use of only small doses of the drug, and it is rarely successful if more than 30 grains per diem are required. Relapse into the abnormal rhythm occurs, in the majority of cases, sooner or later, after the drug has been stopped. This is less likely to happen when the abnormal

rhythm is the result of antecedent acute rheumatism or chorea ; when it is of recent origin ; when the onset of cardiac failure coincided with the onset of the abnormal rhythm ; and when the administration of the drug is continued.

The degree of improvement in the patient's condition which may follow the administration of the drug depends upon the restoration of the normal rhythm, the permanence of this, and whether the ventricular rate has not been increased by the restoration of the normal rhythm, and how great a factor the supervention of the abnormal rhythm has been in inducing and maintaining the cardiac failure. It is important to try to determine whether and to what extent the abnormal rhythm is responsible for the cardiac failure. In this connection, if the onset of cardiac failure coincided with the onset of the abnormal rhythm, we may assume that the cardiac failure was due to this ; the degree of response to rest and digitalis medication is also helpful. In a certain proportion of cases in which the normal rhythm has been permanently restored, and the ventricular rate has not been increased, the standard of health seems to be higher than it was when the ventricular rate was controlled by digitalis, and in some it appears to be even equal to that which existed prior to the existence of auricular fibrillation or of auricular flutter. In some cases after the restoration of the normal rhythm the ventricular rate is higher than when the auricular fibrillation or the auricular flutter existed and the ventricular rate was controlled by digitalis, and it may not be possible to control tachycardia associated with the normal rhythm by digitalis, so that the patient may not be so well, and possibly even a good deal worse. In auricular fibrillation, the consciousness of the irregular action of the heart disappears.

Among the disadvantages of quinidine is the risk— even amounting to a possible fatal issue—attending the administration of the drug, the fact that restoration of the normal rhythm occurs in only about half the cases of auricular fibrillation, there is a danger of relapse into the abnormal rhythm, and in some cases after the restoration of the normal rhythm the general health is worse—possibly even considerably so. Contra-indications for the use of the drug are the presence of a severe grade of valvular disease, widespread myocardial degeneration, great enlargement of the heart, a severe degree of cardiac failure— unless this has been remedied by a course of rest and other therapeutic measures, heart-block, existing or recent acute or sub-acute endocarditis or myocarditis, a recent history of embolism, and in those cases when the patient cannot be confined to bed and be assiduously and carefully watched. The elderly or even the aged need not be excluded on the ground of mere age, but, in the opinion of some, cases of over three years' standing generally are.

A preliminary course of rest in bed and of digitalis medication is advisable. It is the practice of some to stop the digitalis for a few days before commencing quinidine, while others continue its use during the administration of the latter, in order to control the ventricular tachycardia. The patient should invariably be confined to bed, preferably in a hospital or nursing home, absolute rest, physical and mental, should be enjoined, and he should be assiduously and carefully watched. Frequent electro-cardiographic or polygraphic examinations, preferably the former, are very advisable, but they are not indispensable. If the electro-cardiograph is employed, it is better to employ direct leads from the chest, instead of from the limbs, as

the former method supplies a more accurate record of the state of the auricles. If electro-cardiographic or polygraphic examinations are not available, I would lay stress upon the value of auscultation. Quinidine is given preferably in gelatine capsule form. Some people, even those who are not the subject of heart disease, show an idiosyncrasy to the drug. This is as a rule approximately proportionate to the dosage. It is advisable to give a single dose of 5 grains, or two doses of 3 grains at an interval of 2 hours, to test for possible idiosyncrasy, and if none is found to exist, to commence the routine treatment the following day. Five grains three times daily may be commenced with, and the total daily dosage gradually increased until the normal rhythm is restored. The dosage should not exceed 50 grains per diem. The drug should be stopped if severe toxic symptoms, severe cardiac failure, or embolism, occur, or if, according to Lewis, there is an auricular rate of 250 or 240 per minute—because of the risk of inducing 1 : 1 rhythm, or, as a rule, if there is a ventricular rate above 160. After the normal rhythm has been restored, the total daily dosage should be gradually diminished to 5 grains twice, or even once, daily, and this continued for an indefinite time or even permanently. This method lessens the likelihood of relapse.

Recently I have employed 5 grains of quinidine sulphate once daily in a number of cases of paroxysmal tachycardia, in the intervals between the attacks, to prevent their recurrence, and it has been successful in most. Some workers employ about twice this daily dosage.

Investigations which I conducted some years ago showed that *aconite* has no effect upon the pulse-rate.

Caffeine has acquired a certain reputation in the treatment of cardiac affections, but this is, in the main, the result of its diuretic action, which is of great value. It should not, however, be regarded as a substitute for digitalis, for the action of the respective drugs on the heart is not the same. Apart from its diuretic action, caffeine may be tried when digitalis, strophanthus, and squills have failed, particularly where there is no dilatation. It does not slow the pulse, and, therefore, bradycardia is no contra-indication to its use.

Diuretin, *agurin*, and *theocin-sodium-acetate* have a more constant and marked effect upon the kidneys than caffeine. They may be used in conjunction with one of the digitalis group.

Strychnine has acquired a great reputation in cases of cardiac failure when very rapid effects are required, but there appears to be no absolutely reliable experimental or clinical evidence that in medicinal doses the drug has any effect upon the heart or blood vessels; nevertheless, many are of opinion that the prevailing belief is supported by clinical experience. The action of the drug is probably an indirect one as far as the heart is concerned, its essential action being that of a respiratory stimulant.

Diffusible stimulants (alcohol, ammonia and ether) are of value in some cases of cardiac affections, particularly during temporary attacks of cardiac failure, febrile cases, and for the relief of urgent symptoms. With regard to alcohol, it is often a good thing to begin with a small quantity of wine with food. Ultimately stimulants in larger quantities may be employed, and of these old brandy is the best.

Adrenalin.—The use of adrenalin hypodermically in Adams-Stokes syndrome is referred to on page 799. Intracardiac injection of adrenalin may be tried in cases of complete arrest of the heart and respiration. Its

chief use is in syncope during an operation. It has also been tried in cardiac failure from various causes, but its results here are uncertain. Artificial respiration should always be combined with it. The maximum dose should be 1 mg. (1 c.c. of 1-1000 solution), and the solution employed should not be more than 3 months old. No special needle is required; one for lumbar puncture or for inducing regional anæsthesia, with a syringe 2-5 c.c., suffices. The needle should be introduced in the fourth left intercostal space, close to the sternum, or the upper border of the fifth intercostal cartilage. After passing the needle perpendicularly for 2-3 cm., it should be turned slightly to the middle line. The right ventricle is reached, and on penetrating 4-5 mm. the cavity of the ventricle is entered. Care should be taken that the needle is certainly in the cavity of the ventricle, by withdrawing a little blood, before injecting the adrenalin. The drug should be injected slowly. Artificial respiration should be stopped while the injection is being made, but resumed immediately afterwards. After the heart has become re-animated, adrenalin intravenously may be employed.

Barium chloride.—The employment of this drug in Adams-Stokes syndrome is dealt with on page 799.

Atropine is supposed to paralyse the cardio-inhibitory terminations, and cases of heart-block have been recorded in which the writers have stated that in their opinion the drug was the means of increasing the ventricular rate. If this be so, it should be of service in Adams-Stokes syndrome. One-hundredth of a grain may be given hypodermically, and repeated in half an hour if necessary. I am bound to say, however, that I have never yet seen any good result follow its administration in these cases.

Some believe that *iron* and *arsenic* are cardiac tonics, and, therefore, do not restrict the use of these drugs to cases of heart disease in which there is coexisting anæmia, but employ them in the early stages of cardiac failure. Iron, arsenic, strychnine and quinine are often serviceable during convalescence.

The *bromides* are useful in cases of heart disease in which there is excitability or irritability of the nervous system, and in sleeplessness. The *iodides* are said to be of value in gouty conditions, in supernormal blood-pressure, in arterial disease, in angina pectoris, and, most of all, when there is reason to believe that valvular, myocardial or arterial disease is the result of syphilis, and they may be taken for long periods of time; in the last group of cases they should be given in full doses (15 to 20 grains three times a day). *Mercury* may with advantage be administered along with the iodides when the syphilitic infection is recent. With regard to arterial disease, while iodides may exert a beneficial influence in the earlier stages of the disease, it is practically certain that they are valueless in the later stages.

The *nitrites* may be tried in cases of increased blood-pressure, and in angina pectoris—in the latter even if unattended with high pressure. Nitrite of sodium, erythrol tetranitrate, mannitol nitrate, nitro-glycerine, and nitrite of amyl are most commonly employed.

Purgatives are of value when there are indications of distension of the right chambers of the heart, and dropsy, and also in cases of supernormal blood-pressure; salines, administered from half an hour to an hour before breakfast, are preferable.

Diuretics should be given in cases in which the urine is scanty, especi-

ally if dropsy be present. The best diuretics are digitalis, squills, caffeine, diuretin, agurin or theocin-sodium-acetate, scopolarium, and the acetate, citrate, or bitartrate of potassium.

OXYGEN.—This is sometimes of value in cases of cardiac failure, the chief indications for its use being dyspnoea, cyanosis, and angina pectoris, particularly the two former. On the whole, I have been disappointed with the results of its administration, though occasionally substantial good has apparently attended its use. Leonard Hill has introduced a new method of giving it, by which the patient inhales almost pure oxygen. The patient's head is enclosed in a mask, the oxygen entering the mask from a cylinder, and the séance lasting from 10 to 20 minutes at a time. More recently Haldane has introduced a better method.

BLOOD-LETTING.—This is of considerable value in a certain class of cases, and I am inclined to think that this mode of treatment is often not used when it might be employed with great advantage. It should be employed when there are indications of great distension of the right chambers of the heart—as, for example, severe dyspnoea, cyanosis, noticeable turgescence of the veins of the neck, and increased area of impairment of the percussion note to the right—especially when the radial pulse is small and weak, while, at the same time, there is forcible pulsation of the right ventricle in the epigastrium. As a rule, venesection should not be performed in aortic incompetence; in these cases it often does harm. My custom is to choose the median basilic vein, and to withdraw a good quantity of blood—occasionally even up to 20 or 30 ounces; sometimes, however, 8 to 10 ounces are sufficient. If venesection be not practicable, or be objected to by the patient or his friends, 6 to 12 leeches over the right ventricle or liver are a good substitute. When blood-letting is employed, it should be accompanied by dry diet and free purgation.

MASSAGE OF THE HEART.—This desperate measure finds its chief, if not only, indication in arrest of the heart during general anæsthesia. The best route for its application appears to be the subdiaphragmatic. The abdomen is opened, and the heart massaged from below the diaphragm. Artificial respiration should always be maintained at the same time. Not more than 5 minutes should be allowed to elapse before massage is employed after the heart has failed. The compression should at first be rhythmic, and if this method is not successful in 10 minutes, it should be applied intermittently. Adrenalin into the external jugular vein is a useful adjunct.

TREATMENT WHEN CARDIAC FAILURE IS PRESENT

The amount of physical or mental effort should be reduced. In the slightest degrees of cardiac failure it may be sufficient if the patient remain in bed for a couple of hours every afternoon or one day a week, although it is usually better to commence treatment by keeping him continuously in bed for a short time. When heart failure is more pronounced the amount of exertion should be reduced to a minimum, the patient being kept in bed for a period which may extend even to some months. When subject to nocturnal attacks of dyspnoea he may be most comfortable when supported by high pillows or a bed-rest, or he may not be able to breathe with comfort even in bed, and may prefer to sit up in a large easy-chair, leaning forwards and sup-

porting himself with his arms on the back of another chair. In certain cases of cardiac failure, exercise in moderation, provided careful and detailed instructions be given as to its nature and extent, is of value.

In cases of cardiac failure, unaccompanied by nausea and vomiting, light solids form the best diet, and, as a rule, agree better than fluid food, being less likely to cause flatulence; the necessary mastication is also an advantage. The daily amount of fluid taken, particularly at meal-times, should be reduced. Great care should be exercised to see that the patient does not take a larger quantity of food than he can comfortably digest. The food should be easily digestible. When cardiac failure is extreme, the amount of food should be considerably restricted, and only very small quantities at a time, at fairly frequent intervals, should be allowed. Biscuits, small thin sandwiches of potted meat, or small quantities of milk are not infrequently all that can be comfortably digested. Occasionally a pure milk diet, or a modified Salisbury diet, is best. Other therapeutic measures appropriate to the condition should be employed until the requisite effects are obtained; the indications for, and the manner of employment of, each class of these in cardiac failure have already been fully described. When there are indications of distension of the right heart, free purgation, the administration of diuretics, and blood-letting are indicated. Special symptoms should be treated on the lines laid down later on. The return of convalescence should be gradual, and the greatest care should be exercised. Convalescence from severe cardiac failure is sometimes aided at first by gentle massage, and, later, by carefully regulated and gradually increasing exercises—at first passive, and later active—before the patient is allowed to get up. The movements should always stop short of producing symptoms of cardiac distress, and should be followed by a period of absolute rest.

TREATMENT OF SYMPTOMS

Rest, and other measures and remedies previously described in detail, should be employed in the treatment of symptoms.

SLEEPLESSNESS.—The ventilation of the bedroom should receive attention, and, while the patient should be kept warm, the bedclothes should not be too heavy. It should be remembered that insomnia may be due to dyspnoea, and that in these cases the patient is sometimes troubled with "night starts" as he is falling off to sleep; the dyspnoea should be treated on the lines to be laid down later. Similarly, if supernormal blood-pressure be present, this should receive attention. It may be necessary to employ hypnotics in the insomnia of heart disease. I generally begin with the bromides, and usually choose the ammonium salt, on account of its less depressant effect, in doses from 10 to 20 grains three times a day, only gradually diminishing the dosage. Failing bromides, or as an alternative to these, I usually employ medinal (grs. v-x), adalin (grs. x-xv), or paraldehyde (5i-7ii or more). The last is an extremely valuable drug in many cases, especially when there is dyspnoea. Its unpleasant taste may be partly concealed when administered in an almond mixture, or in an emulsion; or it may be given in capsules, each containing 20, 30, or 40 minims. If the patient is more restless or excited after taking the drug it usually means that the dose has been too small. Bromural (grs. v-x), dial, urethane (grs.

x-lx), trional (grs. x-xx), or sulphonal (grs. x-xxx) may be tried. The last two are especially useful in nervous subjects, but they have the disadvantage of being slow in their action, although this makes them very useful in cases in which the insomnia occurs late at night. If these remedies fail, chloral hydras may be tried. This drug has the reputation of being a dangerous remedy in heart disease, especially in degeneration of the myocardium, but I have used it very extensively and have never found this to be the case. It produces a refreshing sleep, and is especially useful when nocturnal dyspnoea and supernormal blood-pressure are present. It may be given in doses of 5-10 grains by the mouth, gradually increasing to 15 or even 20 grains if necessary, the dose being repeated in 2 hours if required, and the effects carefully watched all the time. Chloralamide (gr. xv-xlv) acts nearly as well as chloral hydras in some, although by no means in all, cases, and is supposed to be safer. Bromidia (5i or more) is also useful. If these drugs fail, resort should be had to opium or morphine, which are especially useful when there are accompanying restlessness and dyspnoea. The hypodermic administration of morphine is much more efficacious in cardiac failure than when given orally, and there are disadvantages attending the latter method. It is well to commence with very small doses, and gradually to increase them until relief is obtained, the effects being carefully watched. I generally commence with $\frac{1}{8}$ th grain, gradually and carefully increasing to $\frac{1}{4}$ th grain if necessary; while, later, it may be necessary to increase the dose even still further. Cyanosis is not an absolute contra-indication to the administration of chloral, opium or morphine. Speaking generally, these drugs should not be administered in those cases in which there is much bronchial secretion, or œdema of the lungs, or in Bright's disease; but in individual cases they may be tried if the first dose be extremely small, and the dosage be subsequently increased with the greatest caution. Further, when there is much bronchial secretion, or œdema of the lungs, a sharp look-out must be kept to see whether the administration of the drug increases them; in such a contingency, atropine or strychnine should be administered in combination with the morphine.

DYSPNOEA.—If bronchitis, or gastric or intestinal flatulence be present, they should receive attention; and, similarly, fluid in the abdomen may require to be withdrawn. If there be indications of congestion or œdema of the lungs, dry-cupping is indicated, the best time, as a rule, being when the patient desires to go to sleep. The exclusion of hydrothorax as a cause of dyspnoea should always be a matter of consideration, and, when present, paracentesis thoracis should be performed. Oxygen, diffusible stimulants such as ammonia and ether, and strychnine may be tried in dyspnoea. Strychnine undoubtedly has an action on the respiratory centre, and in patients who suffer from "night-starts" and nocturnal dyspnoea may be given in full doses in the evening. Venesection or leeching is sometimes of value. For paroxysmal dyspnoea, vaso-dilators—such as the inhalation of amyl-nitrite, or the internal administration of nitro-glycerine, erythrol tetra-nitrate, or sodium nitrite—are sometimes efficacious. When these various measures fail, chloral may be tried, and, if this be not successful, opium or morphine. The dosage of these drugs and the contra-indications to their use have already been noted under the head of sleeplessness.

FAINTNESS.—Among temporary measures are plenty of fresh air, fanning,

warmth to the feet, cold to the head, and diffusible stimulants, such as ammonia and ether.

ŒDEMA.—The measures which are of particular value in the treatment of œdema are the restriction of the amount of daily fluid, free purgation, the administration of diuretics, and, in the opinion of most, a salt-free diet. A watery diarrhœa is not necessarily a contra-indication to purgation, because it is frequently due to a passive congestion of the intestinal mucous membrane. Besides the usual purgatives, calomel and colocynth pill, or pil. hydrargyri, followed by Epsom salts or some other saline in the morning, may be given once or twice a week for a time. The infusion of digitalis has a greater reputation than any other preparation of that drug in the treatment of dropsy, but I am not sure that this is warranted. If digitalis fail, theocin-sodium-acetate, agurin or diuretin may be added to it. Many people prefer a combination of drugs, and in many cases this method of treatment appears to be more efficacious. Baillic's or Guy's pill, which consists of mercury, digitalis, and squills, is a well-known combination. It is particularly useful in persistent dropsy due to cardiac failure; indeed, when given along with saline aperients it forms the most useful diuretic in many cases of œdema of heart disease. Among various prescriptions of this combination are:

R Pilulæ hydrargyri, Pulveris digitalis, Pulveris scillæ, Extracti hyoscyami, ãã gr. i. Ft. Pil. One three times a day after meals.

R Pilulæ hydrargyri, grs. ii; Pulveris digitalis, gr. $\frac{1}{2}$; Pulveris scillæ, gr. i. Ft. Pil. One three times a day after meals.

Another good combination is 5 grains of citrate of caffeine, 20 grains of citrate of potash, and half an ounce of infusion of digitalis. It is always best, when possible, to give mercury before commencing the administration of a diuretic, as it appears to start the diuresis.

In early dropsy, bandaging of the lower extremities is often very useful, and this may be combined with massage. When the œdema does not disappear in spite of the measures mentioned, the mechanical removal of fluid should be considered. The means which may be employed are Southey's tubes, acupuncture, and scarification, the first two being better than the third. Whatever method be employed, strict aseptic precautions should be exercised. With regard to acupuncture, the dependent limbs and scrotum may be punctured by means of a sharp broad surgical needle (which is grasped by the finger and thumb from a quarter to half-an-inch from the point), and then wrapped in sterilised dressings to drain. If ascites or pleural effusion do not yield to other treatment, and cause embarrassment, the fluid should be withdrawn. With regard to the former, Southey's tubes or tapping may be employed; in the latter case, tapping is necessary.

COUGH.—The cause of the cough, which may be œdema of the lungs or hydro-thorax, should after investigation be suitably treated, and relief may be sometimes obtained by the administration of hot drinks, and the application of a large mustard and linseed poultice over the bases of the lungs. A linctus may be necessary.

HÆMORTYSIS.—Hæmoptysis is only rarely a serious accompaniment of heart disease, and may be combated by rest, together with the administration of calomel and saline purgatives. It may be necessary, however, to supplement these measures by the administration of morphine. Venesection or leeching is advocated by some writers in severe cases.

PULMONARY ŒDEMA.—Dry-cupping is sometimes beneficial in chronic pulmonary Œdema. The treatment of acute pulmonary Œdema is dealt with on p. 1064.

VOMITING.—Milk is, in the majority of cases, the best food, to which sodium citrate (15 grains to each 10 ounces) may be added. If milk be not tolerated, peptonised milk, whey, albumin water, milk gruel, koumiss, or strong meat essences may be sipped, the patient not being allowed any solid food. If one of the digitalis series of drugs be indicated for the general condition, and the patient be peculiarly intolerant of digitalis, strophanthus, squills, or one of the other substitutes may be tried. A brisk purge should be administered, and bismuth with hydrocyanic acid may be given. Counter-irritation over the epigastrium is occasionally of some help for the relief of vomiting. If, in spite of these measures, the vomiting still continue, all food, and even water and drugs, by the mouth should be stopped, and resort be had to rectal feeding. The great advantage in these cases of rectal feeding with milk pancreatised for at least 24 hours is not sufficiently appreciated.

PALPITATION.—The possible causes of palpitation should be carefully considered and adequately treated; among these, gastric and intestinal dyspepsia and toxic agents are especially to be noted. Rest is indicated in some cases, and a belladonna plaster applied to the præcordium is sometimes efficacious. If these measures fail, the bromides may be given a trial.

CARDIAC PAIN.—As in the case of palpitation, we should first of all consider the possible causes of cardialgia. Rest is especially indicated when it is obviously due to overstrain or dilatation. Iodide of potassium is sometimes efficacious, even when the pain is not associated with supernormal blood-pressure. A belladonna plaster applied to the præcordium is sometimes beneficial; while sometimes—especially in acute inflammatory conditions—counter-irritation in the form of a mustard leaf, blister, leeching, hot applications, or the use of an ice-bag or Leiter's coil, affords relief. If these measures fail, the bromides may be administered, and in the event of their not being successful it may be necessary to resort to opiates, nepenthe or tincture of opium being tried at first, while if the pain still continue morphine may become necessary.

TACHYCARDIA.—We should first of all review the ætiology of the condition, with a view to treatment. The treatment of tachycardia in organic heart disease has, for the most part, been dealt with in the general consideration of cardiac failure. It has been pointed out that, as a rule, the best remedy for cases unaccompanied by auricular fibrillation is prolonged rest, and for cases accompanied by auricular fibrillation digitalis or one of its allies. The question of toxic agents, such as tea and tobacco, febrile states, neurasthenia, and hysteria, as possible causes of tachycardia, should always be considered. The bromides, with belladonna, pushed to the limits of tolerance, appear to be of value in some cases of tachycardia.

Having now discussed the various therapeutic measures which may be applicable to any form of cardiac disorder, these need not be again referred to when we come to consider the treatment of the individual cardiac affections: in this way much repetition will be saved.

FUNCTIONAL DISORDERS OF THE HEART

By functional disorders of the heart are meant those which occur independently of any structural change, whether of the valves, the myocardium, or the arteries; they are merely disorders of function, no organic lesion being necessarily present. It should be remembered, however, that any variety of functional disorder may be found in association with, though independent of, organic disease, especially if cardiac failure be present; and, further, that a persistent functional disorder may terminate in organic disease, although not necessarily so. Some writers deny the existence of functional disorder of the heart altogether, being of opinion that in every case some structural change not only exists but accounts for the malady. Such a view is, in my opinion, untenable. I wish to emphasise at this stage, however, that in a not inconsiderable percentage of cases a diagnosis of functional disorder is erroneously made owing to the fact that the existence of organic disease has not been detected, because the examination has been conducted either with insufficient care or has been incomplete. As far as my experience goes, this applies especially to four classes of cases, namely: (1) Those with enlargement of the heart due to chronic myocardial disease, especially chronic interstitial myocarditis, unaccompanied by valvular disease; (2) cases of arterial disease; (3) less frequently, cases of mitral stenosis; and (4) still less frequently, cases of chronic adhesive pericarditis.

Taking chronic myocardial disease first, I have been surprised at the comparative frequency with which these cases are overlooked, due, in my opinion, to a lack of appreciation of the great importance of determining accurately the size of the heart, especially in cases in which the apex-beat is either faint or absent; and also to a lack of knowledge of the size of the normal heart in persons of different size and weight and age. A combination of the existence of subjective symptoms during or after physical exertion, enlargement of the heart, and an absence of physical signs indicative of a valvular lesion is of the utmost importance in the diagnosis of chronic myocardial disease. With regard to arterial disease, the importance of examining the walls of other arteries than the radial should be remembered; for example, the brachial and temporal, especially the former. How frequently is arterial disease excluded as the result merely of an examination of a short length of the radial artery alone! With regard to mitral stenosis, the lesion is often unrecognised, because the locality of the characteristic murmur is frequently very limited, or because of an omission to examine the patient both in the standing position and on lying down, and before and after exercise, or because in some cases there is from time to time a complete absence of a thrill and murmur. I would emphasise the importance of a searching examination for organic disease of the valves, the myocardium, and the arteries in all cases which on first consideration might be regarded as being merely functional.

Among functional disorders may be included palpitation, tachycardia, bradycardia, irregular action of the heart, paroxysmal tachycardia, "irritable heart,"—including "soldier's heart," primary cardiac overstrain, and cardiac pain—including pseudo-angina. No doubt some of these disorders may be either functional, or due to organic disease. With regard to irregular action

of the heart, it depends upon the type. It is almost universally agreed that sinus irregularity is always functional. Extra-systoles may or may not be due to some structural change in the myocardium. It is true that cases of auriculo-ventricular block have been recorded in which there was an absence of any demonstrable lesion of the junctional tissue; but in some of these the vagus was found to be affected. In the vast majority of cases, auricular fibrillation and auricular flutter are indicative of some myocardial change. The same applies almost equally to cases of paroxysmal tachycardia. With regard to what is called "soldier's heart," as the result of a detailed examination of a large number of cases, I am of opinion that the affection is sometimes due to chronic interstitial myocarditis, frequently in association with arterial disease, which has not been diagnosed. I am equally certain, on the other hand, that primary cardiac overstrain may occur in persons with previously sound hearts, and even in those who are properly trained. A history of excessive physical exertion resulting in primary cardiac overstrain is sometimes not obtained because of insufficient care in taking the history of the case.

It is not my purpose to deal with the ætiology of functional disorders of the heart in general, but I would emphasise the importance of always remembering the possibility of toxic conditions affecting the heart. This may occur without producing structural changes. Such toxic conditions may be brought about by tea, coffee, tobacco, Graves' disease, pulmonary tuberculosis, acute infective disease, and focal sepsis—especially from the teeth, the tonsils, the accessory nasal sinuses, the stomach, colon, and the genito-urinary tract.

PALPITATION

By palpitation is meant the consciousness of the cardiac impact against the chest-wall, and with this there is frequently, but not always, an increase in rate. The term, as used here, does not include the sensations which may be present in extra-systoles, auricular fibrillation, auricular flutter, or paroxysmal tachycardia; it will further be restricted to those cases in which the consciousness of the cardiac impact occurs in attacks.

Ætiology.—While palpitation may occur in organic disease of the heart—valvular or myocardial—it should be remembered that it is probably more frequently and most characteristically met with apart from organic disease. It is more common in females than in males. The condition is often reflex in origin, as, for example, when the result of dyspepsia—particularly those forms of it which are attended with flatulent distension of the stomach or colon, and in uterine disorders. Among other causes are excessive indulgence in the use of tea, coffee, alcohol, or tobacco; conditions which tend to produce exhaustion or undue excitability of the nervous system, among which may be enumerated puberty, the period of menstruation, the menopause, neurasthenia, hysteria, mental excitement or overstrain, exhausting illnesses, and following the acute fevers. The immediate cause of an attack is frequently emotion or excessive physical exertion.

Symptoms.—The attack may last from a few seconds to a few hours. It is usually, though not always, gradual in onset, and it passes off gradually. The subjective symptoms vary from a sensation of a gentle impact in the slightest attacks, to the consciousness of a violent one against the chest-wall,

accompanied by a sense of great distress, and even associated with actual pain in the præcordium in the severer forms of the attack. In some instances there is a sense of faintness, and more rarely the fear of impending death. Complaint is sometimes made of flushing of the face, tinnitus aurium, a sensation of throbbing in the head, and giddiness. The pulse-rate is, as a rule, increased, though in some cases there is an absence of tachycardia; it is increased by physical exertion, which is not the case in paroxysmal tachycardia. The pulse may be of moderate or only small volume, and its character may resemble that of the *pulsus celer*. The large arteries, such as the carotid, may exhibit marked pulsation. The apex-beat is found to be in the normal position, and its area and force are generally much increased. On percussion, the area of cardiac impairment shows no increase in size, unless valvular or myocardial disease be present, while on auscultation, the cardiac sounds are found to be abnormally loud, clear, and ringing in character, and the second sound at the base much exaggerated. Excepting in cases of organic disease of the heart or anæmia, as a rule no murmur is audible, although occasionally an apical systolic murmur, soft in character, may be heard during the attack. In dyspeptic patients, complete or partial relief may coincide with the eructation of a large quantity of gas. A sense of exhaustion is usually complained of after the paroxysm has passed off.

Prognosis.—The prognosis is good, if no organic disease be present, although it may be difficult to eradicate the cause of the condition.

Treatment.—This has already been considered.

CARDIAC PAIN

As has already been pointed out, pain in the præcordium may not only occur in organic disease of the heart, but is also frequently met with apart from organic disease, especially in females. It is often reflex in origin, as, for example, when the result of dyspepsia—particularly those forms of it which are attended with flatulent distension of the stomach or colon, and in uterine disorders. Among other causes are primary cardiac overstrain; toxic conditions, such as occur in influenza and diphtheria, and as the result of excessive indulgence in the use of tea, coffee, tobacco, or alcohol; neurasthenia, hysteria, emotional states, and sexual excess.

Treatment.—This has been discussed previously.

TACHYCARDIA

Definition.—By the term tachycardia is meant frequent action of the heart. It will here be used in a restricted sense, not including the frequent action which is often present during attacks of palpitation—which has already been described, or that due to an abnormal rhythm—which will be discussed later on.

Ætiology.—The condition may be physiological. In some perfectly healthy individuals the normal cardiac rate is always frequent, and has been known, although very rarely, to average 120 a minute. It is difficult, therefore, to decide when an increase of the cardiac rate in an individual is pathological; in this connection, a record of the past history is of value.

The pathological form of tachycardia may be the result of the excessive use of alcohol, tobacco, tea, and coffee, focal sepsis, pulmonary tuberculosis, Graves' disease, most forms of cardiac disease, primary cardiac overstrain, states of exhaustion, acute and subacute inflammatory conditions, pyrexia, tumour or clot in the medulla oblongata, the pressure of a tumour upon the pneumo-gastric nerves, involvement of the vagi in bulbar paralysis or in multiple neuritis, some forms of spinal disease, neurasthenia and emotional states, reflex irritation from uterine or ovarian disease, the use of certain drugs, such as atropine, and as a sequel of influenza.

In the pathological form of the condition, the increase in the cardiac rate may only be induced by change of posture or other forms of physical exertion ; or it may be persistently above the normal.

In contra-distinction to tachycardia due to an abnormal rhythm, the only abnormality in polygraphic and electro-cardiographic curves is the acceleration of the cardiac rate.

Treatment.—This has already been described.

BRADYCARDIA

Definition.—By the term bradycardia is meant infrequent action of the heart. It must be distinguished from infrequency of the *pulse rate at the wrist*, since the latter also includes ventricular extra-systole which is so feeble that the wave fails to reach the wrist. The term bradycardia may be used in two different senses : it may be restricted to infrequent action of the heart as a whole, the auricular rate being diminished *pari passu* with that of the ventricle ; or it may be employed to include also cases of infrequency of the ventricular rate alone, the auricular rate being unaffected, which group includes partial and complete auriculo-ventricular block, some cases of auricular fibrillation, and some cases of auricular flutter. The term will be employed here in the former sense.

Ætiology.—Bradycardia may be physiological, especially in males. In some perfectly healthy individuals the normal pulse is always infrequent, a pulse-rate of 50 not being very uncommon, and, indeed, cases have been recorded of a pulse-rate of 40 in a healthy individual. Further, it must be noted that as age advances the rate of the heart normally becomes less frequent.

The pathological form of the condition, which is found more frequently in males, may be the result of some form of cardiac disease—especially aortic stenosis and fatty degeneration of the myocardium, coronary disease, and primary cardiac overstrain ; states of collapse or exhaustion, and during the convalescence of acute infective diseases, especially influenza, diphtheria, pneumonia, typhoid and typhus ; toxic conditions, such as jaundice, diabetes, uræmia, influenza and diphtheria, and the use of certain drugs, such as digitalis, muscarine, opium, coffee, and tobacco ; hypothyroidism ; affections of the nervous system, such as meningitis, cerebral tumour, or apoplexy, diseases of the medulla, diseases or injuries of the cervical part of the spinal cord, neurasthenia, hysteria, severe pain, epilepsy, melancholia, and general paralysis of the insane ; diseases of the digestive system, such as chronic dyspepsia, gastric dilatation, ulcer, and cancer ; in the puerperal state ; and occasionally in diseases of the urinary or respiratory system, and in sunstroke.

Sino-auricular block is a very rare cause of bradycardia.

IRREGULAR ACTION OF THE HEART

The subject of irregular action of the heart is of very great practical importance. Formerly it was notoriously a source of perplexity and difficulty to the clinician. A patient, or, it may be, a candidate for life assurance or for an appointment, was examined, and in the course of physical examination irregularity of the pulse may have been observed—with or without the usual physical signs of organic disease of the heart. What significance was the practitioner to attach to the irregularity of the pulse in itself? It was known that this might, on the one hand, signify definite and even serious impairment or disease of the heart, or, on the other hand, that it might be of no practical importance. It was not possible, however, to determine the significance of the irregularity in any given case, because there were no means of differentiating the types of irregularity, or what any particular type signified. The employment of the clinical polygraph and of the electro-cardiograph has changed all this, and the problem has been solved; for we are now able to classify almost every case of irregular action of the heart into types, and we know what each type signifies. I would emphasise the fact that the work of elucidation having been accomplished by means of the clinical polygraph and the electro-cardiograph, it is not now necessary to employ either of these instruments in the vast majority of cases, the use of a sphygmograph being sufficient, and in a large proportion merely palpation and auscultation. This is of great practical importance to the general practitioner. For example, by means of the aid of palpation and auscultation alone it is almost always possible to determine whether intermission of the pulse occurring during the course of an acute infective disease, such as acute rheumatism, diphtheria, and pneumonia, is due to an extra-systole failing to reach the wrist, or to partial auriculo-ventricular block—a point of great prognostic importance.

All cases of cardiac irregularity, apart from comparatively rare exceptions, fall into one of six groups: (1) What is called sinus irregularity; (2) irregularity due to premature contraction or extra-systole; (3) irregularity due to heart-block; (4) irregularity due to pulsus alternans; (5) irregularity due to auricular fibrillation; and (6) irregularity due to auricular flutter.

The pulse may be irregular in time, or volume, or both. It may be advisable to describe here what is meant by the terms "intermittent" pulse or a "dropped beat," "pulsus bigeminus" or "coupling of the beats," and "pulsus trigeminus."

Intermission of the pulse is a form of irregularity which is not uncommon. By it is meant a condition in which the normal rhythm of the pulse is interrupted, either occasionally or more frequently, either at regular or irregular intervals, by an abnormally long pause during which no wave is felt at the wrist, a beat being missed. *It is of great importance to understand how intermission of the pulse is caused, especially from the point of view of prognosis.* By far the commonest cause is a premature contraction of the ventricle ("extra-systole") which is so feeble that the wave fails to reach the wrist (Fig. 32); the next most common cause is partial heart-block (Fig. 33), while the condition is occasionally due to sinus irregularity, and very rarely to sino-auricular block. The differential diagnosis between extra-systole

and partial heart-block is fully discussed under extra-systole. The differential diagnosis also between occasional dropped beats due on the one hand to sinus irregularity and on the other to partial heart-block is discussed under heart-block.

By *pulsus bigeminus* or *coupling of the beats* is meant a condition in which the pulse-beats occur regularly in pairs, for long or short periods. The paired

FIG. 32.—Simultaneous tracings of the apex-beat and of the radial pulse, showing intermission of the pulse, due to a ventricular extra-systole failing to send a wave to the wrist.

beats may occur at regular intervals, or at irregular intervals, and some writers restrict the term *pulsus bigeminus* to the former condition, and the term *coupling of the beats* to the latter. When the paired beats fall at regular intervals, the commonest cause is the occurrence of extra-systoles, usually ventricular, in cases in which the fundamental or sinus rhythm is otherwise maintained; either a single extra-systole with its succeeding compensatory

FIG. 33.—Simultaneous tracings of the apex-beat and of the radial artery, showing intermission of the pulse, due to partial heart-block, the ventricle failing to respond to the stimulus of the auricle at A'.

pause occurring regularly after each normal beat (Fig. 34), or such occurring after every two normal beats, the premature contraction in the latter case, however, being so feeble that no wave reaches the wrist. The next most common cause is partial heart-block, when the ventricle fails to respond to every third beat of the auricle (Fig. 35). A rare cause is sino-auricular block, in which the auricle fails to respond to every third impulse generated at the

sinus. When the paired beats fall at irregular intervals, the cause is the occurrence of a ventricular extra-systole occurring regularly after each normal ventricular contraction in cases of auricular fibrillation; this may occur independently of the action of digitalis, although it is usually due to it (Fig. 53).

By *pulsus trigeminus* is meant a condition in which the pulse-beats are

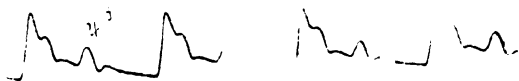

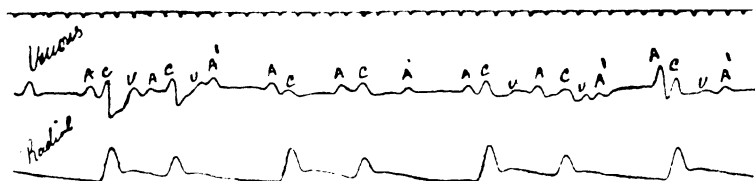

FIG. 34. Pulsus bigeminus, due to a single extra-systole with its succeeding compensatory pause occurring regularly after each normal beat.

grouped in threes. The causes of this condition are: (1) the occurrence of extra-systoles—either a single extra-systole with its succeeding compensatory pause occurring regularly after every two normal beats, or such occurring after every three normal beats and failing to send a wave to the wrist; (2) partial heart-block, when the ventricle fails to respond to every fourth beat of the auricle; and, rarely, (3) sino-auricular block, in which the auricle fails

Pulsus bigeminus, due to partial heart block, the ventricle failing to respond to the stimulus from the auricle at A'.

to respond to every fourth impulse generated at the sinus. As *pulsus bigeminus* and *pulsus trigeminus* are met with in conditions other than extra-systole, they are not pathognomonic of the latter condition. The distinguishing features between *pulsus bigeminus* or *pulsus trigeminus* due on the one hand to extra-systole and to partial heart-block on the other hand may be established, with a view to differential diagnosis, in the same way as in the case of an intermittent pulse.

“IRRITABLE HEART”

This term may be used in two ways, namely, (1) the “irritable heart of soldiers,” and (2) a condition which is sometimes met with during adolescence. The first of these will be discussed later. The second condition is met with more especially in badly developed subjects, and is often associated with an unstable nervous system, auto-intoxication, and dyspepsia. It may or may not have been brought on by excessive or injudicious physical exertion. The symptoms and diagnosis do not differ from those which obtain in the “irritable heart of soldiers.” The prognosis is good, the patient improving as physical and mental development proceeds. With regard to treatment, a searching enquiry should be made for toxic conditions. The patient should

rest before and after meals, all food should be thoroughly masticated, the amount of fluid to be taken with food should be restricted, and digestive disorders treated if present. Breathing exercises, graduated exercises, and all other agencies which tend to physical and mental development, should be tried. Otherwise, the treatment is the same as that of the "irritable heart of soldiers."

SINUS IRREGULARITY

It has already been pointed out that excitability of the heart is most marked in the remains of the sinus venosus at the orifices of the great veins, and that the rhythm of the sinus governs the rhythm of the remaining segments of the heart. Further, it has been shown that the heart possesses

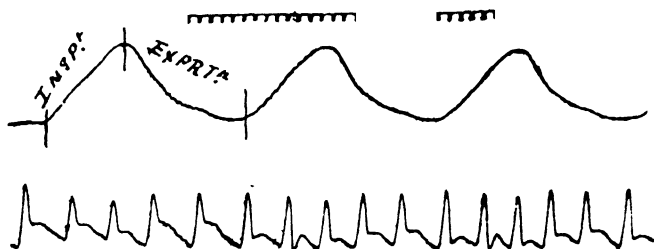

FIG. 36.—Simultaneous tracings of the respiration and the radial pulse, from a healthy boy aged 14, showing sinus irregularity.

the power of contracting and dilating independently of any extrinsic nervous influence; but, at the same time, the activity of the various functions of the muscle-fibres is under nervous control. While normally the rhythm of the sinus is a fairly regular one, in by no means a small percentage of in-

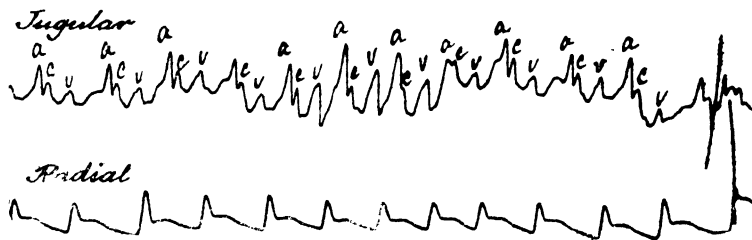

FIG. 37.—Simultaneous tracings of the jugular and radial pulses, from a healthy boy aged 7, showing sinus irregularity.

dividuals the rhythm is not regular. In all probability this irregularity is of vagus origin, due to an unusual susceptibility of the vagus centre to impulses from distant parts, and these impulses being transmitted reflexly to the heart. The chief characteristic of sinus irregularity is the variation in the length of the diastolic period of the cardiac cycle, the systolic period

remaining constant. The irregularity, which may be slight or marked, diminishes, and may even disappear with an increase, while it is apt to increase or return with a diminution, of the cardiac rate.

Ætiology.—Sinus irregularity is much more frequently met with in the young, being indeed fairly common in young adults; but it may occur at all ages. There is a greater tendency to sinus irregularity in children after a febrile illness, and it may be first noticed then. *There is usually a definite relationship to respiration.* The irregularity is most marked during slow respiration, and may indeed only be noted on deep breathing. The rate of the heart usually gradually quickens during full inspiration, and gradually lessens during full expiration; but while generally the rate of the pulse waxes and wanes with respiratory movements, in some cases there is an abrupt slowing of one or two beats with expiration. Sinus irregularity may occur during the administration of digitalis, and even the act of swallowing may produce it—the heart-rate during the act being quickened for a few beats, followed by a reduction in the rate.

Symptoms.—Usually there are no subjective symptoms of the condition: but very rarely the abnormal pause between any two beats of the heart is so long that symptoms of cerebral anæmia, such as giddiness or syncope, occur. On auscultation, the interval between the first and second sounds is found to be constant, while the varying length of the diastolic interval can be detected. If a tracing of the radial artery be taken, the intervals between the beats will be found to vary, but the actual variations are not numerous, while the pulse-beats are of equal or nearly equal size (Figs. 36 and 37). A polygraphic tracing (Fig. 37) and an electro-cardiogram (Figs. 92 to 94) show that a ventricular contraction follows each auricular contraction in the usual way, and that the whole heart is affected by the irregularity.

Diagnosis.—A diagnosis may be made by auscultation, or by a study of a **sphygmogram**, or of a **polygraphic** or **electro-cardiographic** record. When irregularity of the cardiac action is found to be definitely related to respiration, it is in all probability of the sinus type.

Prognosis.—There is no reason to suppose that sinus irregularity is either indicative of an impaired heart, or that it adds to the gravity of any diseased cardiac condition which may be present. The condition itself, therefore, may be entirely disregarded, and the prognosis based upon any other abnormal signs which may exist.

Treatment.—No treatment of this condition is required.

THE EXTRA-SYSTOLE

By extra-systole is meant the premature contraction of the auricle (auricular extra-systole), or of the ventricle (ventricular extra-systole), or of both chambers together (auriculo-ventricular or nodal extra-systole), while the fundamental or sinus rhythm is otherwise maintained in most cases. Usually the extra-systole is followed by a long pause (compensatory pause). Rarely the premature contraction occurs between two normal beats (interpolated extra-systole). Two or more premature contractions of the auricle or ventricle may follow one another (multiple extra-systoles).

It has been shown that, while normally the stimulus for contraction arises in the sinus part of the auricle, if any other portion of the remains of the primitive cardiac tube becomes more excitable the stimulus for contraction arises at that point, and, for this reason, the different parts of the heart are capable of independent contraction. In abnormal conditions the auricle, some part of the auriculo-ventricular junctional tissues—either the auriculo-ventricular node, or the auriculo-ventricular bundle above its division into two branches—or the ventricle below the division of the auriculo-ventricular bundle into two branches, may become temporarily more excitable than the sinus, in which case the stimulus for contraction starts at that particular point, the result being that a contraction takes place before the anticipated time. If the stimulus start in the auricle, there is a premature contraction of that chamber; if in the auriculo-ventricular junctional tissues there is a premature contraction of both auricle and ventricle together; while if it start in the ventricle there is a premature contraction of the ventricle. In each case the sinus rhythm remains unaltered. It will thus be seen that an extra-systole indicates that some portion of the heart below the sinus is temporarily more excitable than the sinus.

Extra-systoles may appear at long, or at frequent irregular intervals, or regularly after each beat, or after every second or third, or more normal beats, or in paroxysms, the last being an infrequent cause of paroxysmal tachycardia. Of the three varieties the auricular and ventricular are the most important from the clinical point of view; the ventricular is the most common; all of them, however, may occur in the same subject.

THE VENTRICULAR VARIETY OF EXTRA-SYSTOLE.—We may take this variety for the purpose of illustration. While the chambers of the heart are contracting in the normal fashion, a premature contraction of the ventricle takes place, this arising independently of a stimulus from the auricle, which maintains its usual rhythm and contracts as the result of the normal stimulus from the sinus. The exact time at which the premature contraction of the ventricle takes place is either immediately before the systole of the auricle (Fig. 38), or—as is usually the case—synchronously with it, or after it, but prior to that point of time at which it would have occurred if this had been in response to a stimulus received from the auricle in the normal way. In most cases the succeeding impulse from the auricle fails to cause a contraction of the ventricle; for this reason the pause which follows the premature contraction is abnormally long, being called the *compensatory pause*. When this prolonged diastole and the preceding shortened diastole together equal in time two normal cardiac cycles, the compensatory pause is said to be *complete*. Since during the prolonged pause the ventricle has had an unusually long period in which to fill and recuperate, the pulse-beat immediately following a compensatory pause has often a greater amplitude than on other occasions. Sometimes, more especially when the cardiac rate is slow, a ventricular extra-systole occurs so early in the cardiac cycle that the ventricle does contract in response to the normal stimulus which is transmitted from the auricle immediately after the premature contraction; in this way a premature contraction is interpolated between two normal beats. This form of the extra-systole is called "*interpolated*" (Fig. 39).

On auscultation, in the vast majority of cases, two heart-sounds are

synchronous with each extra-systole, these forming with those of the preceding normal contraction a group of four sounds. Sometimes, however, the extra-systole occurs early in diastole, and before the cardiac muscle has had sufficient time to recover fully from the preceding systole, in which event the premature contraction is so feeble as to fail to open the aortic valves, and only the first sound is heard; in this way a group of three sounds becomes

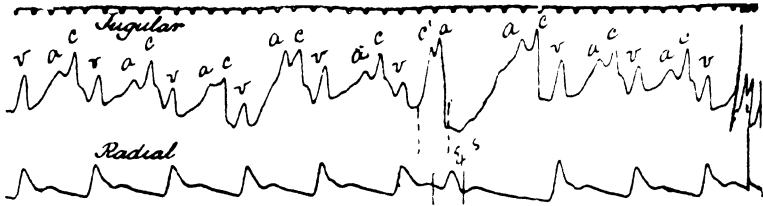

FIG. 38. Simultaneous tracings of the jugular and radial pulses, showing a ventricular extra-systole at *Ex.s.* The usual rhythm of the auricle is maintained. The extra-systole in the jugular tracing is represented by the wave *c'*, immediately before the systole of the auricle. The compensatory pause is complete.

audible. Very rarely the premature contraction is so feeble as not to produce any cardiac sounds whatever.

The amplitude of the pulse-wave of an extra-systole is not so great as that of a contraction occurring at a normal interval, because the heart muscle has not had time to recover from its previous effort. The earlier an extra-systole occurs in the diastole, the more feeble it is; it may be so feeble that no wave is felt at the wrist, so that there is simply an abnormally long pause,

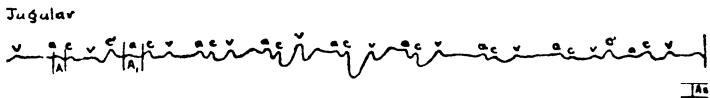

FIG. 39. - Simultaneous tracings of the jugular and radial pulses, showing an interpolated ventricular extra-systole (*c'* and *r'*), represented in the diagram by the downstroke \downarrow . The downstrokes in the space *As* represent the auricular waves (*a*) in the jugular, and the downstrokes in the space *Vs* represent the carotid waves *c*, and the slanting lines connecting them represent the *a-c* interval (Mackenzie).

resulting in what is called a "dropped beat" or an "intermittent" pulse (Fig. 32); as has been already noted, an extra-systole which fails to reach the wrist is, indeed, the most usual cause of an intermittent pulse. If a single extra-systole with its succeeding compensatory pause occurs regularly after each normal beat, then the beats at the cardiac apex occur in pairs, as also do the pulse-beats, the condition being called *pulsus bigeminus* (Fig. 34). Similarly, if a single extra-systole with its succeeding compensatory pause occurs after every two normal beats, then the apex-beat occurs in

threes, as also do the pulse-beats, the condition being known as *pulsus trigeminus*; but if the premature contraction is so feeble that no wave reaches the wrist, the pulse-beats are paired.

If a polygraphic record of a case of ventricular extra-systole (Fig. 38) be analysed, it will be found that, as the normal rhythm proceeds as usual, the *a* wave appears at regular intervals; each *a* wave is followed by a *c* wave, except when an extra-systole occurs, when the *c* wave either precedes the *a* wave, or—as is more commonly the case—occurs synchronously with it, in which case the amplitude of the wave is correspondingly increased.

AURICULAR VARIETY OF EXTRA-SYSTOLE.—In this variety there is a premature contraction of the auricle, the stimulus arising in the wall of the auricle prior to the normal stimulus from the sinus. The premature contraction of the auricle is usually followed by a premature contraction of the ventricle, following the usual transmission of the stimulus from the auricle along the auriculo-ventricular bundle. Not infrequently, in the case of extra-systole the stimulus from auricle to ventricle travels slowly, so that the *a-c* interval is lengthened (Fig. 40), and the prematurity of the ventricular

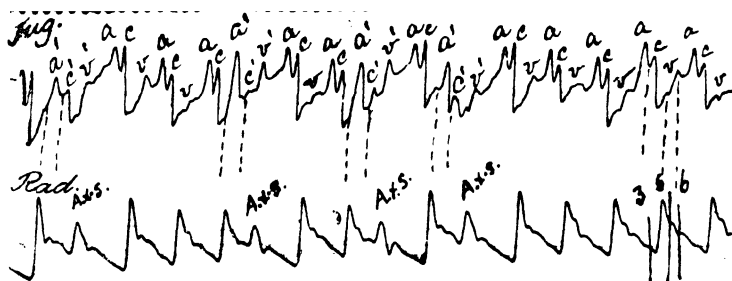

FIG. 40.—Simultaneous tracings of the jugular and radial pulses, showing auricular extra-systoles, marked A.S. in the sphygmogram, and *a'c'* in the jugular tracing. The *a-c* interval of the premature beat is more than $\frac{1}{4}$ th second; with the rhythmic beats it is normal.

systole is consequently not so great as that of the auricle; in this way the compensatory pause is shortened. In some instances the contraction which immediately follows the extra-systole takes place rather earlier than the normal interval, this being probably due to the unusual length of the rest period; in this way there is further encroachment upon the compensatory pause. This is less marked in the case of the second contraction, and it disappears within a few cycles. Sometimes there are variations in the rate of transmission of these auricular premature contractions to the ventricle.

Occasionally the stimulus from the auricle does not reach the ventricle at all, and no premature contraction of this chamber takes place, in which event the premature contraction of the auricle is not followed by a premature contraction of the ventricle, the condition being known as "blocked auricular extra-systoles." In these cases a long pause is to be noted in the sphygmogram. As in the case of the ventricular variety, an auricular extra-systole is followed by a lengthened pause; but, with rare exceptions,

this compensatory pause is not complete. In some cases, however, the compensatory pause is complete.

If a polygraphic record of a case of auricular extra-systole (Fig. 40) be analysed, it will be found that each *c* wave is preceded by an *a* wave, while there is a premature *a* wave and a premature *c* wave, sometimes with an increased *a-c* interval, and an alteration of the relative position of the beats following the extra-systole.

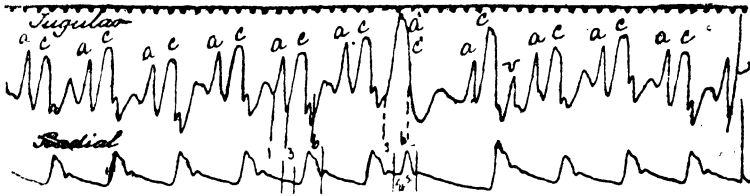

FIG. 41.—Simultaneous tracings of the jugular and radial pulses, showing auriculo-ventricular extra-systoles, marked *ex.s.* in the sphygmogram, and *a' c'* in the jugular tracing. The premature ventricular contraction practically coincides with that of the auricle.

AURICULO-VENTRICULAR OR NODAL VARIETY OF EXTRA-SYSTOLE.—In this variety the stimulus for premature contraction originates in some part of the auriculo-ventricular junctional tissues, travelling upwards into the auricle and downwards into the ventricle, and giving rise to a premature and simultaneous contraction of both auricle and ventricle. The premature ventricular contraction more or less coincides with that of the auricle, but this is by no means absolute; the contraction of both chambers may be absolutely synchronous (Fig. 41), or the ventricular systole may begin after, or before (Fig. 42) that of the auricle. When the auricular contraction occurs

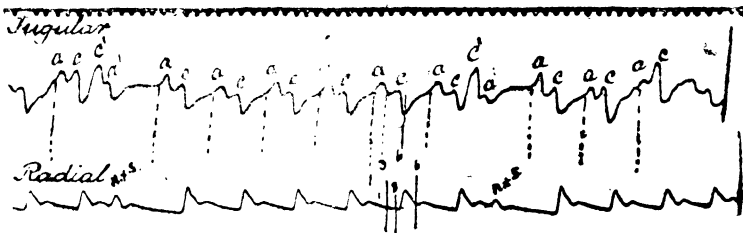

FIG. 42.—Simultaneous tracings of the jugular and radial pulses, showing two auriculo-ventricular extra-systoles (*n.s.s.*). Both auricle and ventricle contract prematurely, but the contraction of the ventricle precedes that of the auricle.

before that of the ventricle, the period of time between the contraction of the upper and lower chambers is shortened. The compensatory pause may or may not be complete.

In a tracing of the jugular vein from a case of auriculo-ventricular extra-systole (Figs. 41 and 42) there is prematurity of the *a* wave, and also of the *c* wave; when the premature contraction of the chambers is synchronous both waves are combined, in which case the amplitude of the wave is in-

creased; when the auricular contraction occurs before that of the ventricle, the *a* wave precedes the *c* wave, but the *a-c* interval is diminished to about 0.10 sec.

In the ventricular and auriculo-ventricular varieties of extra-systoles, in contrast with the "double" venous pulsation in the jugular vein which may be visible in the case of the auricular variety, there is usually an unduly large "single" pulsation coincident with the premature contraction; this is due to the contraction of the upper and lower chambers of the heart occurring synchronously, the result being that the auricle, instead of discharging its contents into the ventricle, does so into the *venæ cavæ*.

Paroxysms of extra-systoles of auricular origin may occur, and may give rise to short paroxysms of tachycardia, with a regular pulse, or to irregularity of the pulse rhythm when the response of the ventricle to auricular contraction is at irregular intervals. Paroxysms of extra-systoles of ventricular origin may also occur (Fig. 112); as a rule these only persist for a few cardiac cycles.

Ætiology and Pathology.—Extra-systoles may be met with at any age, but they are much more frequent in the middle-aged and elderly than in the young. They are rare during the first decade of life. Extra-systoles are of more common occurrence in men than in women, and are also more usual in the subjects of organic heart disease than in those who are not, and are more frequent in myocardial degeneration than in valvular disease. But there is a large group of cases in which extra-systoles are present without any other manifest cardiac abnormality. They are to be found, for example, in persons with a history of rheumatic infection, the victims of tobacco poisoning, in digestive disturbances, supernormal blood-pressure, neurasthenia, and as a result of the administration of certain poisons, especially digitalis and aconitine; while in a considerable proportion of cases there is no ascertainable cause.

Extra-systoles indicate that at the time of the premature contraction some portion of the myocardium below the sinus is more excitable than the sinus. This may or may not be due to some structural change in the myocardium; it may, for example, be caused by poisoning of the heart wall without structural damage.

Subjective Symptoms.—An individual in whom extra-systoles occur may be quite unconscious of their presence. On the other hand, he may experience certain sensations, which may cause worry and anxiety, particularly if he have retired to bed, and for this reason it is most important that the nature of the complaint should be recognised. The patient may experience a sensation of fluttering in the chest when a premature beat occurs; or he may be conscious of the long pause and complain that the "heart stops"; or the contraction of the heart following the pause may be accompanied by the consciousness of a thud or shock in the region of the heart, sometimes followed by a feeling of exhaustion. The patient may complain of a sensation of a "catch in the breath," or of "gripping in the throat." Very rarely, during a prolonged pause, faintness, sweating and actual syncope may take place, and the anxiety of the patient may be great.

Diagnosis.—Extra-systoles may be recognised with certainty by means of the clinical polygraph or the electro-cardiograph. *But it is important for the practitioner to recognise that in the great majority of cases a correct diagnosis can be made simply by palpation and auscultation.* The normal rhythm of

the heart is disturbed by the occurrence of a premature beat in the radial pulse and at the cardiac apex, followed by an abnormally long pause. The auscultatory signs have already been noted; they are of great diagnostic value. When, on palpation of the radial artery, an apparently otherwise regular pulse is sometimes interrupted by an unusually long pause, it should suggest either an extra-systole which is so feeble that no wave is felt at the wrist, or partial heart-block. *When extra-systole is responsible for this unusually long pause a premature beat can be detected at the cardiac apex, and on auscultation one or two heart sounds will, in the great majority of cases, be audible during the early part of the pause, because the ventricle has contracted; whereas in the case of partial heart-block, there will be absence of an apex-thrust and of heart-sounds during the pause, because the ventricle has failed to contract.* Further, in these cases of extra-systole, a wave is usually present in a sphygmographic tracing, and a premature contraction is always visible in a tracing of the apex-beat. These three features are almost invariably sufficient to distinguish between an intermittent pulse due to an extra-systole which fails to reach the wrist and an intermittent pulse due to partial heart-block. A polygraphic tracing or an electro-cardiogram will place the matter beyond all possibility of doubt. It may here be noted that it is necessary to exclude sinus irregularity, and also sino-auricular block, in cases of an unusually long pause in the radial pulse. The differential diagnosis between pulsus bigeminus, pulsus trigeminus, and infrequency, including halving, of the pulse rate, due on the one hand to extra-systoles, and on the other to partial heart-block, can readily be made, as a rule, by means of palpation and auscultation.

It is sometimes very difficult, if not impossible, by palpation and auscultation alone, to diagnose extra-systoles, occurring frequently and at irregular intervals, especially if of auricular origin, from auricular fibrillation; but in such cases a sphygmographic tracing is almost invariably sufficient. It is also necessary to exclude auricular flutter when the response of the ventricle to auricular contraction is at irregular intervals (page 813, and Fig. 110).

Prognosis.—The question of prognosis of extra-systoles is very important. Unfortunately the lay mind has come to attach an unnecessary significance to them. Furthermore, it is important that the medical practitioner should understand that extra-systoles constitute one of the most frequent causes of irregularity of the pulse, and that an extra-systole which fails to reach the wrist is the commonest cause of an "intermittent" pulse. *When extra-systoles are considered by themselves—that is, without reference to the conditions with which they may be associated—there is so far no evidence for supposing that they are either indicative of an impaired heart or that they add to the gravity of any existing morbid condition.* While it is true that extra-systoles may precede the occurrence of other forms of cardiac irregularity, such as the complete irregularity associated with auricular fibrillation, it should be borne in mind that these might have arisen independently. The prognosis, therefore, should be based entirely upon the causal or associated condition.

Treatment.—Our first duty is to reassure the patient; this may be done with absolute confidence. The ~~etiology~~ etiology of extra-systole should be reviewed, the general health should receive attention, and if cardiac failure be present it should be treated on the lines laid down elsewhere. I have never found digitalis or quinidine of any value for the irregularity itself. Bromides are

frequently of benefit for the associated symptoms, especially when there is irritability of the nervous system or insomnia.

HEART-BLOCK

SINO-AURICULAR BLOCK

Sino-auricular block is a rare condition. It is sometimes induced by full doses of the digitalis series of drugs. In this condition the stimulus for contraction arises at the normal site, but either there is a delay in the conduction of the stimulus to the auricle, or the stimulus does not always—either occasionally or more frequently—reach the ventricle, in other words, the auricle does not always respond to the stimulus from the sinus, in which event the auricle and the ventricle fail to contract, so that there is an abnormally long pause; as already stated, sino-auricular block is one of the causes of an “intermittent” pulse or “dropped” beats. The length of the abnormally long pause is generally rather less than the duration of two cardiac cycles. Cases have been published in which more than one stimulus in succession has failed to reach the auricle, and in these cases the Adams-Stokes syndrome may occur. A polygraphic tracing reveals the fact that the auricle and ventricle have not contracted—that is, there is an absence of the *a*, *c*, and *v* waves—during the abnormally long pause.

AURICULO-VENTRICULAR BLOCK

It has been noted that the stimulus for contraction is conveyed from fibre to fibre by means of a specialised function of the cardiac muscle-fibres called conductivity, and that the *a-c* interval in a polygraphic tracing is a measure of this function.

There are three degrees of depressed conductivity: (1) The stimulus from the auricle to the ventricle may be merely delayed—that is, there is merely a prolongation of the interval which separates the commencement of contraction of the auricle and that of the ventricle, each stimulus of the auricle reaching the ventricle, which duly responds. (2) The stimulus does not always reach the ventricle—in other words, the ventricle does not always respond to the stimulus from the auricle. The first two degrees are called “partial heart-block.” And (3) no impulses reach the ventricle from the auricle, so that the auricles and ventricles beat independently of each other; the former in response to stimuli received from the sinus, and at an approximate rate of 72 per minute; and the latter as the result of stimuli arising in the auriculo-ventricular junctional tissues between the site of the lesion and the division of the auriculo-ventricular bundle into two branches, at about 30 per minute, because this is the normal ventricular rate; this is called “complete heart-block,” “disassociation of the auriculo-ventricular rhythm,” “idio-ventricular rhythm,” or the “paroxysmal form of bradycardia.” Rarely complete heart-block is associated with auricular fibrillation or auricular flutter.

FIRST DEGREE OF DEPRESSED CONDUCTIVITY.—This grade of heart-block

may give rise to irregularity of the pulse, on account of variations in the length of the *a-c* interval. Some writers believe that contraction of the auricle produces a faint muffled sound, and that consequently when there is a slight delay between the auricular and ventricular contractions there may be a reduplication of the first sound, while if the delay be considerable, so that the contraction of the auricles falls in early diastole, there may be a

FIG. 43.—Simultaneous tracings of the jugular and radial pulses, from a case of myocardial degeneration. The *a-c* interval is more than $\frac{1}{3}$ th second.

reduplication of the second sound. It is also believed by some that in cases of mitral stenosis unaccompanied by auricular fibrillation a slight interval between the auriculo-systolic thrill and apex-beat, as well as between the auriculo-systolic murmur and first sound, is to be noted. In a polygraphic tracing, there is merely an increase in the *a-c* interval, it exceeding $\frac{1}{2}$ th of a second (Fig. 43).

SECOND DEGREE OF DEPRESSED CONDUCTIVITY.—In this condition what

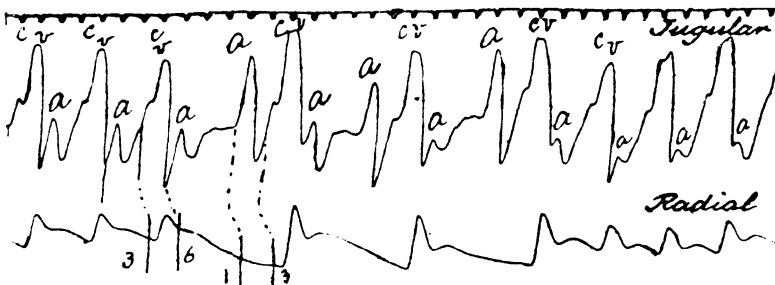

FIG. 44.—Simultaneous tracings of the jugular and radial pulses, from a case of aortic and mitral disease, showing partial heart-block. There are three blocked auricular impulses. The *a-c* interval is $1\frac{1}{2}$ th second.

are called "dropped beats" occur (Fig. 44). These may be only occasional, or they may be more frequent. Or each third or fourth impulse may fail to reach the ventricle; in the former case the ventricular beats are grouped in twos (Fig. 35), and in the latter they are grouped in threes, and in this way a bigeminal or trigeminal pulse results. Or every other impulse may fail to reach the ventricle, giving rise to halving of the ventricular rate, the condition being spoken of as 2:1 rhythm (Fig. 45); or only each third or

fourth auricular impulse may be transmitted to the ventricle, resulting in 3:1 or 4:1 heart-block. In some cases certain ratios alternate.

It might naturally be supposed that the length of the prolonged pause during a dropped beat would be equal to two regular pulse-beats; such, however, is usually not the case, for the following reason. There are variations in the *As-Vs* interval in association with dropped beats, there being a progressive increase of the *As-Vs* interval preceding (Fig. 45) and a

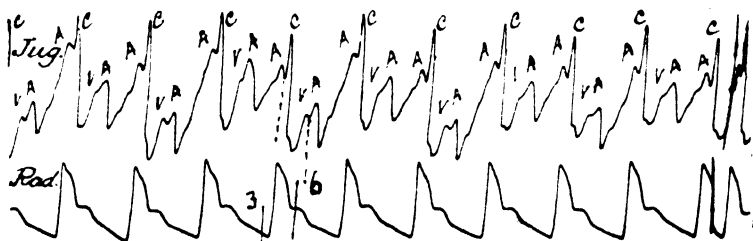

FIG. 45. Simultaneous tracings of the jugular and radial pulses, showing continuous 2:1 auriculo-ventricular block. The pulse-rate is 42 per minute.

progressive shortening of the interval following each dropped beat; the former is due to the increasing difficulty the impulses from the auricle have in reaching the ventricle, and the latter to the rest which the ventricle has experienced during the pause. The result of the progressive increase of the *As-Vs* interval prior to, and of the progressive shortening of the *As* to *Vs* interval after, the dropped beat is that the long pause becomes shortened. When, however, there are no variations in the *As-Vs* interval in association

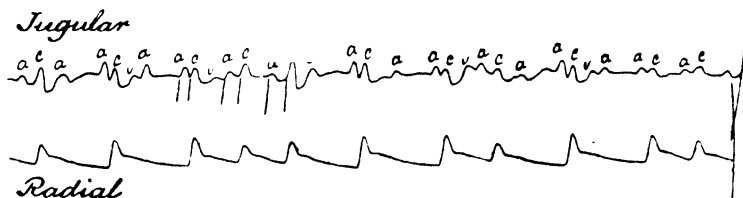

FIG. 46. Simultaneous tracings of the jugular and radial pulses, showing partial heart block. Note the progressive increase in the *a c* interval of three successive rhythmic beats.

with a dropped beat, the length of the prolonged pause is equal to two regular pulse-beats.

2:1 heart-block gives rise to infrequency of the pulse-rate, the rhythm being regular. This grade of heart-block is sometimes continuous, but usually the ventricle responds from time to time to successive stimuli received from the auricle, the pulse-rate, therefore, being usually above 36 per minute.

On analysis of a polygraphic tracing it will be found that the *a* wave is present at uniform intervals, and is of more frequent occurrence than the *c* or *v* waves—it may be even twice, three times, or more

times as frequent, according to the degree of block; but, unlike complete heart-block, each *c* wave is preceded by an *a* wave (Figs. 44 to 46).

COMPLETE HEART-BLOCK.—Here the pulse-rate is slow, usually not more than 36, and not infrequently between 20 and 30 per minute, though some cases have been recorded in which the rate has been up to 60 or more beats per minute; it is little influenced by physical exertion, emotion, or pyrexia, or, as a rule, by atropine. The beats are usually full and strong, and, as a rule, the rhythm is regular, the pulse being irregular, however, when extra-systoles are present. In a tracing of the radial artery small waves occurring at regular intervals on the descending limb of the pulse-beat, probably due to auricular systole, may sometimes be noted (Fig. 47). The systolic blood-pressure is generally high, and during the long pause there is a considerable drop in pressure; the mean blood-pressure is low. There is usually evidence of hypertrophy of the left ventricle. On inspection of the neck, regular pulsations in the jugular veins, at considerably more frequent intervals than, and having a constantly varying time-relation to, those of the radial and carotid arteries and the apex-beat, due to auricular systole, may sometimes be noted;

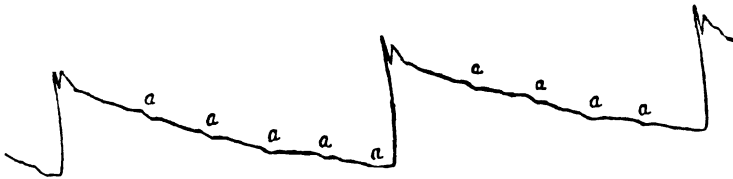

FIG. 47. Sphygmogram from Webster's case of complete heart-block, showing small waves occurring at regular intervals on the descending limb of the pulse-beat (Mackenzie).

and in some instances a large pulsation in the jugular vein is seen from time to time when the auricular and ventricular contractions happen to coincide. On auscultation a first and second sound are found accompanying each contraction of the ventricle, and, in the opinion of some, faint muffled sounds may occasionally be heard during the long pauses, due to the contractions of the auricle. Some writers, too, have noted an accentuation of the first sound, synchronous with the large pulsation in the jugular vein, when the auricular and ventricular contractions coincide. In the case of a lesion of either main division of the auriculo-ventricular bundle, the gallop rhythm may be audible, due to asynchronism of the two ventricles.

If a polygraphic tracing be analysed (Fig. 48), the disassociation of the auricular and ventricular rhythms is manifest. The *a* waves occur at regular intervals, and are more numerous than the *c* or *v* waves, and the time-relation of the *a* and *c* waves is a constantly varying one—the *a* waves at one time preceding, at another following, and at some times again coinciding with the *c* waves. When an *a* wave falls during the limits of ventricular systole its amplitude is increased. Extra-systoles may be present.

Ætiology.—Heart-block is more common in males than in females. Most of the cases fall within two groups—(1) Patients, usually young adults, who have previously suffered from a rheumatic infection of the heart; and (2) patients, usually elderly people, who are suffering from chronic inter-

stitial myocarditis. In the former group the block is almost always of slight degree; but in these cases the higher degrees of heart-block are sometimes induced by full doses of one of the digitalis series of drugs. In the latter group there is a past history of syphilis in a considerable proportion of cases. The milder grades of heart-block may also be found in patients suffering from acute infective diseases, such as acute rheumatism, influenza, diphtheria and pneumonia; the condition, however, is usually temporary in these diseases.

Pathology.—Sclerotic changes, gummata, or acute inflammatory changes of the auriculo-ventricular junctional tissues—either the auriculo-ventricular node, or the auriculo-ventricular bundle above its division into two branches—are found in most cases of heart-block; when the condition occurs during the course of an acute infective disease, acute inflammatory changes are those most frequently found. Cases have been recorded, however, in which there was an absence of any lesion of the auriculo-ventricular junctional tissues, but in some of these the vagus was found to be affected. It should be remembered that in heart-block the morbid condition is rarely limited to

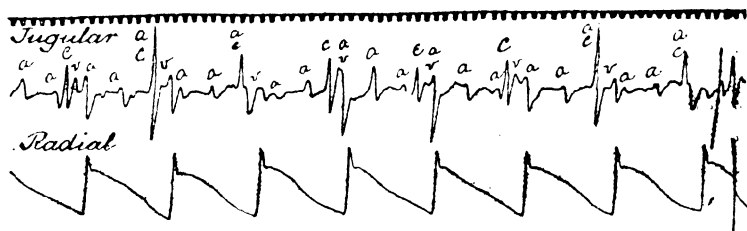

FIG. 48.—Simultaneous tracings of the jugular and radial pulses, from a woman aged 25, with severe heart failure, showing complete auriculo-ventricular block. The auricular rate is 88, and the ventricular rate 30, per minute.

the junctional tissues, the myocardium being usually affected, while valvular disease may also coexist.

Symptoms.—Patients suffering from heart-block may complain of symptoms due to the associated cardiac lesions—whether valvular or myocardial—which are almost invariably present, as well as of those due to the block itself; when, however, the valves and myocardium are normal, there may be a complete absence of subjective symptoms.

The symptoms of valvular and myocardial disease will be dealt with later; the commonest of these are dyspnoea, palpitation, fatigue, and præcordial pain on exertion.

With regard to the symptoms due to the block itself, reference has already been made to the pulse, the blood-pressure, the auscultatory phenomena, and the polygraphic records. In most cases symptoms due to the ventricular bradycardia are present. In the severe grades of partial heart-block and in complete heart-block there may be marked weakness and fatigue; and, owing to temporary anæmia of the brain, brief attacks of faintness, giddiness, or even temporary loss of consciousness. Not infrequently there are temporary periods of excessive slowing, or cessation of ventricular systole for prolonged intervals. Cheyne-Stokes respiration may be present, and the Adams-Stokes syndrome may occur.

ADAMS-STOKES SYNDROME.—Adams-Stokes syndrome is characterised by attacks of loss of consciousness, which may be momentary, and, it may be, also epileptiform convulsions, associated with marked infrequency of the ventricular rate. The patient, as a rule, has no knowledge of an impending attack. During the seizure there may be marked pallor or cyanosis, and deep and even stertorous breathing. Usually the convulsions are confined to the face and the upper limbs, the tongue is not bitten, and urine is not passed involuntarily. There may be repeated seizures. Adams-Stokes syndrome may occur in one of the following conditions: (1) Suddenly developed transient complete auriculo-ventricular block. Several cases of this kind have been reported. The conduction of the stimulus for contraction along the auriculo-ventricular junctional tissues is normal except that there is a liability to transient interruptions. (2) Partial heart-block in which there occurs either an intermittent period of complete heart-block, resulting in a temporary standstill of the ventricles; or, rarely, merely a temporary increase in the grade of the partial heart-block, resulting in a temporary increase in the degree of the bradycardia. (3) Complete heart-block in which the condition has become permanently established, especially if the ventricular rate is below 30 per minute. In these cases pauses of unusual length, due to temporary standstill of the ventricles, the result of diminished irritability of the ventricles, may occur. (4) It may very rarely be met with in marked bradycardia, in such conditions as meningitis, increased intracranial pressure, during convalescence from acute infective diseases, especially diphtheria and influenza, and possibly in fatty degeneration. Taking cases as a whole, Adams-Stokes syndrome is most commonly met with in patients with a severe grade of partial heart-block in whom complete block is developing. When complete heart-block has become permanently established, the ventricles apparently tend to become accustomed to the condition, and the pauses of unusual length referred to are not so likely to occur.

Diagnosis.—Diminished conductivity and the various grades of auriculo-ventricular heart-block are readily recognised by means of the polygraph or electro-cardiograph, since these instruments afford separate records of the movements of both the upper and lower chambers of the heart. The first grade can only be recognised by means of either of these instruments, and a lesion of either main division of the auriculo-ventricular bundle and intra-ventricular block by means of the electro-cardiograph. Fortunately, however, they are not necessary for the recognition of most of the other cases—palpation and auscultation furnishing all the evidence required. As an example of this may be mentioned the differential diagnosis between occasional dropped beats, pulsus bigeminus, and pulsus trigeminus, due on the one hand to extra-systoles and on the other to partial heart-block; this has already been dealt with. It is necessary to remember that sometimes sinus irregularity, and also sino-auricular block, may closely simulate occasional dropped beats due to partial heart-block.

The higher grades of heart-block give rise to infrequency of the pulse-rate. When the ventricular rate suddenly falls to half its former rate, in all probability the case is one of 2:1 heart-block. 2:1 heart-block must be distinguished from the condition in which an extra-systole occurs after each normal beat and fails to reach the wrist on each occasion. This can be done in the same way as in the case of a less severe grade of heart-block.

It is sometimes difficult to distinguish between partial and complete heart-block without the aid of the polygraph or electro-cardiograph. Most cases with a ventricular rate of 36 or under, however, are cases of complete heart-block. Also the presence of more rapid pulsations in the jugular veins, the presence of small waves occurring at regular intervals on the descending limb of a sphygmogram, and auscultatory phenomena afford help in differential diagnosis. A polygraphic or electro-cardiographic tracing may be taken to determine disassociation of the auricular and ventricular rhythms.

Adams-Stokes syndrome is easily recognised; marked infrequency of the ventricular-rate, rapid pulsations in the jugular veins, and the symptoms already described furnish a characteristic clinical picture.

Prognosis.—*The occurrence of partial heart-block during the course of an acute infective disease is a sign, and may be the only sign, of myocardial involvement.* Persistent heart-block of mild degree also is indicative of myocardial damage. With regard to persistent heart-block of severe degree, there are two questions of importance in considering the prognosis, namely—(1) Whether there be involvement of the heart muscle as a whole, and whether this involvement be progressive; and (2) is the patient subject to syncopal attacks, and, if so, their frequency? When there are no symptoms of heart failure, and when also the patient does not suffer from syncopal attacks, the span of life may be prolonged for many years, and he may be able to live a fairly active life without inconvenience. But when indications of cardiac failure are present, and especially if these be progressive, and when the patient is subject to recurrent syncopal attacks, especially if severe and frequent, life is always in danger; and, apart from the risk of a fatal termination, during an attack, death may occur with the usual clinical picture of cardiac failure. A few syphilitic cases have been recorded in which energetic anti-syphilitic treatment appears to have been rewarded with recovery.

Treatment.—When there is reason to suspect that syphilis is the cause, appropriate and energetic anti-syphilitic treatment should be employed. When heart-block occurs during the course of acute infective diseases, rest in bed is indicated, and the cause, such as rheumatism, should be adequately treated. Persistent heart-block of mild degree requires no treatment in itself. But as there is usually valvular or myocardial disease or both, it is of great importance that the patient should live strictly within the limits of the heart's strength, all the more so in cases of persistent heart-block of severe degree. If the patient be subject to fits, he should be warned to avoid anything known to predispose to the attacks, and, as far as possible, he should be protected from the risks of falling. Digitalis is contra-indicated in partial heart-block. It may be tried in complete heart-block in which there is dropsy or some other indication for its use.

ADAMS-STOKES SYNDROME.—The foregoing therapeutic measures may be indicated. Anti-syphilitic treatment is indicated in Adams-Stokes syndrome due to auriculo-ventricular block when this is the result of gummatous infiltration. Potassium iodide, by its depressing effect on the ventricular muscle, may even aggravate the complaint when the cause is other than syphilis. Thyroid appears to be sometimes of value and may even be completely effective. Atropine, administered between the attacks, in order to prevent their recurrence, is indicated in cases of partial heart-

block in which there is vagal over-activity. Digitalis is contra-indicated in partial heart-block. It may be of value in complete heart-block. Caffeine and theobromine are of no clinical value. Of reported cases, the nitrites were found to be only of doubtful value in one case. Adrenalin is of value in the great majority of cases. It is not often effective in preventing the recurrence of the attacks. When employed for this purpose, it may be administered either subcutaneously or intramuscularly, in a dosage of from 5 to 10 minims of 1:1000 solution thrice daily. It is, however, the only potent therapeutic measure at our disposal during an actual attack. It is necessary to point out that when—as in the vast majority of cases—the attack is due to a temporary standstill of the ventricles, with consequent temporary cessation of the circulation, intracardiac injection is necessary, because the beneficial effect of the drug is due to its action in stimulating the sympathetic nerve endings in the heart muscle. The dose should be 0.5 to 1 c.c. of 1:1000 solution. In the rare cases in which the attacks are due to merely a temporary increase in the grade of an existing partial heart-block, the drug may be effective even if given subcutaneously or intramuscularly. Ephedrin has recently been employed as a substitute for adrenalin. It differs from adrenalin in that its effect persists for several hours; and, moreover, it has the great advantage of being effective when administered orally. A highly successful case treated by this drug has been reported, and therefore further investigation of it is advisable. Barium chloride, given by the mouth, should invariably be tried for the prevention of the recurrence of the attacks in cases of Adams-Stokes syndrome due to auriculo-ventricular block. If ineffective alone the drug should be employed with adrenalin, the latter administered either hypodermically or intramuscularly. The following is recommended: That barium chloride be administered, at first in doses of $\frac{1}{2}$ gr. thrice daily. This dosage should, if necessary, be cautiously increased—stopping short of toxic symptoms—to 1 gr. thrice daily. With regard to adrenalin, 0.5 c.c. to 1 c.c. of 1:1000 solution thrice daily until after the attacks have ceased for some time. The dosage of adrenalin should then be gradually diminished until the drug is omitted altogether. Still later, the dosage of barium should be gradually reduced to the minimal dose found necessary to prevent the recurrence of the attacks.

CONGENITAL AURICULO-VENTRICULAR BLOCK.—A number of cases of congenital auriculo-ventricular block, usually accompanied by some other lesion, have been described during the last 20 years or so, but, owing to the absence of polygraphic or electro-cardiographic examination, some of them were very doubtful. In most cases the pulse was over 50 per minute, and only rarely was there Adams-Stokes syndrome. The condition is usually ascribed to a lesion of the auriculo-ventricular bundle, and among the theories put forward as to its nature are (1) that it consists in a severance of the continuity of the bundle by an intra-ventricular communication, (2) that it is due to malformation, and (3) that it is inflammatory in origin.

BUNDLE-BRANCH BLOCK

A temporary or permanent lesion of either the right or left main branch of the auriculo-ventricular bundle is uncommon. The right appears to be much more frequently affected than the left. The aetiology and pathology

are similar to those of auriculo-ventricular block. Sometimes auriculo-ventricular block, and less frequently auricular fibrillation (Fig. 102), may coexist with a lesion of either main branch. Reduplication of the first sound is not infrequently to be observed. The condition can be recognised by means of the electro-cardiograph alone (see page 928). When the condition is permanent, the prognosis is usually very unfavourable.

INTRAVENTRICULAR (ARBORISATION) BLOCK

In this condition there is diminished conductivity of the sub-endothelial arborisations of the auriculo-ventricular bundle, and also the stimulus for contraction does not reach the various portions of the ventricular muscle in normal sequence. It is believed by some that the condition may be recognised by means of the electro-cardiograph (see page 930). The prognosis is almost always grave.

PULSUS ALTERNANS

Definition.—By pulsus alternans is meant a condition of the pulse in which, while the rhythm is perfectly regular, a large beat and a small beat alternate. It is probably indicative of depressed contractility.

In the most typical cases of pulsus alternans, stimulation and contraction of the sinus, the auricles, and the ventricles occur in the order named, the ventricles contracting only in response to stimuli received from the auricles, and ventricular systole following the auricular systole at the normal interval

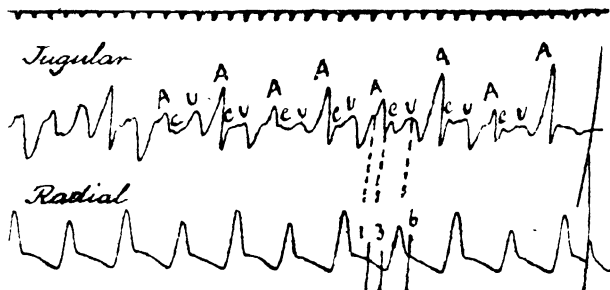

FIG. 49.—Simultaneous tracings of the jugular and radial pulses, showing continuous pulsus alternans, in which stimulation and contraction of the sinus, auricles and ventricles occur in the order named.

(Fig. 49). Sometimes, however, pulsus alternans is associated with conditions in which the mechanism of the cardiac action is abnormal, such as auricular flutter (Fig. 50), or paroxysms of auricular extra-systoles. The condition may be continuous, or it may be only observed on an increase of the pulse-rate, such as follows exercise, or only during a few cycles immediately following an extra-systole.

Ætiology.—Excluding those cases that occur in association with an abnormal cardiac action, such as auricular flutter, in the great majority of cases patients showing pulsus alternans are past middle age, and are the subjects of myocardial degeneration; the condition, however, is sometimes found in

younger people with post-rheumatic valvular disease, and occasionally it has been noted in pneumonia and other acute illnesses.

Symptoms.—The pulsus alternans in itself causes no subjective symptoms. When associated with myocardial disease, evidences of cardiac failure are almost invariably present. It requires long practice to detect pulsus alternans by the finger. Sometimes the small beats are so feeble that no waves are transmitted to the wrist; the condition may, therefore, be a cause of infrequency of the pulse.

Diagnosis.—In the great majority of cases it is necessary to take a tracing of the radial artery in order to recognise the condition. It is necessary to distinguish it from pulsus bigeminus due to extra-systoles. The differential diagnosis can be made with certainty; in pulsus alternans the pause between the large and the small beat is equal to that between the small and the large beat, whereas in the case of extra-systole the pause following the small beat is longer than that following the large one.

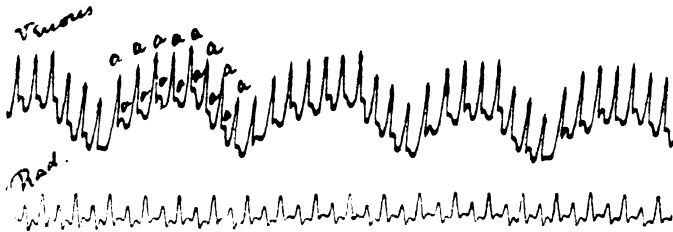

FIG. 50. —Simultaneous tracings of the jugular and radial pulses, showing pulsus alternans associated with an attack of auricular flutter, in which the ratio between the auricular and ventricular rate is continuously 2 : 1.

Prognosis.—When pulsus alternans occurs apart from a disordered cardiac mechanism, it is an indication of extreme exhaustion of the heart muscle; when the condition lasts only for a few cycles, this exhaustion may be only temporary, but even in these cases the prognosis should be guarded; when it is continuous, death may follow within a few months, or at most in a few years. When the condition is associated with tachycardia, it does not appear to have any serious significance in itself.

Treatment.—As pulsus alternans is usually a sign of great exhaustion of the heart muscle, complete and long-continued rest, both physical and mental, is urgently needed.

AURICULAR FIBRILLATION

The discovery of auricular fibrillation is one of the greatest discoveries regarding the functional pathology of the heart which has ever been made. It is of the utmost practical importance that the condition should be recognised, owing to its bearing on the diagnosis, prognosis and treatment of cardiac affections. Auricular fibrillation is a specific clinical condition which can be recognised with certainty. It is characterised in the vast majority of cases by complete irregularity of the arterial pulse, and also by absence of all signs of the normal contraction of the auricles. It accounts for approximately

50 per cent. of all cases of persistent irregularity of the heart, and it is found in from 60 to 70 per cent. of all cases of serious cardiac failure with dropsy. The condition has been known variously as "delirium cordis," "pulsus irregularis," "pulsus irregularis perpetuus," and the "mitral" pulse.

Definition.—By auricular fibrillation is meant a condition in which co-ordinate contraction in the auricle is replaced by inco-ordinate contraction; the individual fibres, instead of contracting in an orderly and simultaneous manner, doing so rapidly and independently of each other, with the result that *systole of the chamber as a whole never takes place*. *When auricular fibrillation has once set in, in the great majority of cases it persists for the remainder of life*. But, instead of this, it may appear for a few moments only and never return, or it may occur at varying intervals for days, weeks, or months and then cease, either spontaneously or as the result of digitalis medication. Many cases of paroxysmal tachycardia are due to transient attacks of auricular fibrillation. The tendency to occurrence increases, however, until finally the condition usually becomes permanent.

EFFECT OF AURICULAR FIBRILLATION ON THE HEART.—The effect of auricular fibrillation on the cardiac action is mainly threefold: (1) The forcible contraction of the auricles driving the blood through the open auriculo-ventricular valves into the ventricles during the latter part of ventricular diastole is lost. This results in the ventricle being less filled. (2) Instead of the ventricle receiving stimuli from the auricle at regular intervals, it receives them at completely irregular intervals. (3) The impulses which escape from the auricle are numerous, and in the vast majority of cases the junctional tissue is able to conduct too many to the ventricle, resulting in an increase in the ventricular rate. The result of these three factors combined is that some of the ventricular contractions are so feeble as to fail to open the aortic valves, and the pulse is diminished in volume and its rhythm is irregularly irregular. In my opinion, the third factor is the most important. The condition usually has a considerable effect on the heart's efficiency.

Ætiology.—The majority of cases of auricular fibrillation fall within two groups—(1) those with a history of rheumatism, and (2) patients suffering from myocardial degeneration. In the case of the former the condition occurs more commonly in early adult life, and the patients frequently have valvular disease—*much more often mitral than aortic disease, and more especially mitral stenosis*. In the second group of cases the condition is more common after middle age. Auricular fibrillation has been also found occasionally in acute infective diseases, such as pneumonia, infective endocarditis, and diphtheria, in thyrotoxic conditions, whether due to exophthalmic goitre or adenoma, and in the terminal stages of various exhausting diseases. Its onset can now and again be traced to bodily effort, especially in the middle-aged or elderly, and rarely to the administration of full doses of digitalis.

Pathology.—Auricular fibrillation is in the vast majority of cases indicative of some myocardial change. Lewis and his co-workers are of opinion that both auricular flutter and auricular fibrillation are due to a single continuously circulating wave, which may be explained as follows:

G. A. Mines has demonstrated that if a ring of muscle is cut from the auricle of a tortoise, and a single stimulus is applied at any point to the quiescent ring, two waves of excitation travel rapidly from this point in

opposite directions and at the same rate, meeting at the centre point on the opposite side of the ring. At the time that the waves of excitation meet, the whole ring of muscle has passed into a state of excitation, and is, therefore, refractory, so that the wave of excitation on either side cannot proceed any further and consequently ceases; the crest of the oncoming wave on either side finding refractory tissue ahead of it. The whole ring of muscle remains in this state for a period, after which responsiveness is restored, this proceeding in the same order as the wave of excitation, until at last the whole ring is responsive, as was the case prior to the application of the stimulus. If, instead of a single stimulus, rhythmic stimuli be applied at one point of the ring of muscle, as long as the intervals between the stimuli are sufficient to allow of full restoration of responsiveness, the series of events described will occur at each stimulation. If, however, rhythmic stimuli be applied at such a rate that the intervals between them are not sufficient to allow full restoration of responsiveness, it may be that the wave of excitation is able to pass in one direction only, and if at this moment stimulation be abruptly withheld, there is, instead of two crests of waves of excitation travelling to meet each other at the centre point on the opposite side of the ring, only one crest, and as there is no wave of excitation meeting it in the opposite direction, when it comes to each part of the ring it finds the muscle fully responsive; and the wave, therefore, travels round the whole ring until it reaches its starting-point by which time the muscle of that segment of the ring has also become fully responsive, the result being that a single wave circulates continuously and for an indefinite period. There is a gap of fully responsive muscle between the crest of the oncoming wave and its receding wake. This is called *circus movement*.

It is believed that auricular flutter and auricular fibrillation are due to a single continuously circulating wave—in other words, to *circus movement*. There is a central or re-entrant path, and each time the wave of excitation travels over this, offshoots or centrifugal waves are thrown on and travel to all the other parts of the muscle of the auricle. The factors which maintain the *circus movement* are: (1) The length of the central path taken by the wave; (2) the rate at which the wave travels from point to point; and (3) the duration of the effective refractory period at any given point; the refractory period being the time taken for the muscle to become responsive after it has contracted. The third factor controls the second, and in large measure also controls the first; for when several paths are open to the oncoming wave, it will naturally take the shortest. There must of necessity be a gap of a sufficient degree of responsiveness between the crest of the oncoming wave and the wake of the receding wave; for if this gap become closed, the former will find refractory tissue ahead of it and so cease, thus allowing the normal pacemaker of the heart to regain control of the cardiac action. The length of the gap is controlled by the three factors mentioned. Any agency which will sufficiently increase the refractory period, or sufficiently increase the rate of conduction will close the gap, and thus bring the *circus movement* to an end. In auricular flutter, owing to the increased rate of auricular contraction, the refractory period is diminished and usually also the rate at which the wave of excitation travels, and both of them tend to induce relatively short *circus movements*.

While what has been described in the ring experiment, namely, that the gap between the crest of the oncoming wave and its receding wake is fully

responsive, is occasionally observed experimentally, more frequently the gap consists of what is called *partially* refractory muscle. The cycle may thus be divided into three phases: (1) The full refractory phase; followed by (2) the partially refractory phase; and (3) a short phase at the end of the cycle during which the muscle is fully responsive. The end of the second phase, however, instead of being sharply defined, gradually fades into the third. The development of the partially refractory phase hastens the closure of the gap between the termination of the fully refractory period and the end of the cycle. As the rate of auricular contraction increases, the second phase bridges the gap between the end of the first phase and the end of the cycle, in which case the cycle will consist wholly of (1) a fully refractory phase, and (2) a partially refractory phase. In auricular flutter, the gap between the oncoming wave and its receding wake usually consists of partially refractory muscle, so that the oncoming crest encounters some fibres which are responsive and others which are still refractory. The latter act as minute barriers to the progress of the oncoming wave, and deflect it, making its course sinuous and diminishing its rate of progress from point to point. It will thus be seen that the diminished rate at which the wave of excitation travels in auricular flutter is not due to a diminished rate of conduction on the part of the fibres, but to some of the fibres being refractory and acting as barriers. In auricular flutter, the circulating wave is repeated at about 300 times per minute, and the paths along which both the main wave and its offshoots travel are constant and finally sinuous. The path which the central wave usually, but not invariably, follows is round a natural ring of muscle formed by the orifices of the superior and inferior venæ cavæ, and, as looked at from above, in a direction opposite to the hands of the clock. In auricular fibrillation, the circulating wave is repeated at about 450 times per minute. The greater rate as compared with a case of auricular flutter is in all probability due to the path taken being shorter, which is probably due to the effective refractory period being shorter than in auricular flutter. But there are other differences, of still greater importance, than the difference noted in the rate of the auricular movements. In auricular fibrillation, the degree of partial refractiveness of the auricular muscle is greater, so that the barriers to the progress of the oncoming wave are larger. The result is that the paths along which the main wave and its offshoots travel are variable and coarsely sinuous, and both the crest and the wake of the wave are deeply and irregularly crenated, and the crenations of the crest and the wake overlap and intertwine. Prolongation of the refractory period in auricular flutter and in auricular fibrillation will help to close the gap between the crest of the oncoming wave and its receding wake, since this gap is necessary for the maintenance of the circulating wave, whether in auricular flutter or fibrillation.

Symptoms.—Patients with auricular fibrillation very frequently complain of fluttering in the præcordium, or of irregular action of the heart, or of both, possible only on exertion. Apart from this, there is occasionally an absence of subjective symptoms. But, when the ventricular rate is much above the normal, symptoms, as a rule, are present, and these are the same as those of cardiac failure from other causes, such as shortness of breath, a sense of exhaustion, cyanosis and dropsy. It would appear, however, that the subjects of auricular fibrillation rarely suffer also from typical attacks of

angina pectoris. When the pulse-rate is very slow, the Adams-Stokes syndrome may be present.

The degree of cardiac failure which arises as a result of auricular fibrillation may be slight or very severe. It depends upon (a) the rate of the ventricular action, and (b) the degree of inherent muscle defect. As a rule, the onset of symptoms is gradual, but may ensue rapidly and the patient may become very ill within a few hours. Similarly, the cessation of auricular fibrillation may be accompanied by an equally rapid improvement in the patient's condition.

There is a wide variation in the ventricular rate, according as the path-

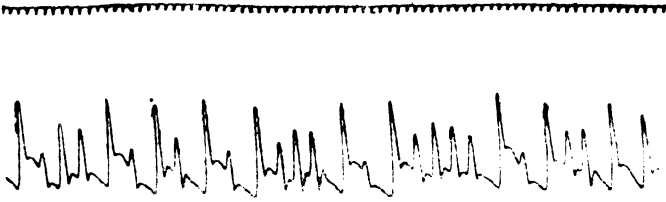

FIG. 51. Tracing of the radial artery, from a case of myocardial degeneration with auricular fibrillation, showing complete irregularity of the pulse.

way for impulses to the ventricle is free or interfered with, this ranging from 140 or even 180 to 40, or, very rarely, even 30 per minute in complete auriculo-ventricular heart-block, the average rate being between 90 and 140. The rate of the radial pulse does not necessarily represent the ventricular rate, for many beats of the heart may not be transmitted to the wrist, especially when the ventricle is beating rapidly; the ventricular rate, therefore, should be counted at the apex, either by palpation or auscultation. Apart from the very rare cases of complete auriculo-ventricular block, when the pulse is regular, *the character of the pulse is important*. It is irregular, the irregu-

FIG. 52.—Tracing of the radial pulse, from a case of auricular fibrillation, showing complete irregularity of the pulse.

larity being continuous in the great majority of cases and persisting for the rest of the patient's life, in this respect differing from most other types of cardiac irregularity. A feature of even greater importance is the fact that the irregularity is *complete*; the rhythm is irregularly irregular (Figs. 51 and 52). In a sphygmogram, it will be found that two beats of the same length or amplitude rarely follow each other. There is often no relation also between the length of a pause and the amplitude of the beat which follows it—*i.e.* a short pause may be followed by a strong beat, and a long pause by a weak beat. There may be superadded ventricular extra-systoles, occurring either isolated at irregular intervals, or, as is more usually the case, occurring regularly after each normal ventricular beat. In the latter event, there is either

coupling of the beats (Fig. 53), or the premature contraction may be so feeble that no wave reaches the wrist, in which case the pulse-rate is halved. When the ventricular rate is slow (Fig. 54), or very rapid, the irregularity may be only slight, and we may have to adopt careful measurements of the sphygmogram to detect it.

In cases of mitral stenosis in which a presystolic bruit, *due to auricular systole*, is present, this disappears with the onset of auricular fibrillation;

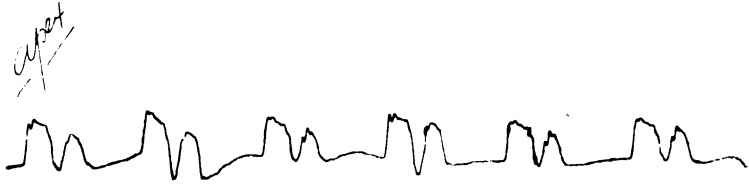

FIG. 53.—Tracing of the apex-beat, from a case of auricular fibrillation, fully under the influence of digitalis, showing coupled beats.

while if a diastolic bruit be present it persists. The jugular veins may be so distended that there is no visible pulsation in them. When pulsation is visible, however, it is of the positive type, only one wave being visible, this occurring during ventricular systole. In a tracing of the jugular vein, apart from the very rare cases of complete auriculo-ventricular block, when the rhythm is regular, the rhythm is completely irregular. There is an absence of the normal *a* wave; in other words, the ventricular form of venous pulse exists (Fig. 54). The normal *a* wave cannot be present because the auricle

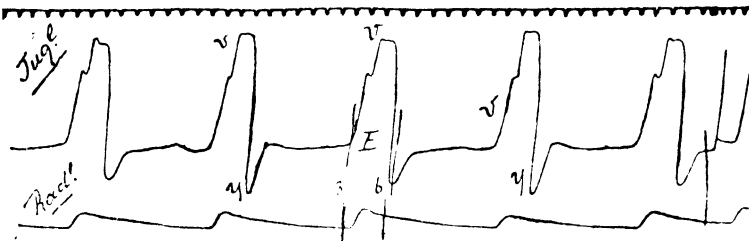

FIG. 54.—Simultaneous tracings of the jugular and radial pulses, from a case of auricular fibrillation, showing the ventricular form of venous pulse, and an unusually slow radial pulse.

does not contract. On the other hand, in cases in which there is infrequent cardiac action, multiple undulations, caused by the fibrillating auricle, may be present during diastole (Fig. 55). There is also an absence of the normal *a* wave in a cardiogram (Fig. 56) and in a tracing of the liver pulse (Fig. 57).

Diagnosis.—Auricular fibrillation can be diagnosed with absolute certainty on electro-cardiographic examination; or when complete irregularity of the arterial pulse, the ventricular form of venous pulse, and multiple

undulations in the jugular pulse are present, together with an absence of all signs of an auricular wave in a tracing of the apex-beat and of the liver pulse. We may be sure that this condition is present when there is complete irregularity of the pulse in conjunction with the ventricular form of venous pulse.

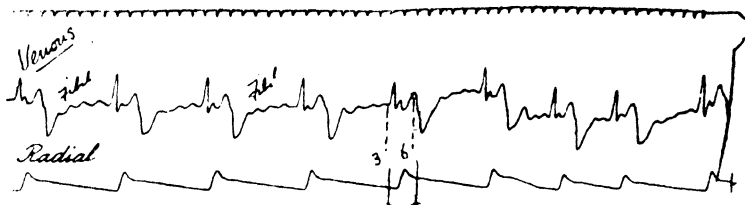

FIG. 55. — Simultaneous tracings of the jugular and radial pulses, from a case of auricular fibrillation, showing multiple undulations (marked *Fibl.*) in the phlebogram, caused by the fibrillating auricle.

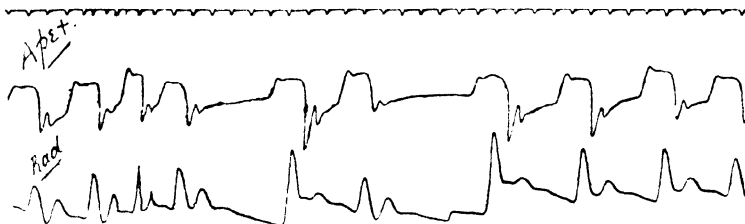

FIG. 56. — Simultaneous tracings of the apex-beat and of the radial pulse, from a case of auricular fibrillation, showing absence of the normal *a* wave in the cardiogram.

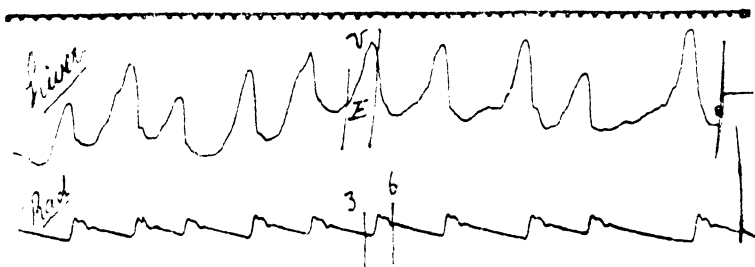

FIG. 57. — Simultaneous tracings of the liver and radial pulses, from a case of auricular fibrillation, showing absence of the normal *a* wave in the former.

Indeed, we may be reasonably certain of the existence of auricular fibrillation from the mere presence of complete irregularity of the pulse. It is possible to determine complete irregularity of the pulse in a large proportion of cases by palpation and auscultation alone. When, however, the ventricular rate is slow, or very rapid, the irregularity may be only slight, and it may be necessary to adopt careful measurements of the sphygmogram to detect it.

It is necessary to exclude irregular action of the heart due to extra-systoles (p. 791), or to auricular flutter (p. 813).

Prognosis.—Auricular fibrillation is in the vast majority of cases indicative of some myocardial change. Furthermore, the condition usually has an effect on the functional efficiency of the organ. Put briefly, the prognosis of auricular fibrillation depends upon the capacity of the heart to carry on its work under the new rate and rhythm, and this in turn depends upon the integrity of the cardiac muscle and the ventricular rate. If the integrity of the cardiac muscle be relatively good there may be for years little or no indication of cardiac failure. In the great majority of cases, however, this is not the case, and so heart failure, usually of considerable degree, results, especially when the ventricular rate is rapid and the heart is dilated. A persistent ventricular rate of 120 or over is usually of serious omen. Occasionally, with the inception of auricular fibrillation, grave cardiac failure may supervene with surprising rapidity, and death may follow within a few weeks, or even within a briefer period.

In endeavouring to form a prognosis, a point of the utmost importance is to ascertain how the heart responds to treatment. In this connection, digitalis therapy and quinidine therapy have been fully dealt with on pages 762-770. Another point of the utmost importance is to ascertain how far the patient is able to modify his life so as to bring it within the limits of the heart's strength. As has been pointed out, transient attacks of auricular fibrillation usually have a tendency to become more frequent, until ultimately the condition becomes permanent.

Treatment.—The aetiology should be reviewed, and the various therapeutic measures applicable to any form of cardiac disorder should be considered in detail. Apart from these, treatment of persistent auricular fibrillation resolves itself largely into the consideration of the employment of digitalis (or one of its allies), or of quinidine. The ultimate object of the employment of either of these drugs in the treatment of persistent auricular fibrillation is the same, namely, to regain the degree of cardiac efficiency which existed prior to the onset of the abnormal rhythm. This in the main depends upon the restoration of the pre-existing ventricular rate. As has already been pointed out, the fundamental functions of digitalis and of quinidine differ. The primary object of administering digitalis in auricular fibrillation accompanied by a rapid ventricular rate is to reduce and control the ventricular rate within normal limits. The drug has no effect upon the auricular fibrillation itself. The indications, the dosage, the choice of preparation, and the important question of the long-continued administration of the drug in most cases of auricular fibrillation have been fully dealt with on pages 762-767. The primary object of administering quinidine, on the other hand, is to arrest the auricular fibrillation—in other words, to restore the normal rhythm, and any beneficial effect of the drug is simply due to this. If successful in restoring the normal rhythm in auricular fibrillation, the forcible contraction of the auricles driving blood through the open auriculo-ventricular valves into the ventricles during the latter part of ventricular diastole is restored, the ventricle receives stimuli from the auricle at regular intervals, any increase in the ventricular rate due to the supervision of the abnormal rhythm is usually, but not always, abolished, physical exertion does not cause such a large increase in the ventricular rate, and the conscious-

ness of the irregular action of the heart, which is not rarely a disagreeable subjective symptom, is relieved. Quinidine therapy has been fully dealt with on pages 767-770.

In considering whether digitalis or quinidine should be employed, the degree of response to digitalis or one of its allies is of important consideration, a manifestation on the part of the patient of a particular intolerance for the former being a special indication for the administration of quinidine. It should, however, be remembered that the greater the degree of response to rest and digitalis medication the more likelihood there is of greater benefit following the administration of quinidine. Another special indication for quinidine is the occurrence of cardiac failure coincidently with the onset of the abnormal rhythm. The absence of indications of cardiac failure does not necessarily mean that this drug should not be tried, as cardiac failure may supervene later on. Other considerations are the risk—even amounting to a possible fatal issue—attending the administration of the drug, the degree of probability of restoration of the normal rhythm, the probable degree of success resulting from this, and the degree of probability of relapse. Cases for the administration of the drug should be selected with the utmost care, and in selecting such cases we are justified in taking a comparatively small risk, while in doubtful cases we should clearly put the pros and cons of this method of treatment to the patient or his friends. Finally, it should be remembered that if quinidine fails digitalis medication is still open to us.

AURICULAR FIBRILLATION (OR AURICULAR FLUTTER) OCCURRING IN THYROTOXIC CONDITIONS.—Auricular fibrillation (or auricular flutter) is not a very infrequent complication of thyro-toxic conditions, whether due to exophthalmic goitre or to adenoma. In those cases in which a toxic state exists at the time, the beneficial results following the administration of digitalis are, as far as my experience goes, only slight or altogether absent. Although quinidine not infrequently restores the normal rhythm, if the thyro-toxic state persists, relapse always occurs on slight exertion, physical or mental, or on emotion. The primary indication, therefore, is to remove the thyro-toxic state. This may occur naturally, or in response to rest and other therapeutic measures. Restoration of a stable normal rhythm follows in a certain proportion of cases. If this does not take place, digitalis or quinidine may be tried. The latter might conceivably result in the restoration of a stable normal rhythm in some cases. If the thyro-toxic state does not subside naturally or in response to rest, or digitalis and quinidine are still unsuccessful, the question of performing a sufficient degree of partial thyroidectomy should be considered. Restoration of the normal rhythm sometimes occurs spontaneously after operation, though it may be delayed to even 3 to 6 months. In a certain proportion of cases, such operative interference is not followed by restoration of the normal rhythm. In such cases, provided there are no contra-indications, the administration of quinidine should be resorted to, and restoration of the normal rhythm usually follows.

It does not follow that because auricular fibrillation or auricular flutter is found in a person who is the subject of goitre, the abnormal rhythm is caused by the goitre, for it may be due to some other morbid condition, such as organic valvular disease. In this connection, search should be made, on

the one hand, for other known causes of the abnormal rhythm, and, on the other, for evidence of hyperthyroidism, and an estimation of the basal metabolic rate should be undertaken.

The treatment of transient attacks of auricular fibrillation is that of paroxysmal tachycardia.

AURICULAR FLUTTER

The term "auricular flutter" was first used clinically by Jolly and Ritchie, and signifies a morbid condition in which a marked acceleration of the rhythmic, co-ordinate contractions of the auricle occurs. Auricular flutter was first induced experimentally by MacWilliam in 1887, and it is now recognised as a not uncommon clinical condition. *Transient attacks of auricular flutter probably account for the great majority of cases of paroxysmal tachycardia with regular rhythm or with pulsus alternans.*

NATURE OF AURICULAR FLUTTER.—As already noted, the contractions of the auricle are extremely rapid; the rate may range from 180 to 380, perhaps being usually between 280 and 300 per minute. The ventricular rate varies considerably in different cases, this depending upon the auricular rate and the ability of the auriculo-ventricular bundle to receive and transmit impulses sent by the auricle. Excepting in rare cases, each systole of the ventricle is the result of a stimulus for contraction received from the auricle in the normal fashion; rarely complete heart-block is present. In the vast majority of cases, the ventricle does not respond to each auricular contraction, partial heart-block being present. There is usually a constant and uniform ratio between the auricular and ventricular rate, this varying from 5:1 to 2:1; it would appear that the order of frequency is 2:1, 4:1, and 3:1. There may be a sudden and abrupt change from one ratio to another. In some cases the response of the ventricle to auricular contraction is at irregular intervals, instead of being in definite ratio—this giving rise to irregularity of the pulse rhythm.

The commencement and termination of auricular flutter are sudden and abrupt. The duration of the condition varies in different individuals, as well as in different paroxysms occurring in the same individual. Auricular flutter may appear for only a few moments and may never return; or it may last for hours, days, weeks, months, or even for years, recurring at intervals. It may be succeeded by the normal rhythm, or in many instances followed by auricular fibrillation; I have seen the latter occur during the administration of digitalis, but it may also occur apart from the use of the drug. There may be alternation of auricular flutter, the normal rhythm, and auricular fibrillation, the change taking place with the greatest abruptness and suddenness, and occurring from day to day or even every few moments, one or other condition ultimately becoming permanently established. Sometimes auricular flutter may persist, but, as the result of the occurrence of partial heart-block, the ventricular rate may diminish, and this may take place during the administration of digitalis or apart from the use of this drug. When once a patient has suffered from an attack of auricular flutter, there is a tendency to its recurrence from time to time.

EFFECT OF AURICULAR FLUTTER ON THE HEART.—The effect of auricular flutter on the heart depends upon the ventricular rate and the integrity of the myocardium. When the ventricular rate is rapid and the myocardium is considerably damaged, the condition produces a marked effect upon cardiac efficiency, frequently resulting in cardiac dilatation, dropsy, and other indications of heart failure.

Ætiology.—It is yet too early to speak with certainty of the ætiology of this condition. Possibly this is much the same as that of auricular fibrillation. But while the condition has been observed as early as 5 years of age, it is most common after middle life, is of much more frequent occurrence in males than in females, and in all probability is most commonly associated with myocardial degeneration.

Pathology.—See pages 802–804.

Symptoms.—The symptoms after the onset of auricular flutter may come on gradually or rapidly, and the patient may or may not be conscious of the change in the cardiac action. He may complain of palpitation, but otherwise there may be an entire absence of subjective symptoms, this depending upon the ventricular rate, the degree of integrity of the myocardium, and the duration of the condition.

Taking into consideration all cases of auricular flutter, in a majority of which the condition has existed for some time, the ordinary symptoms of cardiac failure supervene; or, if these were present before the onset of auricular flutter, they increase in severity, until ultimately indications of extreme cardiac failure may appear. When the ventricular acceleration is marked, as the amount of blood propelled from the ventricle at each systole is so small as to give rise to cerebral anæmia, the patient may complain of vertigo, and there may be from time to time attacks of faintness or even complete loss of consciousness. Cheyne-Stokes respiration is also not an infrequent symptom when the condition has lasted for some time.

The rate and rhythm of the arterial pulse vary greatly in different cases, and, it may be, at different times in the same case. If the ventricle responds to each auricular contraction, the ventricular rate is exceedingly rapid, and graphic methods are necessary to determine it. In the vast majority of cases, however, partial heart-block is present, and as 2:1 rhythm is the most usual, a ventricular rate of 140 to 150 is frequently found. In other cases of partial heart-block, the ventricular rate may not be much increased, and, indeed, there may even be bradycardia, as in 4:1, or more partial heart-block—as well as in complete heart-block. When there is a constant and uniform ratio between the auricular and ventricular rate, the rhythm of the arterial pulse is regular; in these cases, however, if the ventricular rate be above 150, pulsus alternans may be present. When, as is not infrequently the case, the response of the ventricle to auricular contraction is at irregular intervals, there is irregularity of the pulse rhythm, it may be even markedly so; indeed, in some of these cases the sphygmogram may resemble that from a case of auricular fibrillation, detailed measurements being necessary for the purpose of differential diagnosis. On inspection of the neck, the jugular veins may be distended, and no pulsation visible; or extremely rapid movements may be evident. Evidences of cardiac dilatation, as, for example, enlargement of the area of percussion

impairment, may be found. If murmurs of mitral disease were present prior to the onset of auricular flutter, they may become faint or almost disappear if the ventricular rate be greatly accelerated; this applies particularly to the case of a mitral presystolic bruit.

A tracing of the jugular pulse differs in outline according to whether

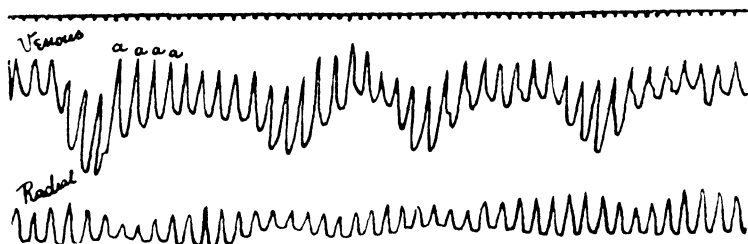

FIG. 58.—Simultaneous tracings of the jugular and radial pulses from a case of auricular flutter, in which the ventricle responded to each auricular contraction. The rate is 188 per minute.

the ventricle responds to each auricular contraction, or to the degree of heart-block which may be present. In the former case there is usually a single wave (Fig. 58). When the ventricle responds alternately to the auricle, there are two *a* waves to each ventricular beat, and these usually fall within the limits of ventricular systole (Fig. 59). In 3:1 rhythm the character of the jugular pulse may be seemingly that of normal cardiac

FIG. 59.—Simultaneous tracings of the jugular and radial pulses from a patient with myocardial and arterial disease, showing the termination of an attack of paroxysmal tachycardia, due to auricular flutter. The first part of the tracing shows auricular flutter, with 2:1 heart-block, the rate of the auricle being 232, and the ventricular rate 116, per minute. The normal rhythm of the heart is resumed after the long pause with the beat 1, 3, 6.

action, and it is particularly in these cases that an electro-cardiographic examination is required to establish the diagnosis. As has been already noted, complete heart-block is rarely found.

Diagnosis.—The diagnosis of the condition rests on the detection of the extremely rapid contractions of the auricle, and this is not infrequently impossible without the employment of the polygraph or electro-cardiograph; indeed, in some cases a correct diagnosis cannot be made with certainty even

though the polygraph be employed, an electro-cardiographic examination being necessary.

We should consider the possibility of auricular flutter whenever an individual is conscious of a marked increase in the cardiac rate, or complains of attacks of palpitation, in either case occurring suddenly and without apparent cause, or suffers from dyspnoea on exertion and other indications of cardiac failure coming on rapidly, especially if the rhythm of the pulse be regular.

Auricular flutter should be diagnosed from tachycardia associated with the normal rhythm. If the tachycardia be due to an abnormal rhythm, and if the ventricular rhythm be regular, the case is probably one of auricular flutter; while if the rhythm be irregular, it is necessary to consider whether the case may not be one of auricular fibrillation. In this connection, *if a sphygmogram from a case of auricular flutter be carefully studied, it will be found that even though the ventricular rhythm is markedly irregular the pulse-beats measure out into groups of equal length, whereas this is never the case*

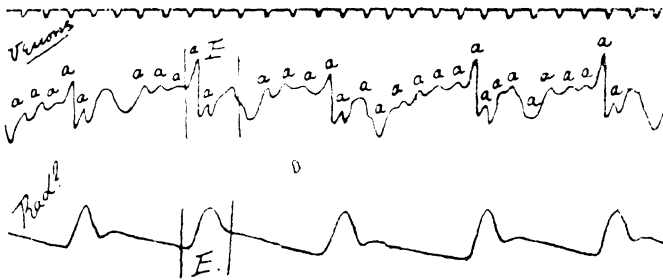

FIG. 60.—Simultaneous tracings of the jugular and radial pulses from a patient fully under the influence of digitalis. The auricular rate is 382, and the ventricular rate is 50, per minute.

in auricular fibrillation. The polygraph and electro-cardiograph are of notable assistance in the differential diagnosis of the two conditions. The diagnosis of auricular fibrillation with a markedly exaggerated ventricular rate in which the irregularity is only slight from auricular flutter should also be considered. Irregularity due to the presence of extra-systoles should also be excluded. Cases of auricular flutter in which the auriculo-ventricular ratio is constantly 3:1 to 4:1, so that the ventricular rate is not much, if any, increased, and in which the ventricular rhythm is regular, are easily missed. The employment of the polygraph or electro-cardiograph is often necessary in such cases.

Prognosis.—The prognosis of auricular flutter depends upon the frequency and duration of the attacks, the ventricular rate, the condition of the valves, the myocardium, and the vessels, and the results of the administration of digitalis. When once a patient has suffered from an attack of auricular flutter, there is a tendency to its recurrence from time to time. The effect which an attack has upon the heart depends upon the ventricular rate and the degree of integrity of the myocardium; these have been already dealt with. Attacks of loss of consciousness, especially when they occur in the subjects of marked cardiac failure, are attended with danger.

Treatment.—The ætiology should be reviewed. When the attacks are transient, the treatment is that of paroxysmal tachycardia. When they are of longer duration, or the condition has become permanently established, the various measures applicable to any form of cardiac disorder should be considered. Apart from these, treatment resolves itself largely into the consideration of the employment of digitalis or one of its allies, or of quinidine. The action of digitalis, its dosage, the choice of preparation, and the choice of either of two plans after the full physiological reaction is obtained, have been fully dealt with on pages 762-767. Quinidine therapy has been discussed in detail on pages 767-770. I have treated the last six or more cases which have been under my observation by the first method of administering digitalis, and in each case it has been successful, so that my present practice is to keep to this method of treatment. If, however, this should fail, the alternative method of digitalis medication may be adopted, and if this induces auricular fibrillation and the abnormal rhythm persists, the subsequent treatment is that of auricular fibrillation. If the alternative method of administering digitalis also should fail, the question of the employment of quinidine should be considered.

The treatment of auricular flutter occurring in thyro-toxic conditions has been referred to on pages 809-810.

NODAL RHYTHM

In nodal rhythm the stimulus for contraction arises in some part of the auriculo-ventricular junctional tissues, travelling upwards into the auricle and downwards into the ventricle, and giving rise to a simultaneous contraction of both auricle and ventricle. The contraction of both chambers may be absolutely synchronous, or the ventricle may begin after, or before, that of the auricle. In the first instance, the *a* and *c* waves of a polygraphic tracing are superimposed, in which case the amplitude of the wave is increased; in the second, the *a* wave precedes the *c* wave, but the *a-c* interval is diminished to about 0.10 sec. Nodal rhythm may occur without or with an appreciable degree of tachycardia. The former is rare. The latter may be persistent, or, more frequently, transient, the latter being one of the forms of paroxysmal tachycardia.

VENTRICULAR FIBRILLATION

Ventricular fibrillation has been observed. It may be induced experimentally by electric and other kinds of stimuli. Complete and abrupt closure of a coronary artery or one of its main branches, and the action of various poisons, including digitalis, may cause it. The experiments of Goodman Levy have shown that in the cat it is very apt to occur under light chloroform anæsthesia. The condition is preceded by a premonitory period, of varying length, of extra-systoles of special form. A certain number of electro-cardiograms showing ventricular fibrillation in the human subject have been published. Recovery in man is rare. It is believed that ventricular fibrillation is the immediate cause of sudden death in complete and

abrupt closure of a coronary artery or one of its main branches, in auricular fibrillation, and some—it may even be most—of the fatalities that occur in chloroform anæsthesia. Unlike auricular fibrillation, the condition is not influenced by increased vagal stimulation.

PAROXYSMAL TACHYCARDIA

Definition.—The term paroxysmal tachycardia is here employed to denote a condition, not uncommon, in which a marked acceleration of the cardiac rate occurs, which commences suddenly and abruptly and without apparent cause, lasts for a varying period, ceases suddenly and abruptly, and is due to an abnormal rhythm—the stimulus for cardiac contraction, instead of arising at the junction of the great veins with the auricle, having its origin at an abnormal point. The return of the cardiac rate to what it was prior to the paroxysm is due to the reversion of the cardiac rhythm to the normal. From the definition given, it will be seen that *paroxysmal*

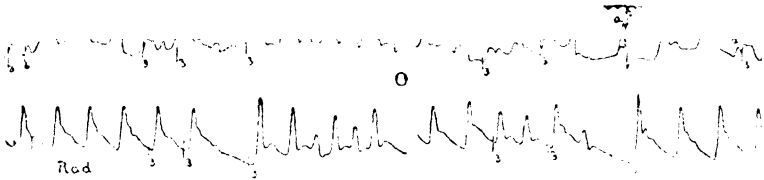

FIG. 61. — Simultaneous tracings of the jugular and radial pulses, showing the commencement and termination of a short attack of paroxysmal tachycardia, due to auricular fibrillation. The first six beats and the last three in the sphygmogram are regular and due to a normal contraction of the heart. The beats between occur during a period of auricular fibrillation. At *O* a period of 1.5 seconds has been cut out. (Mackenzie.)

tachycardia does not include acceleration of the cardiac rate associated with the normal or sinus rhythm. It should be noted that the nature of the abnormal rhythm is not always the same; in other words, the conditions which gives rise to the paroxysm of tachycardia varies. The point of origin of the new rhythm may be situated in the auricle (Fig. 111), or the auriculo-ventricular junctional tissues—either the auriculo-ventricular node, or the auriculo-ventricular bundle above its division into two branches—or in the ventricle below the division of the bundle (Fig. 112). When in the auricle, the cause of the abnormal rhythm may be transient attacks of auricular flutter with tachycardia (Fig. 59), paroxysms of auricular extra-systoles, or transient attacks of auricular fibrillation with tachycardia (Fig. 61). In the first instance, in the vast majority of cases the ventricle does not respond to each auricular contraction, partial heart-block being present. When the point of origin is situated in the auriculo-ventricular junctional tissues, there is a simultaneous contraction of both auricle and ventricle; the contraction of both chambers may be absolutely synchronous, or the ventricular systole may begin after, or before, that of the ventricle. The individual contractions of extra-systoles and those of the other forms of paroxysmal tachycardia are of the same nature, so that it is of importance to be able to compare the records

of the normal and the abnormal rhythms, especially one or both of the transitional stages; in the case of extra-systoles, the first contraction is premature and the last is followed by a long pause. In the case of auricular flutter, in the vast majority of cases the ventricle does not respond to each auricular contraction, partial heart-block being present.

The paroxysm of tachycardia may last only for a few beats, or may persist even for months; as a rule, it lasts for some hours, and only exceptionally does it continue for several weeks, and rarely for months. The patient may experience one attack, and never have another, or he may be subjected to many in the course of 24 hours, or the attacks may occur at varying intervals, frequent or long, for many years. Permanent auricular fibrillation or flutter may supervene.

Ætiology.—The ætiology of paroxysmal tachycardia is obscure. It may occur at any age after five, but usually first occurs during middle life. It appears to be more common in males, and this certainly agrees with my experience. A history of previous infection by rheumatism is not uncommon, and a fair proportion of cases are the subjects of valvular disease, particularly of mitral stenosis, or of myocardial degeneration; but no evidence of organic disease of the heart is found in a considerable proportion of cases. The condition has been noted in association with alimentary toxæmia, in reflex irritation, neurasthenia and other morbid states. Among exciting causes are physical exertion, emotional excitement, digestive disturbances—particularly flatulent distension of the stomach or colon, and in one of my own cases the adoption of a certain posture appeared to bring on the attacks.

Symptoms.—In some cases there is limitation of the field of cardiac response between the attacks, such as dyspnoea and præcordial distress on exertion.

It has been already noted that there is a sudden, abrupt and great acceleration of the cardiac rate, coming on without apparent cause, while at the end of the paroxysm there is a sudden and abrupt return to the rate and cardiac rhythm which preceded the attack. In some cases the patient is able to recognise the onset and termination of the tachycardia, while in others he is unable to do so. After the onset, the patient may be unconscious of the tachycardia, if the attack be brief; but, if it persist for any time, he usually becomes conscious of it, and generally complains of a fluttering sensation in the chest, this sensation being unlike that of palpitation. The patient may also experience a sensation of pulsation in the neck. His face is usually pale, and has an anxious expression. The cardiac rate is usually above 140 per minute, and may reach even 300; in a majority of the paroxysms it is between 150 and 190; it should be counted at the apex, either by palpation or auscultation—unless it is extremely rapid, when graphic methods are necessary. The pulse is of smaller volume than normal, and its character may resemble that of the pulsus celer. It may be quite regular, or very irregular when the condition is due to auricular flutter in which the response of the ventricle to auricular contraction is at irregular intervals, or *completely* irregular when the result of auricular fibrillation. A noteworthy feature is the frequent presence of pulsus alternans; but this can only very rarely be made out by the finger. The blood-pressure is generally lower during the attack. The area and force of the apex-beat may be increased. The jugular veins may be distended, and may show very rapid pulsation.

Analysis of the polygraphic tracings gives different results, according to the nature of the abnormal rhythm.

During the attack the common indications of cardiac failure may be present, their severity depending upon the cardiac rate, the duration of the paroxysm, and the integrity of the myocardium. In some cases, even when the paroxysm lasts for a day or two, there may be only some limitation of the field of cardiac response, with little, if any, cardiac dilatation, hepatic enlargement or dropsy: while, in long-continued paroxysms, and even in some cases in which the paroxysms last for only a few hours, cardiac failure may be extreme. As the amount of blood propelled from the ventricle at each systole is so small as to give rise to cerebral anæmia, the patient may complain of vertigo, and there may be from time to time attacks of faintness or even complete loss of consciousness. Cheyne-Stokes respiration is also not an infrequent symptom when the condition has lasted for some time.

The area of cardiac impairment may become considerably enlarged,—even within a few hours,—the first sound of the heart shortened, sharp, high and clear in pitch, the long pause is often shortened, while the rhythm of the sounds sometimes resembles that of a foetal heart, and if murmurs were previously present they alter in character or even disappear. There may be tenderness of the præcordium and hepatic area, the liver may be palpable and pulsating, ascites and general anasarca may occur, and the urine may become scanty, high-coloured and albuminous.

A remarkable and characteristic feature of the condition is that with the sudden reversion of the rhythm to the normal there is an extraordinarily rapid recovery to the state in which the patient was prior to the paroxysm: within a few hours there may, indeed, be no evidence of cyanosis, distension of the veins, cardiac dilatation, or enlargement of the liver. In some cases the cessation of the attack is accompanied by the passage of large quantities of wind, and excessive eructations, while a large quantity of urine may be voided. Death during the attack is uncommon.

Diagnosis.—The diagnosis of paroxysmal tachycardia is usually not difficult. The most important factors from the diagnostic point of view are: (1) The commencement and termination of the attack of tachycardia. The suddenness and abruptness of the onset and termination of the tachycardia are characteristic features—the maximum rate is attained within a few seconds, and the return of the cardiac rate to what it was prior to the attack occurs equally quickly; whereas in tachycardia associated with the normal rhythm the onset and termination are gradual. (2) The cardiac rate. A persistent rate of over 160 is almost invariably due to an abnormal rhythm, and a persistent rate of over 140 may be due to the same cause. Tachycardia of a rather less severe grade must certainly not be presumed to be due to an abnormal rhythm. (3) With the exception of those cases due to transient attacks of auricular fibrillation, the cardiac rate is not influenced by posture, physical exertion, emotion, pressure upon the vagus, or pyrexia, as is the case in tachycardia associated with the normal rhythm. Electrocardiographic examination will put the diagnosis beyond all doubt.

Prognosis.—The difficulty in forming a prognosis in any case of paroxysmal tachycardia is great. The prognosis may be considered from two standpoints:—(1) That of a particular paroxysm, and (2) the question of recurrence of the attacks. With regard to the former, it may be noted that death during an

attack is comparatively infrequent, although this may occur when the duration of the attack is prolonged. The points which should be taken into account in considering the prognosis of an individual attack are the ventricular rate, the duration of the attack, and the degree of cardiac failure present. When the ventricular rate is not very high, and there is little or no cardiac dilatation, and an absence of œdema of the lungs, hepatic enlargement and anasarca, the outlook is good as far as the risk to life is concerned; while, on the other hand, if the clinical picture be the reverse, the outlook is uncertain, although it should be remembered that the paroxysm may cease at any time, and there is no means of knowing when this may occur, and the patient improves with extraordinary rapidity.

With regard to the question of the recurrence of the attacks, it is impossible to give an answer. For in some cases the patient may never suffer from a second attack; while, on the other hand, they may recur even several times in the course of 24 hours, or at frequent intervals for many years, or, lastly, permanent auricular flutter or fibrillation may supervene even after a few attacks.

Treatment.—This resolves itself into two parts—(1) Prevention, if possible, of the recurrence of the attacks; and (2) treatment during an attack.

With regard to the first of these, the general condition, and whatever appears to be the exciting cause of the paroxysm, should receive close attention. Any gastro-intestinal disorder should always be corrected. Bromides may be tried. In a few cases in my experience the continuous administration of digitalis has proved effective. More recently I have employed 5 grains of quinidine sulphate once daily, in a number of cases, and it has been successful in most. Some workers employ about twice this dosage.

The results of treatment during the attacks are in the great majority of cases very unsatisfactory. It is true that the paroxysm not infrequently ceases when various remedies are applied: thus, bringing up of wind, the act of vomiting, the adoption of a certain posture, pressure upon the vagus—particularly the right, friction of the chest-wall, and local applications in the form of an ice-bag, mustard leaves, or warmth to the præcordium may be followed by relief. But it should be remembered that the nature of the disorder is to stop suddenly, and, therefore, the question of post hoc and propter hoc always arises. The patient should go to bed. If 5 grains quinidine sulphate once daily is being administered, the dosage may be increased (see p. 770). As far as my observations have gone, the remedy which offers most encouragement is strophanthin injected intravenously. Failing this, digitalis may be given by the mouth and pushed to the full physiological reaction. If there be indications of heart failure, such as dyspnoea, cyanosis or dropsy, treatment on the lines laid down elsewhere should be adopted. Bromide and chloral, or morphine may be tried.

FREDERICK W. PRICE.

CARDITIS: THE RHEUMATIC INFECTION OF THE HEART IN CHILDHOOD

Definition.—By carditis is meant inflammation involving the endocardium, myocardium and pericardium simultaneously.

Before dealing with endocarditis, myocarditis, and pericarditis individually, it may be advisable to discuss the rheumatic infection of the heart in childhood. This is a subject of the utmost importance, for by far the larger number of cases of heart disease under 30 years of age, and a considerable proportion of those of later life, are the direct result of this infection. And, notwithstanding the fact that this subject has received a great deal of attention, it is still not sufficiently realised that it is very easy to overlook a rheumatic infection in childhood, and, even when we are especially on the look-out for it, it is not infrequently very difficult to come to a definite conclusion whether the heart is affected or not. This is unfortunate, because the future welfare of the patient in large measure depends upon the adoption of sufficiently prolonged, careful and adequate treatment during the stage of infection.

In all probability the reason why infection of the heart by the rheumatic poison is so frequently overlooked, is that the clinical picture of acute and subacute rheumatism was originally drawn from the disease as it appears in adult life, the result being that many practitioners do not even now realise that rheumatism, as it appears in childhood, presents many and important points of difference.

It is important to bear in mind the following facts: In adult life arthritis is the chief manifestation of the rheumatic infection, and is looked upon as constituting a typical attack, while cardiac involvement is regarded as a complication. In children, on the other hand, arthritis is usually slight, and may be entirely absent, while affections of other parts are more frequent, and constitute a more conspicuous feature in the disease. Thus, sometimes the affection is confined to the tendons or the fascia in the neighbourhood of the joints, as, for example, the tendons of the hamstring muscles under the knee. Subcutaneous nodules, certain exudative erythematæ, and purpura rheumatica are more frequent manifestations of the rheumatic infection. Chorea is a common indication. Tonsillitis is, perhaps, more commonly of rheumatic origin than in adult life. Lastly, cardiac involvement is a much more frequent manifestation of the rheumatic infection in childhood than in adults; it is, at least, as frequent an indication of the rheumatic infection as any other, and should not be regarded as a "complication"; and it may occur in association with any of the foregoing, or with an indeterminate febrile attack, or alone—that is, it may be the only manifestation of rheumatism. Another point to bear in mind is that while endocarditis may occur acutely in children as it does in adults, it often occurs in a subacute and insidious form. There is not infrequently a total absence of subjective symptoms, which if present are often masked by other manifestations of the rheumatic infection. The diagnosis, therefore, rests largely upon physical signs, and the existence of the condition is frequently unknown or unsuspected until the heart is examined. The physical signs,

however, are not infrequently slight and vague in character, and the diagnosis is consequently often attended with extreme difficulty.

Now, if the foregoing be facts, it is clear that when a child complains of pain in the joints, muscles, or tendinous structures, or what are called "growing" pains; or has subcutaneous nodules in the tendons or round the joints, or subperiosteal nodules on the bones; or exhibits an erythematous eruption; or if there be a suspicion of chorea; or if he suffer from malaise and unexplained pyrexia; or complain of pain in the chest, or shortness of breath, or present marked pallor, he should at once be put to bed, and a systematic and most careful examination of the heart be performed daily, and if there be any doubt whether the heart is involved or not, the patient should be kept in bed till this has been set at rest.

ENDOCARDITIS

Definition.—By endocarditis is meant inflammation of the lining membrane of the heart. In the great majority of cases the inflammation involves chiefly the endocardium of the valves, and is not infrequently so limited. The term valvulitis is applied to endocarditis of the valves, while inflammation of the endocardium lining the cavities of the heart is referred to as mural endocarditis. The surface of the valves next the blood stream, namely, the ventricular surface of the semilunar valves and the auricular surface of the auriculo-ventricular valves, is affected. In adults the left side of the heart is far more commonly affected than the right, the mitral valve being more frequently attacked than the aortic; while, on the other hand, during foetal life the opposite is the case. Some degree of myocarditis is probably always present with endocarditis.

A satisfactory classification of endocarditis is not easy, that most commonly adopted being as follows: (1) Acute, (a) simple or benign, and (b) infective, ulcerative or malignant; and (2) chronic or sclerotic. It should be noted that it is impossible to draw a sharp line of distinction between these varieties on grounds of *ætiology*, pathology, or morbid anatomy. Clinically, however, the distinctive features of each are fairly marked, although even in this case the distinction is not absolute. E. Libman, following Osler and Horder, has recently described a *subacute* variety, ulcerative in its character (see Infective Endocarditis).

ACUTE SIMPLE OR BENIGN ENDOCARDITIS

Ætiology.—Acute simple endocarditis occurs most commonly in childhood and adolescence, and is rarely, if ever, a primary disease. Acute rheumatism is responsible for the great majority of cases, the onset of endocarditis occurring usually about the end of the first week. The association between the rheumatic infection and acute endocarditis has been previously dealt with. Chorea and scarlet fever are common causes of acute simple endocarditis; less frequently tonsillitis, pneumonia, small-pox, measles, chicken-pox, diphtheria, and other acute infective diseases; while Bright's disease, gout, diabetes, and pulmonary tuberculosis are also supposed to be responsible for a certain number of cases.

Acute simple endocarditis not infrequently occurs in individuals who are the subjects of the chronic or sclerotic form of the disease—the so-called recurring endocarditis.

Pathology.—In this form of endocarditis the parts affected become swollen, as the result of œdema and connective tissue proliferation, and cauli-flower-like or warty excrescences, varying in size from that of a pinhead to a bean, called vegetations, make their appearance on the segments of the valve or on the mural endocardium. The valvular vegetations are usually not situated at the extreme margins of the cusps, but at those parts which come into apposition during closure, namely, a short distance from their margins. The vegetations consist of blood platelets, leucocytes, and fibrin. Carey Coombs has found foci containing large multinuclear cells in the inflamed valves. Various micro-organisms have been described in association with the vegetations, but they are not present in large numbers in the acute simple form of endocarditis. Fragments may become detached from the affected valves, be carried by the blood to remote parts, and ultimately become impacted in a vessel; this process is known as embolism, and the impacted fragment as an embolus. This may result in obstruction of the circulation, and (1) necrosis, or hæmorrhage, or both, within the area of distribution of the occluded vessel, and the formation of infarcts; or (2) gangrene of the area supplied in the case of one of the larger arteries of the limbs. Infarction most generally occurs in the spleen or kidneys, although it is not infrequently found in the brain or its membranes, the retina, lungs (in right-sided endocarditis), intestines, and skin. In cerebral infarction, softening of the area supplied by the affected vessel takes place rapidly, while in pulmonary infarction localised pneumonia is a frequent sequel.

An attack of acute simple endocarditis may be followed by (1) resolution, a rare event; (2) organisation, which is the usual sequel; or (3) ulceration. When organisation occurs, it results in the formation of fibrous cicatricial tissue, which tends to contract as life advances, giving rise to various deformities of the valves and ultimately to permanent stenosis, or incompetence, or both.

Symptoms.—It has already been noted that while endocarditis may occur acutely in children as in adults, it often occurs in a subacute and insidious form. There is not infrequently a total absence of subjective symptoms, or, when present, they are often masked by other manifestations of the causal infection. Sometimes the onset is accompanied by a rise of temperature above that already existing, this increased pyrexia occurring without any increase in the arthritic symptoms in the case of rheumatism; the degree of pyrexia is usually not marked, but occasionally there is a sharp rise of temperature. There may be toxic rashes, in the form of urticarial erythema, erythema multiforme, or erythema nodosum.

The patient may suffer from palpitation, mild or severe; dyspnoea and præcordial distress may be also present, the former being usually not pronounced, while the latter generally takes the form of an uncomfortable feeling in the præcordium, not amounting to actual pain. Faintness, actual præcordial pain, and œdema are rarely met with until the affection is far advanced. In cases of severe carditis, however, in which great and rapid dilatation occurs, symptoms of marked cardiac failure may be present even

at the onset of the illness. The symptoms of embolism are discussed elsewhere.

The pulse is usually increased in frequency, and is in some cases irregular. The apex-beat may be tumultuous in character, and displaced outwards, and there may also be evidence of enlargement of the area of cardiac impairment transversely; these signs may occur very early in the disease. The first sound at the mitral or aortic area, according to which of these valves is affected, may become slightly prolonged, or roughened, or may exhibit a lack of clearness; within 24 hours it may be accompanied by a distinct murmur, soft and blowing in character, the cardiac sound, however, not being abolished. The murmur is strictly limited to either area. In the case of mitral incompetence, the pulmonary second sound later on becomes accentuated, and may be reduplicated. In the case of the aortic valve, the second sound may become altered, and a soft, blowing, diastolic bruit may subsequently develop; the latter, however, is of much less frequent occurrence during the course of the illness. Reduplication of the second sound and slight accentuation of the first sound at the apex are believed to be early signs of mitral stenosis. A soft, blowing, diastolic bruit in the mitral area is rarely heard during the course of the illness. A mitral presystolic murmur and a short, sharp first sound do not usually make their appearance until some time after the onset of the rheumatic infection, the mitral orifice having become permanently stenosed.

Diagnosis.—The diagnosis of acute simple endocarditis is often a matter of great difficulty. We should suspect its existence in those cases in which there is an increase in the degree of pyrexia without any aggravation of the joint symptoms during the course of acute rheumatism, or when pyrexia persists without any ascertainable cause; or when there is palpitation, dyspnoea, acceleration or irregularity of the pulse, together with the existence of a murmur not previously present.

Increased frequency of the pulse-rate, provided other causes can be excluded, is of considerable diagnostic importance. The same can also be said of the sudden appearance of partial heart-block; it is important, therefore, to be on the look-out for an intermittent pulse, and, if this be found, to ascertain whether it is due to the presence of extra-systoles which fail to reach the wrist or to partial heart-block, as the latter occurring during the course of infectious disease is a sign, and may be the only sign, of myocardial involvement, with which endocarditis is usually associated. The differential diagnosis between extra-systole and partial heart-block has been previously dealt with. When the apex-beat is tumultuous in character it is suggestive of involvement of the endocardium or pericardium. Displacement of the apex-beat and evidence of enlargement of the area of impairment transversely are not necessarily indicative of acute endocarditis, as a certain degree of cardiac dilatation is met with in most of the acute fevers, as the result of toxæmia or anæmia. Neither does a recently developed mitral systolic murmur necessarily indicate endocarditis, for it may be due to anæmia or to simple dilatation. A preliminary prolongation, roughening, or want of clearness of the first sound at the mitral or aortic area is strongly suggestive of valvulitis, as is also the early appearance of the murmur; a murmur which is due to anæmia or to simple dilatation of the left ventricle does not usually make its appearance in the early stages of rheumatism. An aortic systolic is not so

suggestive of acute endocarditis as a mitral systolic murmur, while a pulmonary systolic murmur may be almost disregarded. In acute endocarditis the murmur is definitely limited to the mitral or aortic area. The character of the murmur is of some diagnostic value, a soft blowing, in contrast with a harsh, murmur being in favour of endocarditis. Accentuation of the second sound in the pulmonary area later on in the illness is also suggestive of mitral incompetence. An altered second sound, with later on a diastolic murmur, in the aortic area is indicative of involvement of the endocardium; the latter, however, is rarely heard during the course of an acute illness, and practically never during its early part. The early signs of mitral stenosis have already been noted.

It is necessary to distinguish the murmur of acute endocarditis from that due to previously existing valvular disease. The existence of subcutaneous nodules or pericarditis, the sudden appearance of partial heart-block (indicative of coincident acute myocarditis), or the appearance of new murmurs or the disappearance of old ones, is in favour of a fresh attack of acute endocarditis, whether simple or infective. Embolism is not pathognomonic of acute endocarditis, as it may occur in chronic valvular disease, especially in mitral stenosis. In acute endocarditis, however, it is not infrequently multiple and recurrent, and is of more usual occurrence in the systemic than in the pulmonary circulation.

If acute endocarditis occur in an individual already the subject of valvular disease, the murmur is not of recent development, it is often loud or harsh, audible over a considerable area, and evidence of cardiac enlargement is usually present.

Prognosis.—The immediate prognosis of acute simple endocarditis is, as a rule, favourable, death being of rare occurrence; this may happen, however, if there be accompanying pericarditis or severe myocarditis. With regard to the ultimate prognosis, it has been pointed out that complete resolution in all probability rarely occurs. Organisation is the usual sequel, ultimately giving rise to permanent stenosis, or incompetence, or both; in a certain percentage of these cases, the early murmur may disappear, and a permanent murmur may not become established until much later on, even several years. It should be noted that the future prognosis of a case of acute simple endocarditis largely depends upon whether convalescence is sufficiently prolonged. In a certain number of cases, ulceration of the valve results.

Treatment.—The management of a case of acute simple endocarditis is of great importance, especially with regard to the future of the patient. When there is no doubt that the heart is affected by rheumatism, suitable anti-rheumatic treatment should be adopted. In the opinion of some, salicylates should be avoided when there is undoubted cardiac involvement, in the belief that when given for considerable periods they depress the heart and cause further dilatation. I myself do not share this view. Some prefer iodides, given in full doses over considerable periods. When the cause is other than rheumatism, such as diphtheria, this should be treated.

In all cases, whatever the cause, we should endeavour to arrest the morbid process as early as possible, and to give the heart the best chance of the fullest possible repair. Absolute rest in bed is indispensable. In grave cases, the

foot of the bed may, with advantage, be raised to the extent of 1 or 2 feet. At no stage in the management of a case should the heart be allowed to work beyond the limit of its capacity. In the majority of cases, absolute rest in bed is necessary for 3 months, and in some cases the period should be even longer. The patient should remain in the recumbent posture for at least a month after the fever has subsided. If tachycardia, or irregularity indicative of partial heart-block or of auricular fibrillation, or if pulsus alternans be present, this period should be prolonged, even to 3 or 4 months. During this time he should on no account be allowed to sit upright in bed or to get out of bed for an action of the bowels. Afterwards, the amount of exertion should be most carefully graduated. At first, an extra pillow may be allowed. A few days later, the back may be slightly raised, and this may be gradually increased until the patient is moved to a couch, to which he should be confined for a further period of 3 months. After the first 2 or 3 weeks of this period, massage, at first very gentle and for short periods only, and gradually increased, may be allowed; and during the latter 6 weeks, active movements may be enjoined, and the patient may be gradually allowed to sit up. Later, slight walking exercise may be permitted. For some months later, great care should be exercised with regard to exertion, and the patient should be given rules as to the amount and kind of exercise; for, on the one hand, exercise may do much harm unless carefully regulated, while, on the other, in moderation it is of great value. If, during any of these stages, exertion be accompanied or followed by breathlessness, palpitation, a sense of fatigue, præcordial pain or distress, or unduly increased frequency of pulse, the patient is doing too much and the amount of exertion must be reduced.

The diet should be light, small in bulk, yet highly nutritious, and preferably solid. The daily amount of fluid taken by the mouth should be restricted to 2 pints per diem. Saline infusions per rectum, or in grave cases intravenously, may be used. Strict attention should be paid to the condition of the bowels. The internal administration of iodide of sodium in the later stages is employed by some. Dr. Caton recommended small blisters applied repeatedly to the præcordium; I myself have been disappointed with the results so obtained. Mustard leaves may be used in a similar manner. Alcohol, of which the best forms are good old brandy or champagne, should not be given unless there is much exhaustion, dyspnoea, cyanosis, or an unduly rapid pulse; in these cases, oxygen may also be employed. The amount of alcohol required of course varies with each individual case; it is well to begin with 2 or 3 ounces of brandy per day, gradually increasing the quantity as required, and leaving it off by degrees as the patient improves. Other diffusible stimulants, such as ether and ammonia, may be used. Camphor and tincture of musk are employed a good deal on the Continent. Strychnine has a great reputation in the treatment of cardiac failure due to associated acute myocarditis. It may be tried when there is great exhaustion. In my opinion, it is much better given hypodermically; in urgent cases up to $\frac{1}{100}$ th grain, or even $\frac{1}{200}$ th grain, every 2 hours. Adrenalin, pituitary extract, and ergot are advocated by some in cases in which the blood-pressure is very low. The results of the administration of the digitalis series of drugs are, as a rule, very disappointing; the response is usually very slight, if at all, whether auricular fibrillation is

present or not. In suitable circumstances quinine may be administered, and, if anæmia be present, iron and arsenic may be prescribed.

The treatment of symptoms has, in the main, been dealt with previously. For præcordial pain or distress a hot linseed poultice may be applied to the præcordium; if this fail, the continuous application of an ice-bag may be tried, as recommended by Lees. Dover's powder (10 to 15 grains), or, if necessary, morphine, may be given by the mouth. In less acute pain, a fly-blister is not infrequently efficacious. Sleeplessness and other symptoms should be treated as described elsewhere.

It is well to examine a patient who has suffered from acute endocarditis at regular intervals after the attack, and careful inquiry should be made as to his mode of life. In children, we should be especially on the look-out for any rheumatic manifestation, and, as soon as detected, the condition should be immediately and adequately treated.

FREDERICK W. PRICE.

INFECTIVE ENDOCARDITIS

Synonyms.—Ulcerative Endocarditis; Malignant Endocarditis.

Objections have been raised against each of these names: that all endocarditis is infective, that ulceration is not invariable, and that some cases recover. But that some distinctive name is necessary to mark off a disease-process which is quite different from "simple" or "rheumatic" endocarditis is generally recognised. The assertion frequently made, that no sharp line of demarcation can be drawn between simple and ulcerative endocarditis, though true, does not dispose of the fact that in the great majority of cases the distinction is of fundamental importance and not very difficult of recognition.

The disease has an importance somewhat out of proportion to its frequency, partly on account of its great gravity and partly on account of the difficulties which often beset the diagnosis. The incidence of the disease in the wards of a large general hospital is about 1 in 170 cases.

Ætiology.—*Relation to rheumatism and other diseases.*—In more than half of all cases of the disease there is a clear history of acute or subacute rheumatism or of chorea. In the majority of these cases the patient has suffered from rheumatic endocarditis some time previous to his present illness, and has been left with definite and recognised valvular disease; in a few the condition of rheumatic endocarditis has passed directly, but often imperceptibly, into that of the ulcerative condition. Usually the interval between the occurrence of the rheumatic fever and the onset of ulcerative endocarditis is measured by several years, and these have been for the most part years of good general health. To those few cases in which the transition between the rheumatic endocarditis and ulcerative endocarditis is a gradual one the term "malignant rheumatism" has been applied by some authorities. But the term introduced confusion in respect of the bacteriological questions involved, and is perhaps on this account to be avoided. Next in frequency to the rheumatic group of diseases in the patient's history, but insignificant in comparison, are scarlet fever, gonorrhœa, influenza, typhoid fever, malaria, syphilis, Graves' disease, dysentery and pneumonia.

Influence of congenital defects.—A congenital defect in the heart pre-dis-

poses it to infection, apparently through the medium of that chronic thickening of the endocardium which is often found in connection with these defects.

Other ætiological factors.—Strain is present in some cases as a definite causative factor, either as leading to the original valve defect, or as determining the onset of the ulcerative endocarditis in an old-standing case of valvular disease.

Age.—The chief incidence is between the ages of 15 and 50. Out of 150 cases collected by the writer 122 occurred between these ages. One-half of all the cases occurred between 20 and 40, no doubt on account of the predisposition created by the presence of sclerosis of the heart valves after acute rheumatism, the chief age incidence of which is a decade earlier than this. The youngest case of the series was that of a child aged $2\frac{1}{2}$ years, the subject of congenital heart defects. The oldest cases were those of a woman aged 64, and of a man aged 63, both of whom developed pneumococcus endocarditis with lobar pneumonia.

Sex.—This does not appear to be a determining factor.

Pathology.—The essential pathological condition in infective endocarditis is a progressive microbic infection of one or more of the heart valves, or of the mural endocardium. *The infecting micro-organisms*, as judged by positive blood cultures during life rather than by post-mortem investigations, are very variable. An analysis of 40 cases of the disease in which positive blood cultures were made during life showed streptococci in 26, pneumococci and Pfeiffer's bacillus in 5 each, gonococcus in 2, *Staphylococcus albus* in 1, and an unclassified micro-organism of bacillary form in 1. If post-mortem results are taken, *Staphylococcus aureus* bulks largely in the analysis and the pneumococcus is represented more frequently. A few other organisms, relatively unimportant, also appear—*B. typhosus*, *B. coli* and *B. diphtheriæ*. Streptococci are certainly the most common organisms concerned, and the characters of those members of the group found in this disease deserve special attention. If we except acute cases due to *S. pyogenes*, the type of streptococcus most often found is not highly pathogenic, but of low virulence, such as are found in normal fæces and in normal saliva. They are for the most part short-chained cocci, not lethal for mice, and they yield a set of biochemical reactions that mark them off quite sharply from *S. pyogenes*. These facts harmonise with certain broad clinical and pathological observations and serve to explain them: the chronicity of many of the cases, and the latency of others; the scanty leucocytosis often seen; the æcbrile periods not infrequently present; the absence of suppuration in the embolic infarcts which is such a feature of the disease; the absence of any visible focus of infection in the great majority of the cases; the enormous number of living micro-organisms that may be present in the blood stream at a time, it may be, when the patient is not acutely ill. The writer has shown that it is not difficult to set up a condition of infective endocarditis in the rabbit by the intravenous injection of "saprophytic" streptococci from healthy human saliva and fæces.

The condition of infection once established in the endocardium, a state of "arterial pyæmia" results, the circulation being fed by micro-organisms from the infected area. Minute vessels become plugged by masses of these microbes. Larger emboli, formed of pieces of the fungating vegetations, and of various sizes, add to the pyæmic process. Destructive and vegetative

processes proceed together at the site of infection, which spreads to adjacent structures in the heart, both by contact and by direct extension.

Symptoms and Course.—The disease may be *latent*, and only discovered post-mortem. It may be *fulminating*, in which case it may be suspected, but rarely diagnosed. In the fulminating cases the infection is usually by *S. aureus*, and the ulcerating endocarditis is only one part of the *S. aureus* pyæmia. Such is the endocarditis complicating acute osteomyelitis, and that seen in very acute pyæmia resulting from *S. aureus* infections of the skin. Neither the latent nor the fulminating forms need be further dealt with here. The more important types are the *acute* and *subacute*.

The acute form.—The onset is usually abrupt, often with a rigor, and the symptoms are those of an acute specific fever. Pain in, and swelling of, joints is common, with acid sweats, often leading to a diagnosis of rheumatic fever and calling for the use of salicylates. Not infrequently the failure of response to full doses of salicylates is the first observation to throw doubt upon the diagnosis. The pneumococcus cases are generally of this type, pneumonia or pleurisy with effusion being usually present; the patient remains very ill after the eighth day of his disease, infection of the endocardium being perhaps the most serious cause of absence of crisis. Gonococcus infection is also usually of this form. The duration of the acute cases is from 7 to 30 days. A very few cases undoubtedly recover.

The subacute type ("Subacute bacterial endocarditis").—This is probably the most common type of the disease. Attention has of late years been drawn to it by Osler, Horder, Libman and others. The onset is gradual, often insidious, so that it may not be possible to determine with accuracy when the disease began: it seems certain that in many of the cases the process of endocardial infection has existed much longer than is suspected. The initial symptoms are general weakness with anæmia, or a condition somewhat resembling subacute rheumatism, or fever which is unexplained by the physical signs. The duration of these cases is very variable; from 2 to 6 months includes the majority of them; but a few may last for 12 months or even longer. The infecting micro-organisms are streptococci of the faecal and salivary type (*Streptococcus viridans*, *Streptococcus endocarditidis*). Pfeiffer's bacillus and occasionally the pneumococcus. In some of these cases the pre-existing valve lesion is very slight, although its presence is generally known if the patient is of the private class.

The heart.—In the great majority of cases signs of valvular disease are present at the outset. In a few cases these signs appear during the course of the disease. Rarely, there may be no evidence of valvular disease at any time: this experience is almost confined to cases in which the infection is of a terminal kind, occurring in patients who are too ill to admit of thorough examination, or in whom there is early and considerable dilatation of the heart. As the disease progresses it is common to get evidence of the involvement of other valves than the one originally infected, such as the appearance of signs of aortic regurgitation in a case originally one of mitral disease. Undue importance is perhaps attached to changes heard in the character of the murmurs from day to day. When the heart symptoms are prominent, the case is said to be of the "cardiac type," and such a clinical picture does quite commonly present itself: in which event the patient has, in most instances, been a heart invalid for some time previously. But in a con-

siderable proportion of the subacute cases it is a striking thing that the heart shows little recognisable defect, at least for a considerable time. For the greater part of its course it may be said that subacute bacterial endocarditis is very largely destitute of cardiac symptoms. Arrhythmia, signs of restriction of the field of cardiac response to effort, and the results of so-called decompensation—not only may all of these be conspicuous by their absence, it is unusual to see them.

Embolism.—This event is extremely common and constitutes one of the cardinal signs of the disease. *The importance of the search for emboli and their effects in a suspected case cannot be over-estimated.* But to obtain an adequate conception of the disease-process here considered it is necessary to enlarge considerably the earlier notions of the embolic process in two directions: the diffuseness of the embolic site and the minuteness of the embolic fragment. The skin shows two distinct lesions, both highly characteristic of the disease—(a) Petechiæ, varying greatly as to their number in different cases—there may be no more than two or three, and only discovered after careful search, or there may be a great number, presenting an appearance as though the patient has been flea-bitten. (b) Discoloured areas, usually tender, and most often affecting the terminal phalanges, coming and going in the course of a few hours or days. The appearance of one of these red areas is often accompanied by sudden pain or acute tenderness on pressure. These lesions are of considerable diagnostic importance. They do not occur in rheumatism.

In the kidney there may be gross embolic events leading to infarction and hæmaturia. Of equal if not of greater importance is the occurrence of very minute microbic embolisms in the glomeruli, leading to the appearance of red blood cells and traces of albumin in the urine, and ultimately to a state of true glomerular nephritis, demonstrable under the microscope post-mortem (Bähr; Gaskell). The retina may be affected, exploration of the fundus revealing hæmorrhages. One of the most common seats of emboli of the massive kind is the spleen, leading to enlargement and usually a palpable organ. Acute and severe pain may concur with the event, and friction, due to perisplenitis, may be heard. The brain may suffer, the most common result being hemiplegia. The embolus may lead to infective arteritis, with aneurysm formation and hæmorrhage which may be abruptly fatal. The vessels of the limbs are frequently involved, either the main artery or, more often, their branches, and especially the radial and posterior tibial. Here, again, aneurysms may develop, and gangrene occasionally.

Pyrexia.—Fever is present in nearly all the cases, perhaps in all at some time or other in the course of the disease; but occasional afebrile periods may occur, lasting from 2 or 3 days up to a fortnight, in the subacute cases. In the acute cases a high continued fever is not uncommon, and when this is so the patient is highly toxic and asthenic and the heart symptoms are apt to be in abeyance ("typhoid type"). Irregular remittent fever is the most common form, both in the acute and in the subacute types. A high and regular quotidian intermittent fever is not uncommon—the gonococcus cases are particularly prone to this variety of fever. Rigors are common in the fulminating and acute cases; they also occur in subacute cases when embolism is rife. Whatever the form of the fever the temperature is apt to take a lower range shortly before death. *A fall in the temperature, the patient remaining very ill, is of no service and must not be taken for a good prognostic.*

Such a fall of temperature may occur when signs of renal inadequacy supervene.

The blood shows a progressive and ultimately severe anæmia. The degree of leucocytosis varies with the type of the disease. In acute cases it is generally high (20,000 to 40,000), though this, again, varies with the degree of the patient's response to the infection. In the subacute cases the leucocytosis is rather remarkably constant about the figures 9000 to 12,000. Blood cultures are extremely important in the matter of diagnosis. And yet it not uncommonly happens in the subacute cases that the diagnosis is certain and no growth of micro-organisms is obtained. Of this apparent anomaly we do not at present possess the explanation. The hypothesis that such a state of things indicates that the microbe has died out does not perhaps take sufficient cognizance of the peculiar difficulties seen in the cultivation of certain of the streptococci found in association with the disease. In the great majority of cases, however, positive blood cultures are obtained, given proper technique.

General state.—Loss of flesh is invariable, but rarely a marked feature. Pains are common, and are usually arthralgic in character; they are prone to develop suddenly, are rarely accompanied by effusions, and when severe, are most often due to embolic events. The complexion in the subacute cases tends to a *café-au-lait* tint, which is a point of diagnostic value to the trained eye. Clubbing of the fingers is very common, quite apart from the influence of possible old-standing valvular disease. The patients are often singularly optimistic concerning themselves. Libman lays stress upon areas of deep tenderness about the lower end of the sternum and the sterno-costal junctions. Albuminuria is very common, tending to increase with the progress of the disease, and doubtless associated with the glomerular nephritis to which reference has already been made.

Modes of Termination.—1. *Recovery.*—A rare event, yet one which certainly occurs at times, even when the diagnosis is beyond doubt. It is probably less rare in the acute than in the subacute type.

2. *Death.*—Out of 149 cases studied by the writer, the recorded terminal events occurred in the following order of frequency: heart failure (66), coma (23), sudden death (19), uræmia (18), exhaustion (8), hyperpyrexia (2). Cases dying in coma were for the most part those in which cerebral embolism, with or without hæmorrhage, had taken place. Sudden death was due to perforation of a valve cusp, rupture of aneurysms in the sinus of Valsalva, perforation of the interventricular septum and cerebral hæmorrhage.

Diagnosis.—Evidence of endocarditis, the occurrence of multiple arterial embolism, and the isolation of micro-organisms from the blood stream: the coexistence of these three facts makes the diagnosis of infective endocarditis indubitable. But, as has already been remarked, the diagnosis may sometimes be made quite confidently in the absence of a positive blood culture in certain of the subacute cases. Seeing that the prognosis is so serious, it follows that a diagnosis of infective endocarditis should never be made unless convincing evidence be forthcoming. In the differential diagnosis the following diseases call for consideration:

1. *Pneumonia.*—There may be considerable difficulty here, seeing that consolidation of the lung is usually present in pneumococcus infection of the endocardium. Care must be exercised, because hæmaturia and splenic enlargement in a case of pneumonia do not necessarily imply infarction.

Nor does a positive blood culture in pneumonia necessarily mean endocarditis. But petechiæ, and the presence of emboli in arteries, in a case in which signs of valvular disease and a positive blood culture are present, justify a diagnosis of ulcerative endocarditis.

2. *Typhoid fever*.—A positive Widal test with a leucopenia may be regarded as almost decisive in favour of typhoid fever. Typhoid infection of the endocardium is very rare.

3. *Rheumatic fever*.—The recurrence of acute rheumatism in a patient who has previously developed valvular disease often gives rise to considerable anxiety on account of the similarity which may exist between the symptoms present and those of pyogenic infection of the endocardium. The rheumatic process may spread itself over several months, salicylates notwithstanding. These difficult cases usually occur in children between the ages of 10 to 16 years. Endocarditis is always present, and often there is pericarditis, or pleurisy, or both. There may be considerable loss of flesh and marked anæmia. The form of the temperature chart rarely affords help. The facts which help to exclude ulcerative endocarditis are the presence of nodules, or of chorea, and the absence of petechiæ, of hæmaturia, of enlarged spleen, and especially of micro-organisms in the blood stream.

4. *Peliosis rheumatica* may cause even greater difficulty, but the condition is uncommon. The association of fever, purpura, anæmia, albuminuria and joint pains in a case of old-standing aortic regurgitation under the writer's care naturally raised fear of infection of the damaged valve cusp. But the purpuric spots and the joint pains were bilateral and symmetrical, there were ecchymoses in addition to the petechiæ, there were effusions into the joints, and blood cultures yielded no growth.

5. *Malaria*.—The resemblance is but superficial, owing to the fact that in some cases of infective endocarditis the fever may be markedly intermittent, and rigors with heavy sweats may occur. The absence of malarial parasites in the blood and the absence of leucopenia are much against a diagnosis of malaria.

6. *Tuberculosis*.—General tuberculosis may be closely simulated by acute ulcerative endocarditis with continued fever when the heart signs are equivocal. But there is leucopenia in general tuberculosis, a sterile blood stream (on repeated culture), and signs of embolism do not occur. Sometimes cases of infective endocarditis find their way into sanatoria for the treatment of phthisis, on the ground that they are cases of "phthisis without physical signs."

Prognosis.—As has already been stated, recovery occasionally takes place in the acute, and still less frequently in the subacute form of the disease. All the same, the diagnosis once definitely established, the outlook is of the gravest, treatment notwithstanding. That the patient is very little affected in general health, that he is extremely hopeful concerning his condition, that the state of the heart in itself gives no cause for concern and that the number of micro-organisms per c.mm. of blood has fallen very considerably—none of these things should tempt the physician to abate anything from the serious view he takes of the case. Periods of improvement often occur, with or without special lines of treatment, but the fatal issue seems only to be delayed. It is very difficult to surmise the length of time the patient will live after the diagnosis is made. If there are already present

the signs either of renal or of cardiac failure the end is not far off: weeks measure it. Otherwise, developments may proceed quite slowly, and the patient may live some months. But there remain to be reckoned with the various accidents attending upon the dissemination of the endocardial vegetations, or the ulceration of the valves, either of which accidents may bring about a speedy termination. Not seldom, when it seems certain that the course of the disease has been checked, death, more or less sudden, and due to some purely mechanical cause, cheats the physician and those who watch his efforts.

Treatment.—**PREVENTIVE MEASURES.**—Reference has been made to the undoubted fact that the source of the infecting agent in most cases is the mouth or intestine. This suggests that special attention should be directed to these regions in all persons who are the subjects of valvular disease. Oral sepsis of all sorts should receive treatment. Dead teeth, crowned or not, should be sacrificed. Septic tonsils should be removed. The condition of the intestinal tract should be investigated, and measures adopted to lower the content of streptococci if this appears high.

CURATIVE.—The general (non-specific) measures adopted in the treatment of all cases of septicæmia are applicable here: plenty of fresh air and light, good food frequently administered, and hæmatinic drugs for the anemia. The writer considers that open-air treatment, as for cases of pulmonary tuberculosis, should be adopted whenever possible. The various measures that have from time to time been tried in order to inhibit the bacterial factor in the disease are the following:

Chemical antidotes.—"Blood antiseptics" have, as a rule, proved very disappointing in the history of the treatment of septicæmia. Quinine, mercury, arsenic, carbolic acid, formalin, the sulpho-carbolates and many others, whether administered by mouth, subcutaneously or intravenously, lead to no results worth recording. Salvarsan and its equivalents, given intravenously, have not, in the experience of the writer, justified further trials, and these remedies are not without immediate disasters in the matter of the production of embolism. Silver salts, in combination with nuclein, and colloid silver preparations, have their advocates; so also has yeast; but it does not appear that any of these remedies has a recovered case to its credit. More recently, one or other of the hypochlorite solutions has been used intravenously, following some promising results in surgical cases of septicæmia. The writer has seen three cases so treated, and although there was apparent improvement in two of the cases, there was no cure. Mere absence of fever, as already remarked, is of no benefit if the general state of the patient is not improved. In one of the cases there certainly was an afebrile period of some 12 to 15 days after the treatment (by eusol), but during all this time the patient's general condition was worse than it had been just prior to the injection. The technique is simple: from 200 to 500 c.c. of a 0·05 per cent. solution of the drug in normal saline is given slowly as an intravenous injection. In one case the writer tried the effect of a saturated solution of ether in normal saline. When considering these methods of "irrigation" of the blood stream it should be remembered that the condition to be combated is not merely one of free bacteria in the circulation—there is also a very great deposit of bacteria lying in the sub-endothelial tissue of the endocardium.

Anti-sera.—As most cases of infective endocarditis are of streptococcal origin, it was hoped that the use of anti-streptococcus serum might lead to cure. The result of a good many trials has been very disappointing. Nor has the use of an autogenous serum, as first attempted by the writer in 1904, led to any better result. The same may be said in general of the use of anti-pneumococcus serum in the pneumococcus cases.

Inoculation.—The experience of vaccine therapy in this disease is not much more cheering than that of serum therapy. Certainly the use of "naked" vaccine has on the whole been singularly disappointing. The writer has not had a case so treated which recovered, although he has seen periods of marked and prolonged improvement which he felt could be attributed to the vaccine. Latham and Hunt have put on record a streptococcus case which recovered after the administration of vaccine *per os*. The writer considers the most hopeful method to be by the employment of sensitised vaccine, augmented in its action by the use of liberal quantities of an autogenous serum whenever this can be obtained. In conjunction with Hemsted the writer described a case of considerable duration treated successfully in this manner. The infection was in this case grafted upon a congenital heart lesion.

Transfusion sometimes acts as a very useful adjunct to whatever specific measures are being employed.

It would seem that we still lack a scientific method of control of the disease process by any of the measures yet adopted. It seems certain that cure can only come through inhibition of the bacterial growth in the endocardium, and not merely through cleansing the circulating blood of micro-organisms. This, and a method of detaching the thrombi which hang from the valve cusps in such a fine state of subdivision that no vessel of conspicuous size is obstructed by the particles cast into the blood stream, constitute the therapeutic problem with which the physician is faced. The chief hope would seem to lie in establishing the diagnosis at a very early date so as to employ whatever measures promise success before the vegetations have attained any size and the sub-endothelial colonisation has become established.

THOMAS HORDER.

CHRONIC OR SCLEROTIC ENDOCARDITIS

Chronic endocarditis is a sclerosis of the valve, and may be (1) secondary to the acute—especially the rheumatic form, which is the more common event or (2) primary.

Ætiology and Pathology.—When the condition is the result of a previous attack of acute endocarditis, it is more apt to occur in earlier life, the mitral valve being more commonly affected; while if it is primary it is more apt to occur in middle or later life, the aortic valve being more commonly affected than the mitral.

With regard to the ætiology of primary chronic endocarditis, heredity is certainly a factor, and the condition is more common in males, and during or after middle life. Prolonged muscular or mental strain, over-indulgence in food or drink, auto-intoxication—especially from the teeth, the tonsils, and the colon, the various forms of chronic rheumatism and gout, chronic

metallic poisoning—particularly that due to lead, and supernormal blood-pressure are among the most common causes. Chronic renal disease probably has no direct relation with primary chronic endocarditis, but the associated high blood-pressure is an important causal factor. With regard to syphilis, see pages 888–889.

When organisation occurs in acute simple endocarditis, the result is the formation of fibrous tissue, which tends to contract as life advances, and as a result there may be thickening, shortening, puckering, chronic vegetations, coalescence of two or more segments, cartilaginous changes, or calcification of the valves; there may also be shortening and thickening of the chordæ tendineæ and apices of the papillary muscles. These structural changes ultimately give rise to permanent stenosis, or incompetence, or both, and there is a tendency in these cases to recurrent attacks of valvulitis, resulting in still greater deformity.

In primary chronic endocarditis there is sclerotic thickening of the endocardium, often occurring in patches, and frequently associated with fatty or calcareous changes, to which the term atheroma is usually applied. There may be thickening, small nodular prominences, shortening, puckering, coalescence of two or more segments, and calcification of the valves; the chordæ tendineæ and apices of the papillary muscles may also be affected. These structural changes also ultimately give rise to permanent stenosis, or incompetence, or both.

Primary chronic endocarditis is frequently associated with atheroma, which may be widespread. When it affects the aortic valve it may be limited to the valve, or, as is more frequently the case, may also affect the walls of the aorta. In the latter event, diffuse dilatation of the aorta may follow; and the neighbourhood of the mouths of the coronary arteries is often involved, frequently resulting in narrowing or occlusion of one or both of these vessels (see page 860).

It may here be noted that foetal endocarditis is usually of the sclerotic form, the right heart being more commonly affected than the left.

Symptoms.—Primary chronic endocarditis produces no symptoms until a certain degree of structural changes in the valves has taken place, when stenosis, or incompetence, or both occur.

FREDERICK W. PRICE.

CHRONIC VALVULAR DISEASE

Definition.—By chronic valvular disease is meant a chronic affection of the cusps of the cardiac valves, or of the orifices, or both. Not only may the orifices and cusps be affected, however, but also the chordæ tendineæ and the muscoli papillares. In many cases the cusps are only secondarily affected; to illustrate this it may be mentioned that incompetence of a valve may be due entirely to dilatation of its orifice, or, in the case of the auriculo-ventricular valves, to an affection of the muscoli papillares or chordæ tendineæ. Whatever the nature and form of the valvular lesion, it gives rise to stenosis or narrowing, which results in obstruction to the flow of blood; or to incompetence, which allows of regurgitation; or frequently to both of these together. Along with the

valvular lesions there are usually coincident changes in the cardiac musculature, the aorta, or coronary arteries.

THE RELATIVE PROPORTION AND THE COMBINATIONS OF THE DIFFERENT VALVULAR DISEASES.—It should be noted that not infrequently more than one valve is involved at the same time, especially in the case of rheumatic valvular disease.

If we include what is termed the *relative variety* of incompetence, tricuspid incompetence will be found to be the most common chronic valvular disease. If this be not included, the mitral is the valve most commonly affected, accounting for half the number of the cases of chronic valvular disease, incompetence of this valve being more frequent than stenosis. When mitral incompetence results from a previous attack of acute endocarditis, there is usually some degree of stenosis as well; when it is due to causes other than lesions of the cusps, it is often associated with tricuspid incompetence. Pure mitral stenosis is comparatively infrequent; in the process of thickening and contraction, there is usually some degree of incompetence.

In the majority of cases of aortic disease a double murmur is present; but this does not necessarily indicate the presence of stenosis as well as of incompetence, for there are other causes of an aortic systolic bruit besides aortic stenosis. Aortic regurgitation is very common; a greater or less degree of stenosis, however, not infrequently accompanies the incompetence. Pure aortic stenosis, on the other hand, is one of the rarest of valvular affections. Tricuspid incompetence is the most common form of right-sided valvular affections. It is rarely primary, however, and then stenosis is usually present with it, and also mitral or aortic disease, particularly the former. Tricuspid incompetence is a common result of mitral disease, there being no lesion of the cusps, but *relative* incompetence of the valve. When tricuspid incompetence occurs alone, it is in all probability congenital. Tricuspid stenosis is extremely rare. Though murmurs with their area of maximum intensity at the pulmonary area are common, disease of the pulmonary valve is rare, and is usually of congenital origin. Pulmonary stenosis is one of the most frequent forms of congenital heart disease, and is usually associated with other lesions, such as a patent interventricular septum; as an acquired condition it is very rare. Pulmonary incompetence is the rarest of valvular lesions.

Ætiology.—Chronic valvular disease may be of congenital origin (*vide* Congenital Heart Disease), or may be due to a previous attack of acute endocarditis resulting in chronic endocarditis, or to primary chronic endocarditis, new-growths, traumatism or, in the case of the aortic valve, to syphilitic mesaortitis. This list does not include *relative* incompetence of a valve. The causes of acute endocarditis, and also of primary chronic endocarditis, have been fully dealt with. When chronic valvular disease is due to a previous attack of acute endocarditis, it is more apt to occur in early life, and when due to primary chronic endocarditis in middle or later life. Neoplasms may arise from the walls of the heart or from the valves. They rarely cause obstruction. A traumatic lesion of a cusp or of the chordæ tendinæ, the result of excessive physical exertion, may cause stenosis or incompetence of a valve, and is of much more common occurrence in the case of the aortic than the mitral valve. It rarely takes place, however, in the absence of pre-existing disease of the valve.

In relative incompetence of a valve the cusps themselves are healthy. This is more common on the right than on the left side of the heart, and is almost unknown in aortic disease, and is not nearly so frequent as in the case of the mitral valve. The condition may occur from the following causes: (1) Dilatation of the cavity of the ventricle—this produces an alteration of the relation of the cavity and of the cusps, the segments of which cannot properly approximate, with consequent regurgitation through the orifice. (2) Enlargement of the orifice on account of relaxation of the surrounding muscular structures; in these cases the tonicity of the muscular ring is impaired, and the cusps do not completely come together. (3) Enlargement of the ventricular cavity and dilatation of the orifice combined. (4) Shrinkage or stretching of the muscoli papillares or chordæ tendinæ as a result of disease.

Pathology.—See chronic endocarditis and syphilitic mesaortitis.

EFFECTS OF VALVULAR DISEASE UPON THE WALLS OF THE HEART AND OTHER ORGANS.—In the case of stenosis of a valve, there is beyond the narrowed orifice a tendency to a diminished blood supply, and in consequence to diminished general nutrition. As the progress of the narrowing of the orifice is as a rule slow, the muscular wall of the chamber immediately behind the orifice usually hypertrophies, this process enabling the chamber to overcome the obstruction, and being referred to as “compensatory” hypertrophy. In a large majority of cases there is also dilatation, owing to the fact that the cardiac chamber has to accommodate a larger amount of blood than normal.

In the case of valvular incompetence, on the other hand, there is not necessarily a diminished blood supply beyond the orifice. The cavity immediately behind the orifice has to accommodate the regurgitant stream of blood in addition to the normal amount of blood arriving in the normal manner, and, therefore, an increase in its capacity is necessary: in other words, dilatation occurs. This excess of blood must be propelled with each systole of the chamber, with resultant hypertrophy of the muscular wall. It can be readily understood that in order to maintain the circulation adequately it is necessary that a larger quantity of blood be propelled, in order to compensate for the amount of blood which regurgitates. In this way dilatation with hypertrophy ensues, the former being greater than in the case of pure stenosis.

When in valvular disease dilatation is not in excess of hypertrophy we have what is termed complete or perfect “compensation.” When dilatation is in excess of hypertrophy, we have failure or loss of “compensation.” In order that hypertrophy may take place there must be an inherent capacity for development in the cardiac musculature. This is greater in the young, and is more notable in the case of the ventricle than the auricle, and of the left rather than the right side of the heart. It should also be noted that the nutrition of the myocardium is a most important factor in determining the relative preponderance of hypertrophy and dilatation, as for the development of full hypertrophy an adequate blood supply is necessary, and in this connection the state of the general nutrition, as well as the anatomical and physiological condition of the coronary arteries, are factors of considerable importance. In any circumstance, however, long-standing hypertrophy is apt to be followed by dilatation.

Valvular disease of the left side of the heart is apt to cause dilatation of the pulmonary veins and capillaries, giving rise to passive hyperæmia and œdema, dilatation of the pulmonary artery, and subsequent changes in the right side of the heart. Valvular disease of the right side of the heart is apt to cause dilatation of the venæ cavæ and their tributaries, and consequent cyanotic changes in the liver, spleen and kidneys, chronic venous congestion and catarrh of the mucous membranes of the hollow viscera, œdema or anasarca, and transudation of fluid into the serous sacs.

Passing to the consideration of the different valvular lesions: In pure aortic stenosis the left ventricle hypertrophies, it may be in a very great degree. For some time—perhaps for a very considerable time—there may be no corresponding degree of dilatation, although some believe that dilatation of slight degree is always present. In time, however, the degree of dilatation increases, and still later, owing to dilatation of the ring supporting the mitral valve, relative mitral incompetence and regurgitation into the left auricle may occur. In that event, dilatation and hypertrophy of the left auricle, passive hyperæmia of the lungs, and changes in the right side of the heart are apt to supervene.

In aortic incompetence, dilatation and hypertrophy of the left ventricle take place. These reach their greatest limit in this form of valvular disease, and there may be enormous enlargement of the heart, the organ in such cases being spoken of as a "beefy heart" or a "*cor bovinum*." The balance between hypertrophy and dilatation for the time may be perfect; but later on the dilatation may become greater in degree than the hypertrophy, and cardiac failure supervenes. Mitral incompetence may ensue, either as the result of dilatation of the ring supporting the valve, or owing to damage to the cusps due to their being subjected to strain.

On account of the regurgitation of blood into the left ventricle, the peripheral arterial circulation is apt to suffer. The difference between the arterial pressure during cardiac systole and diastole is augmented, and there is a rapid fall at the beginning of diastole; as a result the flow in the arterial system is less continuous. The larger vessels near the heart are subject to great variations in blood-pressure, while the distal vessels do not receive the blood supply which they get in health. Further, the coronary arteries are not well supplied with blood, and may also undergo degenerative changes; as a result of these changes the myocardium in turn suffers from an insufficient blood supply.

In mitral stenosis the left auricle hypertrophies. There are some who believe there is always coincident dilatation also, but others are of opinion that it is only when cardiac failure supervenes that dilatation of that chamber occurs. In a mild degree of stenosis there may be, for a time, enlargement of the left auricle only. Eventually, however, in the great majority of cases changes occur on the right side of the heart. The increased pressure in the left auricular chamber causes obstruction to the return of blood from the pulmonary veins. This results in increased pressure in the pulmonary circulation, and a greater demand is put upon the right ventricle, which as a consequence hypertrophies. Compensation is then said to be complete. Hypertrophy is usually accompanied by some degree of dilatation. In time the dilatation increases, and relative tricuspid incompetence (to be described later) may supervene. The pulmonary artery and veins some-

times become atheromatous, on account of the increase of pressure. In mitral stenosis the quantity of blood passing from the left auricle to the left ventricle may be less than normal, and when this is so the latter chamber has less blood to propel into the aorta, so that in uncomplicated mitral stenosis the left ventricle may be actually smaller than normal. In a considerable proportion of cases of mitral stenosis, however, there is a certain amount of hypertrophy of the left ventricle. This may be due to mitral regurgitation, aortic valvular disease, pericardial adhesions, supernormal blood-pressure, arterial disease, or kidney disease. When there are pericardial adhesions there is apt to be dilatation and hypertrophy of the whole heart. The immediate effect of mitral incompetence is dilatation of the left auricle, since that chamber has to accommodate the regurgitant stream of blood in addition to the normal amount of blood arriving from the lungs by means of the pulmonary veins. In this case also to dilatation is added hypertrophy of the auricular walls. As a larger quantity of blood is driven by the auricle into the ventricle during auricular systole, dilatation of that chamber occurs, and its walls hypertrophy. Changes in the pulmonary circulation and right side of the heart, as described above, may follow.

In pulmonary incompetence, hypertrophy and dilatation of the right ventricle, and usually of the right auricle also, occur; in tricuspid stenosis there is hypertrophy and a certain amount of dilatation of the right auricle; while in tricuspid incompetence, dilatation, and sometimes hypertrophy, of this chamber takes place. There may follow dilatation of the *venæ cavæ* and their tributaries, and consequent chronic venous congestion and other systemic changes as already described.

AORTIC STENOSIS

Aortic stenosis may be absolute or relative. In absolute stenosis the orifice is less than its normal size, while in relative stenosis the size is normal, but dilatation of the aorta just above the valve is present.

Ætiology.—Aortic stenosis is more commonly found in middle or later life, and in males. Absolute stenosis may be due to a previous attack of acute endocarditis, in which case the mitral valve is also as a rule similarly affected. It is, however, commonly due to primary chronic endocarditis, and is for this reason more common in middle or later life and in males. Syphilitic *mesaortitis* is occasionally the cause. The affection may be congenital, and is rarely due to injury, direct or indirect.

Symptoms.—When aortic stenosis is the result of a previous attack of acute endocarditis, the subjective symptoms are as a rule long delayed, and indeed the condition may be latent all through life. The most common subjective symptoms are giddiness, sleeplessness, a sense of oppression or constriction behind the sternum, pain and dyspnoea on exertion. Later, dilatation of the left ventricle and relative insufficiency of the mitral valve, and ultimately dilatation of the right side of the heart, may occur. Even when the stenosis is the result of primary chronic endocarditis, so long as the lesion is slight, there are usually no subjective symptoms; when, however, this is considerable, the symptoms just enumerated may be present, and angina pectoris may be superadded.

The pulse is sometimes very characteristic; indeed, not infrequently, the diagnosis of the lesion is greatly assisted by the peculiar character of the

Fig. 62.—Sphygmogram from a case of aortic stenosis.

pulse. In moderate degrees of stenosis the pulse may not show any striking abnormal features. As the lesion increases, however, it becomes infrequent, and the sphygmogram shows a pulse of smaller amplitude, the percussion wave is oblique, and the summit is gradual and slow, while to the finger the pulse is full between the beats (Fig. 62). It may be *anacrotic*, or of the *bisferiens* type. When in addition to stenosis aortic incompetence is present, which is not uncommon, the pulse which is characteristic of the former will be modified by the latter condition. The blood-pressure is variable: it tends to be subnormal, but is often supernormal, as the result of coexisting arterial disease, or chronic interstitial nephritis. When aortic stenosis is associated with atheroma, as is frequently the case, the vessel wall may be thickened and tortuous.

Almost always there are signs of hypertrophy of the left ventricle. There is sometimes a certain amount of bulging of the præcordium. The apex-beat is displaced chiefly downwards,—it may be as far as the sixth intercostal space or lower,—but as a rule only slightly outwards. The area and force of the apex-beat are increased; it may be heaving or thrusting in character. A characteristic sign of aortic stenosis is a gradual, slow rise of the apex-beat—a “slow heave,”—which is sustained. A thrill, systolic in time, is often palpable; this has its maximum intensity in the aortic area, and may be felt over the whole præcordium, and, indeed, sometimes all over the chest and the large vessels of the neck. On percussion, the area of deep cardiac impairment is almost always increased, the enlargement being chiefly downwards, and to a less extent to the left, while in uncomplicated cases the right border extends very little beyond the normal limit. The area of superficial cardiac impairment is as a rule unaffected. On auscultation, a systolic murmur is audible, with its point of maximum intensity in the aortic area, or over the manubrium sterni, or to the left of the sternum. The murmur, however, may be audible all over the chest, and even at the back, in which case it is loudest at the level of the fourth vertebra close to the left border of the spinal column. The direction of selective propagation is upwards along the vessels of the neck. It is usually loud, and has been heard several feet away from the patient. It is generally rough and grating, but may be musical, or soft and blowing. The first sound in the mitral area is sometimes long, low in pitch and muffled—as in hypertrophy of the left ventricle from other causes. The second sound in the aortic area varies considerably in loudness, largely according to the nature of the lesion of the valve (for example, the fusion of the cusps may be such as not to allow such apposition as is necessary to cause an aortic second sound), and the presence or absence of arterial disease. It is usually diminished and may be practically absent, but occasionally may be louder than normal. Later, owing to dilatation of the ring supporting the mitral valve, relative mitral incompetence may occur, when enlargement of the left auricle, passive hyperæmia of the lungs, and

changes in the right side of the heart are apt to supervene; diminution of the force of the apex-beat and increase to the right of the area of cardiac impairment are among the other physical signs to be noted.

DIAGNOSIS.—It is not sufficiently appreciated that *it is not justifiable to make a diagnosis of aortic stenosis from the mere presence of a systolic murmur over the aortic area, additional evidence being required, as the murmur may be due to other causes.*

A diagnosis of aortic stenosis can readily be made when the characteristic pulse and apex-beat, an aortic systolic thrill and murmur, with the direction of selective propagation upwards along the vessels of the neck, and a diminished or absent second sound are present. These features combined distinguish the condition from others that may give rise to a systolic bruit with its point of maximum intensity over the aortic area; when, however, only one or few of these characteristic features are present, difficulty with regard to the diagnosis may easily arise. An anacrotic pulse is characteristic, but not pathognomonic, since other conditions besides aortic stenosis may produce it; nevertheless, it is of greater diagnostic value than *pulsus bisferiens*. While the presence of a thrill is a valuable diagnostic sign, it should be remembered that it may also be found in dilatation of the aorta. A systolic murmur with the direction of selective propagation upwards along the vessels of the neck is at least strongly presumptive, and, in the opinion of some, is almost sufficient evidence.

Certain conditions must be excluded in considering the diagnosis of aortic stenosis; among these are bruits due to anæmia, cardio-pulmonary or cardio-respiratory murmurs, pulmonary stenosis, patent ductus arteriosus, pressure upon the aorta by a mediastinal tumour where no definite pulsation is present, mere roughening or stiffness of the aortic cusps or orifice, fusiform dilatation of the aorta just above the valve—what is called “relative stenosis”—and aneurysmal dilatation of the ascending aorta.

Harmonic murmurs are always systolic in time, and are most frequently heard in the pulmonary area, next most commonly in the mitral area, the tricuspid area, and the aortic area—in the order named, the last named being comparatively rare. The “*bruit du diable*” is frequently present as well. Cardio-pulmonary murmurs are not absolutely synchronous with the beginning of systole or diastole and may precede or follow either; the point of maximum intensity does not coincide with any of the valvular areas, the murmurs being usually heard best over the margins of the lungs; and they vary with the phases of respiration. One point alone is sufficient to distinguish aortic stenosis from pulmonary stenosis; in the latter the murmur is never propagated into the arteries at the root of the neck. Further, the character of the respective pulses differs materially, while in aortic stenosis there is evidence of hypertrophy of the left, and not of the right, ventricle, and the apex-beat is characteristic. The physical signs of patent ductus arteriosus are described elsewhere. In the case of pressure upon the aorta by a mediastinal tumour where no definite pulsation is to be felt, the murmur is often audible over the vessels of the neck. An area of impairment may usually be detected, however, and there is rarely any alteration in the character of the second sound. When an aortic systolic bruit is due merely to roughening or stiffness of the aortic cusps or orifice, there is an absence of the characteristic pulse, of hyper-

trophy of the left ventricle in a young person who is free from kidney disease, and of the characteristic apex-beat. In fusiform dilatation of the aorta just above the valve, the murmur is often heard over the vessels of the neck, but occasionally the area of impairment at the level of the second and third costal cartilages extends farther out to the right than the normal limit, and the second sound is not only accentuated, but is low-pitched, ringing, and usually audible over a much wider area. As a rule, there is very little difficulty in diagnosing aortic stenosis from aneurysmal dilatation of the ascending aorta.

Prognosis.—In the opinion of some the prognosis of pure aortic stenosis is more favourable than that of any other chronic valvular lesion; others again place it after mitral incompetence. In my experience, it largely depends upon whether the affection is due to a previous attack of acute endocarditis, or is the result of primary chronic endocarditis. In the former case, the lesion is less serious than any other chronic valvular lesion, and the risk of sudden death is slight. In the latter case, however, the prognosis is less favourable than in mitral incompetence, as degenerative processes are apt to be progressive, and while these may be limited to the valve, more frequently they affect the walls of the aorta also. The neighbourhood of the mouths of the coronary arteries also is often involved, and partial occlusion of one or both of these vessels is of not infrequent occurrence; in this case, chronic myocardial degeneration is likely to ensue, and sudden death may result.

Treatment.—This (together with the treatment of the other forms of chronic valvular disease) will be discussed later.

AORTIC INCOMPETENCE

Ætiology.—Aortic incompetence is more commonly found in middle or later life, and in males. There are three main causes. (1) A previous attack of acute endocarditis, in which case the mitral valve is, as a rule, similarly affected. This is the commonest cause of the condition in young adults. (2) Secondary involvement of the valve by syphilitic mesoaortitis of the ascending part of the aorta just above the valve is an important cause, and should always be thought of in a person who has not suffered from a previous attack of acute endocarditis. (3) Primary chronic endocarditis, more particularly when the affection occurs at a later period of life. Aortic incompetence is the most frequent cardiac lesion due to injury, and may follow sudden physical overstrain, causing a rupture of a valve segment; in such cases it is apt to end fatally. The condition is extremely rarely of congenital origin. Relative incompetence of the aortic valve is almost unknown. In relative incompetence there is no affection of the valve segments, the incompetence being due to stretching of the fibrous aortic ring—in other words, to widening of the orifice itself. This may occur in great dilatation of the commencement of the arch of the aorta.

Symptoms.—There may be an absence of subjective symptoms for some time. When the condition is due to primary chronic endocarditis, the onset of symptoms is usually very insidious. When of syphilitic origin, see pages 889–891. Shortness of breath on exertion is perhaps the most frequent symptom. The face is usually pallid and anxious, although in some cases

the colour is flushed; while if relative mitral incompetence supervene, the facies resembles that of mitral disease. Cerebral symptoms are more apt to occur early than in mitral disease, the patient complaining of giddiness, syncopal attacks, headache, or sleeplessness. Præcordial pain is usually more severe in aortic than in mitral disease. At first there may be merely a sense of oppression behind the sternum, becoming worse on physical exertion; or there may be more or less continuous pain. Ultimately, angina pectoris is apt to occur, especially when the lesion is due to primary

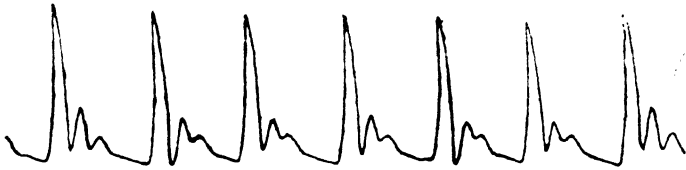

FIG. 63. — Sphygmogram from a case of aortic incompetence.

chronic endocarditis, or to syphilis. Angina pectoris may be associated with, or alternate with, syncopal attacks. The patient may complain of palpitation. There may be a sensation of beating in the head, nose bleeding is not a rare occurrence, and there may be loss of flesh.

Whether the lesion is post-rheumatic or not, increasing dyspnœa, cough, hæmoptysis, physical signs of pulmonary congestion and œdema, especially of the bases, hepatic enlargement, dropsy, and other evidence of mitral incompetence and dilatation of the right heart, may supervene; while in the late stages mental symptoms, such as delirium, hallucinations, delusions, or even a suicidal tendency, may be present.

The typical pulse is very characteristic, and is called the collapsing, the water-hammer, or Corrigan's pulse. Its collapsing character may be intensified by raising the arm above the head, and this method of examination should always be employed in suspected aortic regurgitation. The typical pulse is one of great amplitude, with an abrupt upstroke and a sudden fall. The tidal wave may be considerable, but is maintained only for a short period, the dicrotic notch falls low on the downstroke, while the dicrotic wave may be well marked, small, or altogether absent (Fig. 63). The

FIG. 64. — Sphygmogram from a case of aortic stenosis and incompetence. The characteristic pulse of the latter condition is modified by the presence of stenosis.

artery is empty between the beats. When in addition to aortic incompetence stenosis is present, the characteristic pulse of the former will be modified by the latter condition; this is of great diagnostic importance in stenosis (Fig. 64). A high pulse-pressure is almost invariably a feature of aortic incompetence; the minimum pressure is sometimes considerably below and the maximum sometimes considerably above, the normal. When the condition is associated with atheroma, as is frequently the case, the vessel wall may be thick and tortuous. A characteristic feature of aortic incompetence is exaggerated pulsation of the arteries; this may be especially

noted in the carotid, temporal and brachial arteries. Increased pulsation of the retinal arteries is sometimes to be noted with the ophthalmoscope. The phenomenon of the capillary pulse may be observed, and pulsation in the superficial veins, especially in the veins of the back of the hand, when hanging down, is sometimes to be noted. In the opinion of some writers, pulsation over the upper part of the præcordium, and in the second and third right intercostal spaces, is occasionally to be noted, even in the absence of dilatation of the aorta.

In aortic incompetence signs of hypertrophy of the left ventricle are almost constant, and there is some bulging of the præcordium—it may be to a considerable extent. The apex-beat is displaced, sometimes to a marked degree; the displacement is to some extent outwards, but more markedly downwards, sometimes reaching to the sixth or seventh interspace and the mid-axillary line. The extent and force of the beat are usually considerably increased, and it is frequently heaving or thrusting in character.

A diastolic thrill is rarely present; when it is, its maximum intensity is not infrequently at a lower level than the aortic area, and may even be felt towards the lower part of the sternum and in the neighbourhood of the apex-beat.

The area of deep cardiac impairment is usually increased downwards, it may be markedly so, and to a slight degree to the left. In uncomplicated cases the right margin of the heart extends only a little beyond the normal limit. On auscultation, a diastolic murmur is audible, which may continue for a variable distance into the long pause, becoming fainter and fainter. Its point of maximum intensity is very variable, the typical position being over the inner end of the second right intercostal cartilage. Frequently, however, it is in the second left space, or immediately over the sternum. More rarely it is at a lower level than this, approaching even the level of the apex-beat, and in the writer's experience more often nearer the left than the right border of the sternum. The murmur has a tendency to be propagated downwards towards the lower end of the sternum. It is often heard over a wide area, and is usually soft and blowing, but may be musical, and more rarely rough and grating. An aortic systolic bruit is also usually present, but, as has been already pointed out, its presence does not necessarily indicate stenosis. The second sound may be audible or may be absent. The first sound at the apex is sometimes long, low in pitch, and muffled. Austin Flint believed that in certain cases of aortic incompetence a presystolic murmur is audible at the apex, and most writers agree with him. A diastolic murmur may be audible in the carotid, brachial and femoral arteries; the last of these is referred to as the murmur of Duroziez. Physical signs of dilatation of the aorta are sometimes also present.

Later, dilatation of the left ventricle may occur, in which case the force of the apex-beat becomes diminished, and the left border of cardiac impairment is found to have extended still farther to the left. Owing to dilatation of the ring supporting the mitral valve, relative mitral incompetence may supervene, and then enlargement of the left auricle, passive hyperæmia of the lungs, and changes in the right side of the heart are apt to supervene, so that the area of cardiac impairment is also further displaced to the right.

Course.—The course of aortic incompetence is very uncertain. Gradual

cardiac failure is the rule, but, on the other hand, death may occur suddenly, from syncope or angina pectoris.

Diagnosis.—There is little or no difficulty in recognising aortic incompetence in the great majority of cases. The characteristic radial pulse, the high pulse-pressure, the greatly exaggerated pulsation of the arteries, the physical signs of hypertrophy of the left ventricle, the characteristic murmur, capillary pulsation, and, rarely, visible pulsation in the superficial veins, present a definite clinical picture with regard to the diagnosis of which there should be no mistake. It should be remembered, however, that the phenomenon of the capillary pulse and pulsation of the superficial veins are occasionally also seen in other conditions. The murmur of Duroziez is pathognomonic of the lesion.

When the point of the maximum intensity of the murmur is in the pulmonary area, the condition may be mistaken for pulmonary incompetence. In this event, the points which should be remembered in considering the differential diagnosis are that pulmonary incompetence occurs more frequently in early life, that the pulse is not collapsing in character, that there is an absence of greatly exaggerated pulsation of the arteries and of capillary pulsation, that there is evidence of hypertrophy of the right, and not of the left, ventricle, and that the accompanying murmur is very rarely propagated as far down as the apex of the heart, and is never audible over the carotid artery. Dyspnoea, cyanosis, and clubbing of the fingers are also more suggestive of pulmonary incompetence. It should be remembered, however, that both lesions may occur in the same individual, in which case there is usually a blending of the physical signs of both conditions. I have occasionally seen a diagnosis of mitral stenosis made in cases of aortic incompetence, when the point of maximum intensity of the diastolic bruit—especially when the bruit is only audible towards the latter part of the long pause—is as low as, or lower than, half-way down the sternum and on the left side of the middle line, and especially so when it is near the apex-beat. The points of differential diagnosis are the following: In mitral stenosis the pulse is markedly different from that of aortic incompetence, and, further, there is an absence of greatly exaggerated pulsation of the arteries and of capillary pulsation, there is evidence of hypertrophy of the right, and not of the left, ventricle, the murmur is harsher in character, the first sound is short, sharp and clear, and the area of the thrill and murmur is usually very limited. The diagnosis of syphilitic aortitis is discussed on pages 890–891.

Prognosis.—The prognosis of aortic incompetence is usually serious. Sudden death is more frequent than in any other form of chronic valvular disease, and may occur even when there are no indications of cardiac failure. In attempting to form a prognosis, we should endeavour, among other inquiries, to ascertain the extent of the lesion, and whether it is due to a previous attack of acute endocarditis, or to primary chronic endocarditis or to syphilis, the condition of the myocardium and coronary arteries, and whether the affection is stationary or progressive. In the absence of cardiac failure, the pulse-pressure is an indication of the degree of aortic incompetence. When the lesion is the result of a previous attack of acute endocarditis, the prognosis is, other things being equal, much more favourable than when due to primary chronic endocarditis or to syphilis; indeed, if there be no indications of cardiac failure, and if the rate and character of the pulse, the

pulse-pressure, and the size of the heart, exhibit little or no alteration, and if the murmur accompany, but do not replace, the second sound, the patient may live to an advanced age. If, on the other hand, the lesion be due to primary chronic endocarditis, and be progressive, the patient in all probability will not survive for more than 4 or 5 years. For syphilitic aortitis, see page 891.

It is a matter of vital importance to ascertain whether the myocardium and coronary arteries are also affected. In this connection it may be noted that, when the affection is due to a previous attack of acute endocarditis, the myocardium and coronary arteries may not be implicated for a long time and may even escape altogether; whereas, when due to primary chronic endocarditis or to syphilis, they are apt to be affected at an early period. Needless to say, when aortic incompetence is due to rupture of a cusp, the prognosis is still graver, and a fatal termination may rapidly supervene. When the result of dilatation of the orifice, the affection is likely to be progressive. Syncopal attacks and attacks of angina pectoris are of grave significance. The gravity of the prognosis is in every case increased by widespread atheroma and kidney disease.

MITRAL STENOSIS

Ætiology.—Mitral stenosis is always organic. It commences much more commonly in early life, and is much more frequent in females than in males. It is usually the result of a previous attack of acute endocarditis. It sometimes originates in adults as a result of primary chronic endocarditis, not infrequently in association with chronic interstitial nephritis. In a not inconsiderable proportion of cases its ætiology is obscure.

Pathology.—In mitral stenosis the commonest type of lesion is for the cusps to be united by their margins; but it may be situated elsewhere, as, for example, at the level of the auriculo-ventricular ring. When the lesion consists of a union of the margins of the cusps, two well-marked types of stenosis may result—(1) The “funnel-shaped mitral,” which is more common in childhood; and (2) the “button-hole mitral,” which is by far the more common in adults and persons of advanced years.

In the former, the united cusps form a funnel-shaped membrane which projects downwards into the left ventricle, the wide mouth of the funnel being situated at the ring, and the smaller end being drawn down towards the apex of the heart, by shortening of the chordæ tendineæ and papillary muscles. In the case of button-hole stenosis, the united cusps form a diaphragm, perforated by a narrow slit-like aperture, which almost closes the orifice. A combined form, that is, a funnel having a narrow slit at its lower end, instead of a circular aperture, has also been described.

Symptoms.—In mitral stenosis there is not very infrequently an absence of subjective symptoms for many years, except that dyspnoea, palpitation, or præcordial pain may accompany any sudden severe demand made on the cardiac muscle. Later, the heart muscle is liable to fail, and dilatation may result. Dyspnoea is induced by less and less effort, cough is a frequent symptom, the patient is liable to attacks of bronchitis and broncho-pneumonia, palpitation and præcordial pain may be present, and epistaxis, hæmoptysis and infarction may occur; embolism is of more frequent occurrence

in mitral stenosis than in any other variety of chronic valvular disease. There is often a persistent dusky flush over the cheeks, and clubbing of the finger-ends, gradual loss of flesh, and, in the young, stunted growth are sometimes to be noted. Later, there may be lividity of the lips, ear-tips, and cheeks, and puffiness around the angles in the evening. Ultimately dyspnoea may become continuous, and there may be orthopnoea and cardiac asthma, especially at night-time, sleeplessness and restlessness, evidences of congestion and oedema of the lungs and hydro-thorax, a sallow hue of the skin, watery bile-stained conjunctivæ, marked cyanosis, loathing of food, vomiting, enlargement of the liver and spleen, ascites, anasarca, and albuminous and sometimes smoky urine. Sudden death is rare, a fatal termination being usually the result of gradual cardiac failure.

The subjects of mitral stenosis are liable to subacute and acute rheumatic attacks, and chronic renal disease may be a complication.

Usually the pulse is small, the upstroke being short and soon attaining its maximum, the pulse-wave is long, and dicrotism is absent (Fig. 65). The maximum blood-pressure is usually rather below the normal, but the minimum pressure is rather high, so that the pulse is full between the beats. When cardiac failure supervenes, both the systolic and diastolic pressures fall.

FIG. 65. Sphygmograms from cases of mitral stenosis.

The complete irregularity of the pulse which is associated with auricular fibrillation is often found in mitral stenosis with cardiac failure.

On inspection and palpation the following points may be noted in cases of pure mitral stenosis. Sometimes, more especially in children, there is a certain amount of bulging of the præcordium in the region of the ensiform cartilage, due to enlargement of the right ventricle. The apex-beat may be in the normal position or displaced. In pure mitral stenosis the displacement is usually directly to the left, it may be beyond the nipple line; less frequently it is also somewhat downwards. The apex-beat may be normal, diffuse or indefinite. On palpation, there is sometimes a peculiar sudden tap communicated to the fingers, which is very characteristic. Not infrequently there is pulsation in the epigastrium, diastolic in time. There may be a heaving impulse in the epigastrium and over the lower sternum and costal cartilages when marked hypertrophy of the right ventricle exists; in these cases this is the chief impulse, being more marked than that of the left ventricle. Occasionally there is systolic pulsation in the third or second left interspace, near the sternum; this may be due to enlargement of the conus arteriosus or of the pulmonary artery.

In many cases there is a thrill, having its maximum intensity at the apex or somewhat nearer the parasternal line. This may be absent at some periods and present at others; it may be absent when at rest, and in evidence after exertion or when the arms are extended. Examination for the characteristic thrill and murmur of mitral stenosis should be conducted with the patient

lying down, sitting up and inclined forwards, standing up with the arms extended, and after gentle exercise. The thrill is usually presystolic in time, but may be diastolic. When presystolic, on palpation of the præcordium there is a sensation communicated to the hand resembling that produced by the purring of a cat. Sometimes an impulse may be made out at the base of the heart, coincident with the closure of the semilunar cusps, with its maximum intensity in the second left intercostal space.

On percussion the area of cardiac impairment may be found to be unaltered when the obstruction is slight; but usually the transverse diameter is increased, especially to the right. The left border may be displaced outwards, even beyond the nipple line. The upper border of the area of impairment is sometimes found to be higher than normal, and may reach as high as the second costal cartilage, and an extension of the area of impairment outwards along the third and fourth intercostal spaces, due to enlargement of the right auricle, may be occasionally detected.

On auscultation the physical signs are very characteristic. In the large majority of cases a murmur is present. This may be audible at some times and not at others. It is heard at the apex, or between this point and the left border of the sternum. The murmur is usually presystolic in rhythm; as in the case of the presystolic thrill, it is due to the systole of the auricle driving blood through a narrowed orifice, and *disappears with the onset of auricular fibrillation*. The murmur is almost invariably rough; it may be harsh and vibratory, and this quality of the murmur is almost pathognomonic; *Laennec compared the sound to the rasping noise made by a file*. The first sound which terminates the murmur is altered in a characteristic way, to be described later. *The locality of the murmur is almost always very limited and the area may not be larger than 1 inch in diameter; this should be particularly noted, because it accounts for the fact that the lesion is so often unrecognised*. Instead of presystolic the bruit may be diastolic in time. Diastolic murmurs tail off, and do not have, as a rule, the harsh and vibratory character of the presystolic bruit; they are, instead, soft and blowing in type, and are due to the passive inflow of blood from auricle to ventricle. There may be a combination of two murmurs; there may be a long murmur beginning immediately after the second sound, and continuing all through ventricular diastole and auricular systole, the early part being diminuendo and the latter part crescendo. Or, at one time, there may be a presystolic, and at another time a diastolic, murmur. Sometimes a diastolic murmur, usually soft and blowing in character, with its point of maximum intensity in the pulmonary area, due to *relative pulmonary incompetence*, is to be heard. It is often called the *Graham Steel murmur*.

The first sound becomes short, sharp and clear, like a sudden snap. It may resemble the second sound so closely as to be mistaken for it, especially when the second sound is not well heard at the apex. As mitral stenosis is usually accompanied by incompetence, a mitral systolic murmur is usually audible. The second sound is usually accentuated, particularly in the pulmonary area, and may be reduplicated, the effect resembling a "postman's knock." According to the late Sir William Broadbent, in a later stage of the disease the second sound at the apex may disappear, the short, sharp first sound may become louder, and the murmur become more frequently diastolic in time. In the absence of a diastolic, as well as of a

presystolic, murmur, all that is audible at the apex now is the altered first sound.

When cardiac failure supervenes, the pulse-rate increases, the apex-beat becomes diffuse and less forcible, the transverse area of cardiac impairment increases, and all the signs of tricuspid incompetence may be present.

Diagnosis.—When the characteristic physical signs of mitral stenosis—the pulse, the thrill, evidence of hypertrophy of the right ventricle, the murmur, the short, sharp and clear first sound, and the reduplicated second sound—are present the diagnosis is easy. The thrill is almost pathognomonic. Some writers believe that a similar thrill may be present in aortic incompetence, and therefore that this affection should always be first excluded. The thrill must be distinguished from a mere vibration of the chest-wall, which may be occasioned by a forcibly acting heart when the ribs are rigid. In this case, by separating the fingers and placing them in the intercostal spaces the osseous vibrations are not felt.

The murmur is sometimes not detected, on account of the area over which it is audible being very limited; or in some cases there is from time to time a complete absence of a thrill and murmur. In the latter case we are justified in inferring that in all probability mitral stenosis is present from the character of the pulse and first sound, together with evidence of hypertrophy of the right ventricle, and accentuation or reduplication of the second sound.

Some writers are of opinion that a rumbling presystolic bruit is sometimes heard in the case of adherent pericardium in children. Even if this be so, the bruit is not rough and vibratory in character, neither does it terminate abruptly at the first sound, nor is the first sound modified in the way already described, and, further, there are usually definite physical signs of adherent pericardium. As it is generally believed that a presystolic murmur at the apex is heard in certain cases of aortic incompetence, the question whether mitral stenosis is present in addition to aortic incompetence has occasionally to be considered. In this connection it may be noted that Flint's murmur has not the harsh and vibrating character which is commonly found in a presystolic bruit due to mitral stenosis, and if a thrill be present it is not "purring" in character. It should be borne in mind that both lesions may be present at the same time, and, therefore, it is sometimes difficult to say whether the murmur is that described by Flint or one due to the presence of mitral stenosis. In coming to a decision, the character of the murmur, the thrill and the pulse—the characteristic collapsing pulse of aortic incompetence being modified if mitral stenosis be present as well—will be of assistance.

Mitral stenosis is sometimes unrecognised in cases in which there is associated incompetence; the presystolic murmur, instead of ending in the first sound, ends in a systolic murmur, and a diagnosis of a long systolic murmur is erroneously made. There is, however, a difference in character between the former and the latter parts of this continuous bruit, the earlier portion being rough and vibratory in character, and the latter blowing or musical. Further, we can observe the position in the cardiac cycle of the two parts of this continuous murmur by placing the fingers upon the apex-beat or over the carotid artery. When the second sound at the apex has disappeared, the presystolic murmur may be mistaken for a systolic murmur, and the modified first sound for the second sound. In this event a differential

diagnosis can be made from the difference in character of the two murmurs, from the fact that a presystolic murmur ends, while a systolic murmur begins, with an accent, and by timing the murmur in the manner already indicated. When, in addition to the absence of a second sound at the apex, there is also no bruit present, mitral stenosis may not be diagnosed, and a diagnosis of dilatation of the left ventricle made; in dilatation, however, a second sound is audible.

The differential diagnosis between aortic incompetence and mitral stenosis has already been discussed. A differential diagnosis may have to be made between tricuspid and mitral stenosis. The former is extremely rare, and the point of maximum intensity of the thrill and murmur is in the tricuspid area. Occasionally a mere reduplication of the first sound is mistaken for mitral stenosis; but no careful observer should make this mistake.

Prognosis.—Mitral stenosis ranks after aortic incompetence in gravity among the chronic valvular lesions, and the prognosis is much less favourable than in the case of mitral incompetence.

There is apparently a tendency for mitral stenosis to be progressive, pulmonary complications are frequent, chronic renal disease may also accompany it, and embolism is relatively frequent. When the lesion occurs in the early years of life, physical and mental development are apt to be retarded, and the patient is liable to fresh attacks of rheumatic valvulitis. The prognosis depends upon, among other things, the degree of stenosis, which when considerable is almost invariably accompanied by incompetence. It has been pointed out that in a later stage of the disease the second sound at the apex may disappear, the short sharp first sound become louder, and the murmur more frequently diastolic; these phenomena, therefore, signify a downward grade. Sudden death is of rare occurrence, a fatal termination being usually the result of gradual cardiac failure, which in most cases is associated with the supervention of auricular fibrillation.

MITRAL REGURGITATION

Mitral regurgitation may be organic or relative, the latter being also termed functional.

Ætiology.—When organic, by far the most common cause is a previous attack of acute endocarditis, but sometimes it is due to primary chronic endocarditis. Rarely it is due to trauma, in which case there is usually a rupture of a chorda tendinea or of a cusp. *Relative* incompetence is a somewhat common cause of mitral regurgitation. It may be due to simple overstrain of the heart, wasting states, toxic conditions—such as alcoholism, lead, pneumonia, and diphtheria—acute febrile affections, anæmias, Graves' disease, acute myocarditis, fatty or fibroid degeneration of the myocardium, supernormal blood-pressure, chronic Bright's disease or aortic incompetence.

Symptoms.—In by no means an inconsiderable proportion of cases the disease is latent throughout the whole course. When symptoms are present the clinical picture resembles that of mitral stenosis; it should be noted, however, that hæmoptysis and embolism are of less common occurrence.

When the lesion is slight, the pulse, as a rule, scarcely differs from the normal. When the lesion is considerable, the amplitude is apt to be smaller

than normal, the upstroke rather steep, there is often very considerable dirotism, the pulse being easily compressible and not felt between the beats, and the blood-pressure is low. The complete irregularity which is associated with auricular fibrillation is often found in mitral incompetence with cardiac failure.

In mitral incompetence, due to organic valvular disease, there is sometimes, more especially in children, a certain amount of bulging of the præcordium. The apex-beat is usually displaced outwards, it may be even as far as the anterior axillary line; as there is hypertrophy of the left ventricle, the apex-beat may be also displaced somewhat downwards. Usually its area and force are greater than normal, and it may be heaving in character. Sometimes there is pulsation in the epigastrium, diastolic in time; and when there is marked hypertrophy of the right ventricle, there may be a heaving impulse in the epigastrium and over the lower sternum and costal cartilages. Occasionally there is visible pulsation in the second or third left intercostal space, and more rarely a thrill, systolic in time, which has its maximum intensity at the apex. A shock, accompanying the second sound, may be occasionally detected, particularly in the pulmonary area.

On percussion the area of cardiac impairment is found to be enlarged. Its transverse diameter is increased, the left border being displaced outwards, even as far as the anterior axillary line, and the right border as much as an inch and a half or more to the right of the sternum. The upper border of cardiac impairment may be as high as the second rib, and an extension of the area of impairment outwards along the third and fourth intercostal spaces, due to enlargement of the left auricle, may occasionally be detected.

On auscultation a systolic murmur is audible. This usually commences with the first sound, which it may entirely replace or merely accompany—usually the latter—and may extend all through the short pause; rarely it follows the first sound. Its point of maximum intensity is at or near the apex-beat, and its direction of selective propagation towards the axilla and the angle of the scapula. Occasionally it can be heard over the whole chest. The area of conduction of slight mitral systolic murmurs is frequently not large. A mitral systolic murmur is usually soft and blowing, occasionally musical, and more rarely rough and grating. It is usually louder when the patient lies down, and becomes feebler in the sitting or standing posture; in any doubtful case, therefore, the patient should be examined in these several positions. The second sound at the pulmonary area is, in the great majority of cases, accentuated, and may be reduplicated.

When cardiac failure supervenes the pulse-rate increases, there is usually present an increased degree of dilatation of the left ventricle—the apex-beat becoming more diffuse and its force lessened, and the left cardiac border being found still farther to the left—and in addition dilatation of the right heart, while all the signs of tricuspid incompetence may be present.

In relative mitral incompetence the apex-beat may be displaced outwards, but not downwards, and instead of being more forcible than normal it is usually less so. The systolic murmur is, as a rule, not propagated beyond the mid-axillary line, and there is often no accentuation of the pulmonary second sound.

Diagnosis.—At the outset it is necessary to point out that a systolic bruit audible over the apex of the heart is not infrequently erroneously inter-

puted as indicative of organic disease of the mitral valve, when in reality the murmur is functional. In order to say that a mitral systolic murmur is indicative of organic mitral incompetence, we must satisfy ourselves that certain other physical signs are present. With this object in view, it is advisable to note—(1) The position and character of the apex-beat; (2) the area of propagation of the murmur; and (3) the existence or absence of accentuation of the pulmonary second sound. In the case of a mitral systolic murmur due to organic valvular disease, owing to the presence of hypertrophy of the left ventricle, the apex-beat is usually displaced downwards as well as outwards. When the degree of valvular disease is so slight that no definite downward displacement of the apex-beat is present, its force is almost invariably increased, whereas in functional conditions it is apt to be less forcible than normal. If the murmur be propagated towards the angle of the scapula beyond the mid-axillary line, we may be practically certain that it denotes the existence of organic disease. A definite accentuation of the pulmonary second sound, provided there is no condition of the lungs to account for it, is in favour of the view that we are dealing with organic disease. The diagnosis is further strengthened by evidence of the existence of mitral stenosis. The diagnosis of relative mitral incompetence due to chronic Bright's disease or to aortic disease from organic mitral incompetence is particularly difficult, since chronic nephritis and aortic disease in themselves give rise to hypertrophy of the left ventricle. In these cases the history of the case is of importance.

In addition to the points of differential diagnosis just enumerated, murmurs due to anæmia and those associated with respiration have other distinguishing features. These have been discussed on page 839.

Prognosis.—The prognosis of mitral incompetence is more favourable than that of aortic stenosis or incompetence, or mitral stenosis. If the lesion be slight and the conditions of life favourable, the individual may even live to the normal span of life without experiencing much, if any, inconvenience. When, on the other hand, the lesion is severe, as indicated by marked cardiac enlargement, and more especially when symptoms of cardiac failure are present,—more particularly pulmonary symptoms,—the patient may live only for a few years, especially when the lesion is accompanied by pericardiac adhesions. It should be remembered, however, that even when considerable or marked cardiac failure exists, if rest and other suitable therapeutic measures be adopted, the patient may improve for a considerable time. In attempting a prognosis, we should note, among other things, the pulse-rate, the degree of displacement of the right margin of cardiac impairment, and the existence or otherwise of any indications of venous stasis.

With regard to the prognosis of mitral regurgitation due to *relative* incompetence, this depends upon the cause.

MITRAL STENOSIS AND REGURGITATION (DOUBLE MITRAL DISEASE)

It has been already explained that when mitral incompetence results from a previous attack of acute endocarditis, there is usually some degree of stenosis as well, and also that pure mitral stenosis is comparatively infrequent, as it is usually accompanied by incompetence. We thus get the double lesion.

Ætiology.—Double mitral disease is always organic; it is usually due to

a previous attack of acute endocarditis, although in elderly people it may be due to **primary chronic endocarditis**.

Symptoms.—The symptoms partake of the character of both lesions. Auricular fibrillation, cardiac failure, and tricuspid incompetence are more likely to supervene than in the case of a single lesion. There is usually considerable enlargement of the heart, and on auscultation the combined murmurs may be heard, but not infrequently a mitral systolic is the only murmur present. Accentuation of the pulmonary second sound is usually more marked than in the case of a single lesion.

PULMONARY STENOSIS

Pulmonary stenosis may be due to a lesion of the cusps, of the conus arteriosus, or of the pulmonary artery.

Ætiology.—The disease is almost always congenital; indeed, it is perhaps the most common congenital cardiac affection. When it occurs as an acquired condition, it may be the result of a previous attack of acute endocarditis, of which rheumatism and the eruptive fevers are the principal causes; and when this is so, it is usually associated with tricuspid stenosis. It has been supposed that the condition sometimes results from atheroma of the pulmonary artery, or from pressure of an aortic aneurysm. In some cases the ætiology is obscure.

Symptoms.—The symptoms of the congenital form of the disease will be discussed under Congenital Heart Disease. In the acquired form, the degree of dyspnœa is, as a rule, not great, and some authorities are of opinion that there is little tendency to cyanosis in these cases; similarly, there is a difference of opinion as to the existence of clubbing of the fingers and toes. The tendency to chronic venous stasis is not great, and as a consequence œdema of the lower extremities and ascites are not prominent features, although there may be tenderness over the liver, hepatic enlargement and pulsation, and the urine may become scanty, high coloured, exhibit an excess of urates, and may contain albumin or even blood.

Prognosis and Treatment.—These will be discussed later.

PULMONARY INCOMPETENCE

Pulmonary incompetence is the most rare of all valvular lesions.

Ætiology.—The condition occurs more commonly in early life, and with about equal frequency in both sexes. It is frequently a congenital affection, and is then usually accompanied by pulmonary stenosis. In the majority of cases it is the result of a previous attack of acute endocarditis, of which rheumatism and the eruptive fevers are the principal causes. It is believed by some that the condition may be caused by primary chronic endocarditis. Relative incompetence may occur, and is more common than was formerly supposed; the incompetence is due to dilatation of the pulmonary artery and its ring, caused by increased blood-pressure in the pulmonary circulation, such as may be found in chronic valvular disease of the left side of the heart, more especially mitral stenosis, in pulmonary fibrosis, fibroid tuberculosis, emphysema, and chronic diseases of the bronchi.

Symptoms.—There may be a certain degree of cyanosis and dyspnœa,

usually only present on exertion, while not infrequently there is also clubbing of the fingers. At a late stage cyanosis becomes marked, dyspnoea occurs apart from exertion, there may be anasarca of the dependent parts, catarrh of the mucous membranes, enlargement of the solid abdominal viscera, transudation of fluid into the serous sacs, the urine may become scanty, high coloured, exhibit an excess of urates, and may be albuminous or even bloody, while affections of the respiratory system are especially apt to occur. There may be evidence of chronic venous congestion and oedema of the lungs, particularly of the bases, and more rarely pulmonary infarction occurs.

The pulse may be small and feeble, and the blood-pressure is, as a rule, subnormal. Occasionally there is visible pulsation in the third and fourth intercostal spaces to the right of the sternum. There is also frequently some bulging of the præcordium in the region of the ensiform cartilage, due to enlargement of the right ventricle, while the apex-beat is usually displaced to the left. There may be pulsation in the epigastrium, diastolic in time, and when there is marked hypertrophy of the right ventricle there is frequently a heaving impulse in the epigastrium, and over the lower sternum and costal cartilages. Distension or pulsation of the jugular veins may be present. Rarely a diastolic thrill is present, having its point of maximum intensity over the pulmonary area. On auscultation, a diastolic murmur, with its point of maximum intensity in the pulmonary area, usually soft and blowing in character, is audible, sometimes over a considerable area, its direction of selective propagation being downwards towards the lower end of the sternum.

Diagnosis.—The diagnosis of pulmonary incompetence is frequently a matter of considerable difficulty. The lesion with which it is most likely to be confounded is aortic incompetence, because the point of maximum intensity of the thrill and murmur of the latter is not infrequently to the left of the sternum. The differential diagnosis between these two conditions has been discussed under aortic incompetence. It should be noted that both lesions are rarely present in the same individual. The symptoms of pulmonary incompetence and patent ductus arteriosus resemble each other: in the case of the latter the murmur occupies both systole and diastole.

Prognosis.—When due to organic disease and when unaccompanied by any other valvular lesion, the prognosis in pulmonary incompetence may not be unfavourable; instances, indeed, have been recorded in which life has been prolonged almost to the normal span. In *relative* incompetence, on the other hand, the prognosis is always grave. Death in either case may result from right-sided cardiac failure, bronchitis or broncho-pneumonia, or pulmonary tuberculosis.

TRICUSPID STENOSIS

Ætiology.—Tricuspid stenosis occurs much more commonly in males than in females—in a proportion of at least three to one. While a considerable proportion of cases are congenital (in which case there is usually also some other cardiac lesion), the majority arise after birth. The acquired form is usually associated with mitral stenosis, and is due to a previous attack of acute endocarditis caused by rheumatism, chorea, or more probably one of the acute specific fevers. In many cases, however, the cause cannot be ascertained.

Symptoms.—In the acquired form of the disease, cyanosis is the most conspicuous symptom, and may be very marked; ~~dyspnoea is less evident,~~ and may be only present on exertion. The skin temperature of the extremities is often subnormal, and the individual complains of feeling cold and is very susceptible to any fall of temperature. The cerebral functions are not infrequently affected. Cedema about the ankles is sometimes present, and at a later stage may become general, together with tenderness over the liver, hepatic enlargement, and pulsation, ascites, splenic enlargement, and scanty high-coloured urine, which may contain albumin and even blood.

The radial pulse may show no abnormality, or its rate may be increased and its volume diminished. The apex-beat may be displaced to the left, and there is usually distension, and it may be pulsation, of the jugular veins. There may be a presystolic, or more rarely a diastolic thrill, with its point of maximum intensity in the tricuspid region. On percussion, the right border of the heart is found to be displaced to the right, on account of enlargement of the right auricle, and the left border may be found to be displaced outwards. On auscultation, a murmur may be present, limited in extent, having its point of maximum intensity in the tricuspid area. It is usually presystolic, but may be diastolic. The presystolic murmur is almost invariably rough; it may even be harsh and vibratory in character. The diastolic murmur, on the other hand, is usually soft and blowing. In some cases no murmur of any kind is audible. In certain instances, some writers have recorded a short, sharp first sound in the tricuspid area. When pulsation of the liver is present, the pulsation is of the auricular and not of the ventricular type.

Diagnosis.—In by no means an inconsiderable proportion of cases of tricuspid stenosis the lesion is entirely overlooked, no doubt on account of the absence of any murmur. In the opinion of Mackenzie, we may infer that tricuspid stenosis in all probability exists when pulsation of the liver is found to be auricular in type.

The differential diagnosis of tricuspid and mitral stenosis is often a matter of great difficulty. The early appearance of marked cyanosis and of extensive dropsy are features in favour of the existence of the former lesion. When the point of maximum intensity of the murmur is strictly in the tricuspid area, we can be fairly certain of the diagnosis. It should be remembered that both lesions may be present; in this case a murmur with its point of maximum intensity midway between the tricuspid and mitral areas, or two murmurs with separate points of maximum intensity, may be detected. The value of the auricular type of hepatic pulsation has been noted.

Prognosis.—The prognosis in this affection is by no means easy. It largely depends upon whether mitral stenosis also exists, and if present, in what degree; if this be present, the prognosis is usually very unfavourable.

TRICUSPID INCOMPETENCE

Ætiology.—It should be remembered at the outset that the reflux of a certain amount of blood through the tricuspid orifice may occur under physiological conditions. In severe muscular exertion, for example, where the intracardiac pressure on the right side of the heart is excessive, a natural function of the tricuspid valve is to provide for a certain amount of regurgita-

tion, and thus afford relief to the temporary embarrassment due to distension of the right ventricle.

Pathological tricuspid incompetence is rarely congenital, and when it is, is usually associated with pulmonary stenosis. Apart from those of congenital origin, there are two classes of cases—(1) Those in which the incompetence of the valve is primary, that is, due to a lesion of the cusps themselves—a rare condition; and (2) cases of *relative* tricuspid incompetence, in which the cusps are normal, the incompetence being due to dilatation of the right ventricle. The latter constitute the great majority of cases.

With regard to the first group, the lesion may be the result of a previous attack of acute endocarditis, in which case the tricuspid incompetence rarely occurs alone; there is usually tricuspid stenosis, and also some other valvular lesion, more especially some structural alteration of the mitral cusps. Infective endocarditis may affect the tricuspid valve alone.

Relative incompetence is always consequent on some other condition. It may result from chronic Bright's disease or aortic disease, resulting in dilatation of the left ventricle and venous stasis in the lungs, mitral disease, and affections of the lungs which cause embarrassment in the pulmonary circulation, such as emphysema, cirrhosis, chronic fibroid tuberculosis, and chronic diseases of the bronchi. Among other causes are pulmonary stenosis or regurgitation, wasting states, toxic influences (such as alcoholism, lead, pneumonia, and diphtheria), acute febrile conditions, *anæmia*, acute myocarditis, and myocardial degeneration.

Symptoms.—There is always a tendency to cyanosis, which may be marked, while dyspnoea on exertion is almost always present. Headache and giddiness are of common occurrence, while insomnia or disagreeable dreams, hallucinations, and even insanity may occur. Digestive disturbances and even jaundice may be present, and in rare instances hæmatemesis and melæna. Œdema about the ankles may also be noted. These patients are very liable to attacks of bronchial catarrh, while, later, there may be evidence of chronic venous congestion and œdema of the lungs, particularly of the bases, hæmoptysis, and hydro-thorax, the latter being more likely to occur in tricuspid incompetence than in affections of the left side of the heart. Hepatic enlargement and pulsation, ascites, general anasarca, and albuminous and even bloody urine may be also present in the later stages of the disease.

The pulse is usually small. In children a certain amount of bulging of the præcordium may be present in the region of the ensiform cartilage, due to enlargement of the right ventricle, and there may also be pulsation in the epigastrium, diastolic in time. A powerful heave in the epigastrium may be sometimes noted when the right ventricle is hypertrophied, and less commonly also visible pulsation in the fourth and fifth right intercostal spaces near the sternum. More rarely a systolic thrill is present in the tricuspid area. Visible distension and pulsation of the jugular veins may exist. If the vein be emptied from below by means of the finger, and its upper extremity kept closed by pressure, it rapidly fills from below. The pulsation of the jugular vein is usually of the ventricular form, but occasionally is of the auricular type. The liver may be enlarged and pulsating, the pulsation being strictly systolic in time—unless tricuspid stenosis also exists.

The area of cardiac impairment is increased to the right, sometimes to a considerable extent.

On auscultation, a murmur, systolic in time, having its point of maximum intensity in the tricuspid area, and usually soft and blowing in character, is usually, but by no means always, audible. It is conducted towards the right, but as a rule its area of conduction is slight. The pulmonary second sound is diminished in cases of tricuspid incompetence uncomplicated by a mitral or pulmonary lesion.

As relative incompetence of the tricuspid valve is always consequent upon some other condition, the physical signs of the primary affection are, of course, present.

Diagnosis.—When, after being emptied from below by means of the finger, the jugular vein rapidly fills from below, and when pulsation of the liver occurring synchronously with the apex-beat, evidence of enlargement of the right side of the heart, a soft blowing systolic murmur having its point of maximum intensity in the tricuspid area, and diminution of the pulmonary second sound are also present, no doubt need arise regarding the diagnosis. In marked tricuspid incompetence the murmur may be absent in which case a positive diagnosis can be made when the first three signs mentioned are present; most writers, indeed, agree that the first sign is sufficient for a diagnosis. In slight cases, a systolic murmur audible in the tricuspid area may be the only existing physical sign; but we should make certain the murmur is not propagated from any other area. Lastly, it has been pointed out that on severe muscular exertion a natural function of the tricuspid valve is to provide for a certain amount of regurgitation, and thus a tricuspid systolic murmur may appear under physiological conditions.

Prognosis.—The prognosis of tricuspid incompetence depends upon the cause and associated condition. When the affection is due to organic disease, the outlook is serious.

With regard to the prognosis of tricuspid regurgitation due to *relative* incompetence, when this is the result of aortic or mitral disease it is usually serious; it may be the precursor of a fatal termination in the near future. When, on the other hand, it is due to intercurrent pulmonary affections, wasting states, toxic conditions, acute febrile states, or anæmia, the prognosis may be good.

TREATMENT OF CHRONIC VALVULAR DISEASE

The ætiology should be reviewed. In this connection, the treatment of syphilitic aortitis is described on page 892. Explicit and detailed instructions with regard to his manner of life—as fully described under Treatment in Cardiac Affections—should invariably be given to the patient. The importance of always living within the limits of the heart's strength, and avoidance of sudden and violent effort, should be specially emphasised in aortic disease. The question of oral sepsis is an important one, and this should receive attention, with the object of diminishing the risk of infective endocarditis. In mitral disease the patient is liable to attacks of bronchitis and broncho-pneumonia, and in both mitral and aortic disease in children and young adults there is a liability to recurrent acute and subacute rheumatic attacks; preventive measures should therefore be adopted, and if, notwith-

standing, an attack of either occur, it should be immediately and adequately treated.

When there are indications of cardiac failure, such as dyspnoea, it is imperative that the work of the heart should be lessened by rest. If the cardiac failure be slight in degree, continuous rest in bed is often not necessary; it is often advisable, however, to begin the treatment by keeping the patient in bed for a short time. Other measures which may be adopted in addition to rest, as well as the treatment of symptoms, have been dealt with.

The Surgical Treatment of Mitral Stenosis.—Samways, in 1898, anticipated that, with the progress of surgery, some of the most severe cases of mitral stenosis might be relieved by "slightly notching the mitral orifice." Lauder Brunton, in 1902, suggested elongating the natural opening, or cutting through the valves at the middle at right angles to the normal opening. Doyen, later, operated on a case, but the patient died very shortly afterwards. Cutler and Levine, in 1923, published the case of a girl, aged 12, on whom they had operated. A valvulotome was plunged into the left ventricle an inch from the apex, and pushed upwards for $2\frac{1}{2}$ inches, until it had reached as far as what was thought to be the mitral orifice. They believed that the aortic leaflet was cut. The patient recovered from the operation, but it was too early to form an opinion as to any benefit that might have accrued. They were of opinion that the mitral diastolic thrill and murmur had diminished in intensity, while the systolic murmur had increased. A pericardial to-and-fro friction had developed, and had gradually grown fainter. Numerous experiments have also been made by Cushing and others. Goodall and Rogers discussed the subject in a paper, and expressed the opinion that the auricular route is better than the ventricular, as an instrument passed from the ventricle into the auricle is more likely to injure the latter than it is to damage the ventricle if passed in the opposite direction. The reasons for and against the ventricular and auricular routes were considered. The same writers published another paper on the subject, almost identical with the former. Souttar published a case in which he used the auricular approach, and dilated the valve with the finger. The patient was a girl, of 15 years of age. She recovered, and, although still breathless, was much improved. Jarotzky, while not putting the operation into practice, suggested that, in cases of mitral stenosis where the general condition is good, but in which the patients from time to time suffer from the formation of infarcts, an opening should be made between the two auricles by passing an instrument through the jugular vein and the superior vena cava directly into the right auricle.

FREDERICK W. PRICE.

DISEASES OF THE MYOCARDIUM AND CORONARY ARTERIES

Affections of the myocardium are of profound importance. It has been pointed out that valvular defects, diseased conditions of the blood vessels, and disturbances of the cardiac mechanism should be regarded from the point of view of their relation to the myocardium, and not so much as specific affections in themselves. It has also been noted that, along with valvular lesions, coincident changes in the cardiac musculature, the aorta, or coronary arteries are, as a rule, present. We are, however, now concerned with affec-

tions of the myocardium occurring independently of valvular disease, and of these inflammation of the myocardium, or myocarditis, is undoubtedly of most importance.

MYOCARDITIS

Varieties.—The varieties which may be met with are—(1) **Acute**, (*a*, simple, and (*b*) suppurative—of uncommon occurrence; and (2) **chronic**. Chronic myocarditis will be discussed under chronic myocardial disease. (3) Tuberculous myocarditis is rare.

ACUTE MYOCARDITIS

Ætiology.—Acute simple myocarditis is usually due to one of the acute infective diseases, especially acute rheumatism, diphtheria, influenza, pneumonia and scarlet fever. Some degree of myocarditis is always present with pericarditis, and probably also with endocarditis. Suppurative myocarditis is usually the result of pyæmia or infective endocarditis. Tuberculous myocarditis is almost always the result of extension from a tuberculous pericarditis.

Pathology.—Acute simple myocarditis may be general, or limited to one or more portions of the cardiac wall. Acute degenerative processes, especially fatty degeneration, of the muscle-fibres are usually found; the interstitial connective tissue, on the other hand, may show little or no change, or may exhibit considerable cellular infiltration. It has been noted by Romberg, Carey Coombs, and others that this cellular infiltration is often focal, the foci being from 0·1 to 0·2 mm. in diameter, and situated in the neighbourhood of the mitral orifice; these foci have a homogeneous centre, surrounded by a zone of giant cells, and are believed by some to be pathognomonic of the rheumatic infection. Some writers recognise two forms of myocarditis, the parenchymatous and the interstitial; in most cases, however, both the parenchyma and interstitial tissue are affected. Dilatation of one or more chambers of the heart usually supervenes. In suppurative myocarditis, large abscesses in the myocardium are of rare occurrence; they may perforate into the ventricle or pericardium. Minute abscesses, on the other hand, generally at the base of the left ventricle, are not rare. Tuberculous myocarditis usually takes the form of miliary tubercles.

Acute simple myocarditis may be followed by—(1) Complete resolution, in which no permanent changes supervene; or (2) organisation, with the formation of connective tissue, which tends to contract as life advances, and which may occur in limited areas or may involve the whole myocardium. The latter condition is known as chronic myocarditis.

Symptoms.—The clinical picture in acute myocarditis varies considerably in different cases; not infrequently it is indefinite, and, indeed, in rare instances the condition may remain latent during its whole course and is only discovered post mortem, death being due to the severity of the primary illness. The onset may be insidious, or there may be a definite change in the clinical picture of the causal disease. If pyrexia be already present, there may be a further rise of temperature, or if there have been no pre-existing pyrexia it may develop; it may be signalised by a rigor, and be slight or considerable in degree. Not infrequently dyspnoea and cough are present, respiration shallow and more rapid, while Cheyne-Stokes

breathing may be occasionally noted. There may be great prostration, and syncopal attacks may occur if the affection be severe. There is pallor or lividity of the face, according to the degree of severity of the disease. Vomiting not infrequently occurs, and, indeed, may be the first symptom. Jaundice has been noted in some cases. Dropsy may develop, and the urine contain albumin and blood; in the severe form of diphtherial myocarditis, albuminuria is generally present. As the illness progresses, the patient may sink low in bed, complain of headache, with restlessness, insomnia, convulsions, muttering delirium, stupor, and even coma. *The severity of the subjective symptoms may be out of all proportion to the physical signs.*

The pulse is feeble and soft; it is usually, but by no means always, increased in frequency, and, indeed, bradycardia may be present. Bradycardia may be met with during the convalescent stage of diphtheria, influenza, and pneumonia, and occasionally during the febrile stage, and may be due to irritation of the vagus, or sometimes to partial heart-block. In some cases there is irregularity of rhythm, due to extra-systole (Fig. 66) or partial

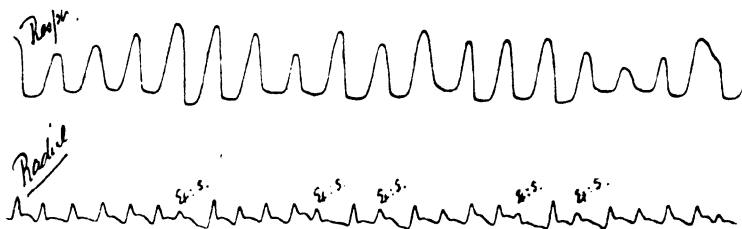

FIG. 66.--Tracing of the radial pulse, from a child suffering from croupous pneumonia, showing extra-systoles. Note the slight pulsus alternans following the extra-systoles.

heart-block (Fig. 67), or auricular fibrillation; exceptionally, complete heart-block is present. The apex-beat, which may or may not be displaced, is diffuse and diminished in force, and even abolished in severe myocarditis. The area of cardiac impairment is usually increased transversely, both to the left and right, as the result of dilatation, which may sometimes come on rapidly.

On auscultation, the first sound is short, sharp and clear, and diminished in intensity, and in the case of rapidly acting hearts the foetal type of cardiac action may be approximated. The second sound over the pulmonary area is sometimes accentuated, and occasionally reduplicated. The gallop rhythm may be present. A systolic murmur is not infrequently heard over the mitral, and sometimes over the tricuspid, area, due to functional inefficiency of the valves; a systolic bruit is perhaps more commonly noted over the base of the heart. Not infrequently physical signs of oedema of the lungs, bronchitis, or effusion of fluid into the pleural sac are to be found.

In diphtherial and influenzal myocarditis, the symptoms may appear either during the febrile stage of the disease or during convalescence; this applies also, but less frequently, when some other cause of myocarditis is present. When the symptoms appear during convalescence, they are not so acute or so severe. Among them may be noted anorexia, languor and pallor; dyspnœa, fatigue, præcordial distress or actual pain, and, possibly,

syncopal attacks on exertion; tachycardia, subnormal blood-pressure, an enfeebled cardiac impulse, evidence of slight cardiac dilatation, a modified first sound at the apex, an accentuated pulmonary second sound, and sometimes a mitral systolic bruit.

The diphtherial form of myocarditis may be mild or severe. There may be bradycardia; in the severe form there is usually albuminuria, and a fatal termination may take place rapidly from cardiac failure. A severe form of myocarditis may also occur as the result of influenza. A grave form of myocarditis has been met with in septicæmia and in severe cases of enteric fever.

Diagnosis.—The diagnosis of acute myocarditis is often extremely difficult, the condition not infrequently presenting an indefinite clinical picture, and at times, indeed, remaining latent; we may often suspect or infer its existence, although it may not be possible definitely to affirm it. It is necessary at the outset to emphasise the importance of being on the lookout for the occurrence of partial heart-block during the course of an acute in-

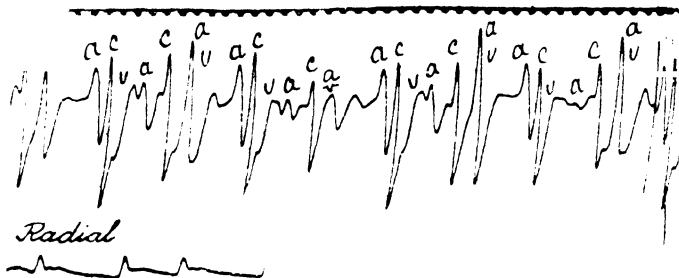

FIG. 67. Simultaneous tracings of the jugular and radial pulses, from a case of acute myocarditis occurring during diphtheria, showing partial heart-block. Every third stimulus from the auricle fails to reach the ventricle.

fective disease, for it is a sign, and may be the only sign, of myocardial damage. The presence of severe myocarditis may be presumed when there are indications of marked cardiac failure coming on rapidly during the course of an infectious disease, and out of proportion to the severity of the latter—cyanosis, vomiting and increase of the area of cardiac impairment being perhaps especially significant. A diagnosis of the mild form of myocarditis occurring during or after the febrile stage of an infectious disease may be arrived at from a consideration of the symptoms already enumerated. It may be necessary in a given case to differentiate myocarditis from acute endocarditis, and this is often a matter of extreme difficulty, for it should be remembered that both conditions may coexist, and a mitral systolic murmur may be due to either.

Prognosis.—The prognosis of the severer forms of acute myocarditis is extremely grave, the mortality being high; the course of the disease is rapid, a fatal termination occurring usually within a week, and in some cases even within 24 hours, although life may be prolonged for several weeks. Death is usually due to cardiac failure, which may occur suddenly; in rare instances to rupture of the wall of the heart. Sudden death is particularly prone to occur in diphtherial myocarditis, and may take place even when the patient is considered convalescent. Among the symptoms of bad

omen are marked pallor, restlessness, syncopal attacks, vomiting, a greatly accelerated pulse of low tension, bradycardia, and a modification of the heart-sounds resembling the foetal type. In the milder forms, however, recovery is the rule, if early and adequate therapeutic measures be adopted.

Treatment.—The treatment of acute myocarditis is of great importance, and is the same as that of acute simple endocarditis.

DISEASES OF THE CORONARY ARTERIES

Before dealing with the various forms of chronic myocardial disease, it may be advisable to discuss the diseases of the coronary arteries, as they bear an important causal relation to some of them, coronary disease being usually accompanied by morbid changes in the cardiac musculature.

Ætiology and Pathology.—Syphilitic mesaortitis and atheroma of the ascending aorta may give rise to narrowing or complete occlusion of the orifice of one or both of the coronary arteries. Among diseases of the coronary arteries themselves, the two most important are: (1) chronic arteritis, and (2) atheroma. In syphilis of the coronary arteries the aorta is usually affected at the same time. Chronic arteritis and atheroma give rise to narrowing of the lumen, and eventually a thrombus may form, resulting in complete occlusion of the vessel.

Complete occlusion of a coronary artery or of one of its main branches is more frequent than has hitherto been supposed. It is much more common in males than in females, and is found particularly in middle or later life. Atheroma is a more frequent cause than chronic arteritis. It is rarely due to embolism, usually intracardiac in origin. The left coronary artery, or one of its main branches, is much more commonly affected than the right.

If the lumen of a coronary artery or of one of its main branches be completely and abruptly closed, as the result of one of the causes mentioned, sudden death, without the occurrence of structural changes, may occur; or infarction may ensue. The latter usually occurs near the apex of the left ventricle, or, less frequently, near the base of that chamber or in the intraventricular septum. Later, the infarct becomes surrounded by dense fibrous tissue, from which strands radiate between the adjacent muscle-fibres, resulting finally in scar formation. The result of this infarction is a weakening of the cardiac wall, which may lead to aneurysm or rupture. Thrombi may form within the aneurysm, or before it has formed, and result in embolism and consequent infarction in the brain, kidneys, spleen or elsewhere.

In those cases in which closure of a coronary artery or of one of its main branches is gradual, or is only partial, and in cases of narrowing or occlusion of the terminal branches, infarction does not take place; local anæmia results, and consequent atrophy of the muscle-cells and secondary fibrosis.

Symptoms of Coronary Disease.—The symptoms of those cases in which closure of a coronary artery or of one of its main branches is gradual, or is only partial, and of cases of narrowing or occlusion of the terminal branches, are those of chronic interstitial myocarditis.

Complete and abrupt closure of a coronary artery or of one of its main branches results in sudden death—this, indeed, being one of the common causes of sudden death; or the symptoms of infarction ensue.

INFARCTION OF THE HEART

Symptoms.—Pain is the most frequent and prominent symptom. Its onset is usually sudden, and the pain usually occurs without physical or mental exertion, or emotion. The pain is felt most commonly in the retro-sternal region, next most frequently across the front of the chest, next most commonly over a wide area of the back of the chest, and occasionally in the præcordium or in the epigastrium. It may be localised, or may radiate in certain directions, the latter being less frequent than in the case of ordinary angina pectoris. If the pain does radiate, the direction of the radiation is usually the same as that in angina. It may vary from that which is moderate to intense anguish. It is usually sudden, and may persist for hours or even days. The expression of the face is usually anxious or even one of intense anguish. The skin is usually pallid or even cadaveric in hue, and there is frequently a clammy sweat. There may be nausea or vomiting. The breathing is usually shallow, and the patient is afraid to make an effort to breathe normally. Cardiac asthma, or, less frequently, Cheyne-Stokes respiration, may be present. Acute pulmonary œdema is rarely met with. The mind is usually clear, but occasionally there is mild delirium. The pulse is usually increased in frequency, and is of smaller amplitude and weaker. I have seen a few cases in which there has been bradycardia, even pronounced. The blood-pressure almost invariably falls, usually considerably and it may be markedly so, and frequently continues to do so and rapidly. The transverse area of cardiac impairment becomes increased, usually considerably and it may be even markedly so, and the dilatation is generally rapid. On auscultation, both cardiac sounds are found to be weaker, and, further, the first sound is often short, sharp and clear, resembling the second sound. The long pause is often diminished, and occasionally a tic-tac heart-beat is present. Rarely gallop rhythm is to be heard. Extra-systoles, or, less frequently, paroxysmal tachycardia, transient or persistent auricular fibrillation, or auriculo-ventricular block, may be present. A mitral, and a tricuspid, systolic bruit may develop—due to *relative incompetence of the valves*. There may be signs of chronic venous congestion and œdema of the lungs, particularly the bases. Localised pericardial friction in the area of the infarct may sometimes be noted, and if so, is of great diagnostic importance. If the patient lives for a day or two, there is usually slight or moderate pyrexia and frequently a moderate leucocytosis, the polynuclear cells being relatively increased in number.

The forms of the electro-cardiograms which may be met with are described on pages 922-923.

Diagnosis.—A correct diagnosis is practically always possible from a careful consideration of the clinical features, including the onset, together with the results of electro-cardiographic examination; indeed, it may usually be made without the aid of the latter. All that may be usefully added to the clinical features already described is that the pain is not relieved by vaso-dilators. The electro-cardiograms are usually characteristic and of great diagnostic value. Those of the first stage are perhaps pathognomonic; those of the second stage are not so characteristic as those of the first, but, taken together with the clinical features, they afford strong

corroborative evidence; while even the changes in the *T* deflections in lead III sometimes found ultimately are very suspicious.

The pain of ordinary cardiac failure, ordinary angina pectoris, rupture of a saccular aneurysm of the thoracic aorta, colic, whether of intestinal, hepatic or renal origin, perforated gastric or duodenal ulcer, acute pancreatitis and other abdominal emergencies should be excluded.

Prognosis.—Death may occur within a few minutes or a few hours. If the patient lives for a few days, he may die from chronic venous congestion within a few weeks or months; or, more frequently, he survives. In the latter event, progress is very slow; there is subsequent cardiac impairment, although rarely the patient is almost as well as previously; while subsequent attacks may occur.

Treatment.—The various measures which may be applicable to any form of cardiac disorder should be considered in detail. Complete and long-continued—at least 3 months—rest, both physical and mental, is imperative. Depletive measures should be avoided. The food should be nutritious and easily digestible, and given in small quantities at frequent intervals. In the early stages, warmth to the body, stimulating liquid foods, and diffusible stimulants are indicated, and the bowels should be opened by means of enemata. For the pain, morphine hypodermically, in sufficient dosage, and preferably with atropine, should be employed. No attempt should be made to hurry convalescence.

CHRONIC MYOCARDIAL DISEASE

Of the various forms of chronic myocardial disease, the three most common are fatty infiltration or cardiac lipomatosis, fatty degeneration, and chronic interstitial myocarditis; the last of these has also been variously termed chronic myocarditis, fibrous myocarditis, sclerotic myocarditis, cardio-sclerosis, fibroid infiltration and fibroid degeneration. Fatty degeneration and fibroid degeneration often coexist, and to this condition the name of fibro-fatty heart is sometimes given.

FATTY INFILTRATION

Fatty infiltration consists in an excess of fat in those situations in which it is naturally found, and also in its deposit between the fasciculi of the cardiac musculature.

Ætiology.—Heredity is certainly a factor, and the condition is more common in males, and during or after middle life, being rare in early life, and comparatively rare before middle age. It is usually associated with general obesity, a generous appetite, and lack of exercise and fresh air. It is more especially found in connection with over-indulgence in carbohydrates, fats and alcohol, particularly malt liquors and sweet wines, and faulty metabolism is generally present. It is also apt to occur in individuals suffering from affections of the lungs which cause embarrassment of the pulmonary circulation, such as emphysema, cirrhosis and chronic fibroid tuberculosis.

Pathology.—The affection is chiefly distributed along the arterial branches, often causing atrophy of the muscle fibres by compression. It is usually most marked over the right ventricle. The deposit of fat commences

in the subepicardial fat, and may even extend to the subendocardial tissue. In some instances the atrophied muscle fibres become the seat of true fatty degeneration, due to interference with their nutrition. In fatty infiltration, more or less dilatation of the cardiac chambers is usually present, and is often accompanied by hypertrophy.

Symptoms.—The patient is usually stout and flabby, and the subjective symptoms are those of an enfeebled circulation. Exertion is frequently accompanied by dyspnoea, a sense of oppression in the chest, and slight cyanosis, with a tendency to perspire easily; the association of cyanosis with dyspnoea on exertion is one of the most usual features of the affection. The patient is easily fatigued by physical or mental effort, and there is often giddiness or faintness. The digestive functions are, as a rule, little, if at all, impaired; on examination, however, there may be evidence of gastric dilatation and of hepatic enlargement. The functions of the nervous system are often affected; there is frequently impairment of memory, and not infrequently the patient is soporose, although, on the other hand, he may complain of insomnia. Cheyne-Stokes respiration is occasionally to be noted. The urine may be large in quantity, pale in colour, and of low specific gravity. The characteristics of the pulse vary considerably; as a rule the rate is increased, it is weak, the vessel is empty, there is hypotension, and the vessel wall is not thickened. On the other hand, the vessel may be full, the blood-pressure supernormal, and the wall thickened. The pulse is usually regular, but may exhibit one of the forms of irregularity. The cardiac impulse is usually feeble, unless hypertrophy is also present, when its area and force may be increased, and pulsation in the neck may be noted. The area of cardiac impairment is generally increased, as the result of dilatation or hypertrophy. On auscultation, the heart sounds, especially the first, are found to be weak, low in tone and muffled; indeed, in the advanced stage the first sound may be almost inaudible: this may be due not only to an enfeebled left ventricle, but also to the unusual thickness of the thoracic parietes in these cases. Murmurs are usually not present, but a soft mitral or tricuspid bruit may be audible, owing to cardiac dilatation.

Later on, there may be evidence of œdema of the dependent parts and of the lungs, while the urine may be scanty, high coloured and albuminous.

Diagnosis.—Fatty infiltration may be diagnosed from the indications of an enfeebled circulation, together with evidence of weakness of the cardiac impulse and sounds, occurring in a person who is the victim of obesity.

Prognosis.—If appropriate therapeutic measures be carried out, the prognosis is usually favourable; otherwise the condition is apt to be progressive. As has been already noted, if fatty infiltration persist for some time, true degeneration is apt to arise.

Treatment.—This consists mainly in dieting, systematic elimination, and abundance of fresh air, while carefully regulated exercise and other measures which have for their object the reduction of bodily fat should also be employed. The diet should be strictly moderate in amount, and sugars and starches, especially bread and root vegetables, should be proportionately diminished; the diet, therefore, should be mainly nitrogenous. The food should be eaten slowly and thoroughly masticated. The amount of fluid with meals should be restricted, and taken at the end of the meal, while,

on the other hand, a considerable quantity of fluid between meals is advisable. It is better to avoid alcohol altogether; but, if this be not possible, brandy or whisky, well diluted, Moselle, or claret is much preferable to malt liquors, Burgundy, port, or champagne.

Regulated exercise in the open air, such as walking, riding, golfing, and cycling, is valuable. Graduated exercises are of special value in cases of slight cardiac failure due to fatty infiltration. In my opinion the simple forms of movements are, certainly in the majority of cases, better than the resistance exercises as practised at Nauheim, and I am inclined to favour Swedish exercises. With regard to any form of physical exertion, care should be taken that it is at first limited in amount, and only gradually increased, while it should in every case stop short of producing any indications of cardiac distress. Systematic elimination, by means of purgatives, Turkish baths, or a visit to some spa, is sometimes useful.

FATTY DEGENERATION

In fatty degeneration the muscle-fibres are more or less replaced by fat.

Ætiology.—Heredity is certainly a factor, and the condition is more common in males. While it may occur at any period of life, it is far commoner during middle life and in the elderly. The condition is found in altered states of the blood, especially pernicious anæmia and leucoeythæmia, while it has been noted in scurvy, purpura, hæmophilia and diabetes. The chemical poisons, especially alcohol, phosphorus, arsenic, antimony, and lead, and the acute infective fevers, especially typhus, enteric fever, diphtheria, erysipelas, small-pox, septicæmia, pneumonia, and influenza, as well as cachectic states the result of cancer, tuberculosis, long-continued suppuration, and other wasting diseases, are also responsible factors in the production of the disease. Among other causes are the retention of waste products in chronic gout and nephritis; chronic venous congestion due to mitral disease and those affections of the lungs which cause embarrassment of the pulmonary circulation; long-standing valvular disease with dilatation; and as a sequel to fatty infiltration. It may be noted that phosphorus, even in small doses, may cause fatty degeneration within a few days.

Pathology.—The affection may be general or local in its distribution, the latter being the more common. In both cases, but especially in the local form, the ventricles are affected to a greater degree than the auricles, and the left ventricle than the right, and the muscoli papillares and the muscle beneath the endocardium are principally involved. The heart may or may not be enlarged; indeed, in pure degeneration it may be even smaller than normal. In this connection it may be stated that fatty degeneration may accompany or succeed dilatation or hypertrophy, while, on the other hand, dilatation may follow degeneration. The organ is softer in consistence and flabby, and is more easily torn. The colour may be uniformly pale yellowish, or buff, or light yellowish brown—the so-called “faded-leaf” colour. The condition is, however, more apt to occur in patches, resulting in a streaked or mottled appearance as a whole, which has been likened to that of the breast of a thrush—“thrush’s-breast,” or to that of the fur of a tabby cat—“tabby cat striation.” On microscopic examination of a section which has been

stained with osmic acid, the small fat globules are seen inside the muscle-fibres, their envelopes being blackened by the acid.

Symptoms.—The clinical picture is in most cases indefinite; in rare instances, indeed, the disease is latent during its whole course, until a fatal termination occurs, due to syncope or angina pectoris, or from some other cause.

The general appearance of the patient varies, which may be due to the causal factor, *e.g.* pernicious anæmia. The countenance not infrequently is pale and waxy, but, on the other hand, it may be ruddy, or even cyanotic; cyanosis, however, is rarely seen unless there is much cardiac dilatation. *Arcus senilis*, coldness of the extremities, and a subnormal temperature may be present. The most common subjective symptoms are dyspnœa, together with some degree of cyanosis of the face, and perhaps giddiness and acceleration of the pulse-rate, on exertion—dyspnœa on exertion being an early and persistent symptom. In some cases there is a sense of uneasiness, and even actual pain, in the præcordium on exertion, but it should be noted that cardiac pain is not usually a prominent feature of the disease except in those cases in which angina pectoris accompanies it; the latter, however, is by no means uncommon. Complaint is sometimes made of debility and general lassitude. The digestive functions are usually impaired, as evidenced by anorexia, drowsiness after meals, atonic dyspepsia, with a tendency to flatulent distension of the stomach, torpidity of the functions of the liver and bowel, and occasionally gastro-intestinal catarrh. Cerebral symptoms, as described on page 754, due to a diminished supply of blood to the brain, are often present and of great diagnostic importance. It is possible that very rarely Adams-Stokes syndrome may occur. There may be a persistent tendency to sighing or yawning, while occasionally Cheyne-Stokes respiration is present; this, however, is usually not met with until an advanced stage of the disease, when it is not infrequent, and occurs for the most part during sleep.

The urine is usually of low specific gravity, and not infrequently contains a trace of albumin and tube casts. There is sometimes a certain amount of œdema about the ankles, but general dropsy is rare, unless there is much cardiac dilatation.

The pulse is almost always altered, the rate varying considerably in different cases; it may be increased, especially in the more acute forms of the disease. On the other hand, there may be bradycardia, even of marked degree, in the more chronic forms, especially in the senile variety. The pulse is usually small, ill-sustained, and the blood-pressure is almost always subnormal; but, on the other hand, its volume may be full. It may be perfectly regular, or irregular. The vessel wall may be normal in the acute forms, or thickened, as occurs in a large proportion of cases of the senile type.

The apex-beat is frequently not visible, and may not be palpable; if present at all, it is usually extremely weak, giving the impression to the hand of a short feeble tap, and there is usually an absence of pulsation in the epigastrium. Stokes pointed out that the impulse may only be felt in the neighbourhood of the left border of the lower end of the sternum. The apex-beat is, as a rule, not much displaced outwards. The area of cardiac impairment is generally enlarged, but usually not to any great extent, unless much dilatation has supervened or hypertrophy exists.

On auscultation the first sound is usually found to be short, sharp and clear, and diminished in intensity; indeed, in the advanced stage of the disease it may be almost, if not entirely, inaudible at the apex, although faintly heard in the neighbourhood of the left border of the lower end of the sternum. In the case of rapidly-acting hearts, the fœtal type of cardiac action may be approximated. A mitral and tricuspid systolic murmur may be present, especially when the cause is anemia or one of the acute infective fevers.

Diagnosis.—The diagnosis of fatty degeneration of the heart is often extremely difficult, as the clinical picture is in most cases indefinite, and indeed in rare instances the disease is latent during its whole course until the occurrence of a fatal termination. We may often suspect the existence of fatty degeneration without being able to confirm it; a positive diagnosis, indeed, is in the opinion of some not possible. The presence of arcus senilis is in itself of no diagnostic importance, but is of some value when accompanied by other symptoms. Cheyne-Stokes respiration is not pathognomonic of fatty degeneration, since it is also to be met with in other morbid affections.

The following points are of importance in a consideration of the question of diagnosis: a causal factor, an absence of valvular disease, the presence of dyspnoea and cyanosis on exertion, the occurrence of angina pectoris, cerebral symptoms, especially syncopal and epileptiform attacks, a pulse of small volume and of low tension, an enfeebled cardiac impulse, general enlargement of the area of cardiac impairment, and an alteration of the cardiac sounds as already noted.

In the opinion of some the differential diagnosis between fatty and fibroid degeneration is impossible, and it should also be remembered that they often occur in association. The existence of constant torpor, Cheyne-Stokes respiration, and apoplectic attacks, and the occurrence of a fatal termination before marked cyanosis, general anasarca, hepatic enlargement, and other indications of a failing right heart occur, are more suggestive of fatty degeneration. Further, in the fibroid form of myocardial degeneration, the pulse is usually more frequent, stronger, and of normal or supernormal tension, while the vessel wall is thickened, the enlargement of the area of cardiac impairment is usually greater, and the aortic second sound accentuated. It should, however, be borne in mind that fatty degeneration may supervene upon the hypertrophy of valvular disease. In the differential diagnosis from valvular disease with cardiac failure, the history may be helpful, as also the characteristic murmurs of the various forms of valvular disease. In mitral disease, for example, hypertrophy is more marked, and, if cardiac failure be present, the usual clinical picture is one of chronic venous stagnation—a condition which is comparatively rare in fatty degeneration—and the degree of cardiac dilatation is greater.

Prognosis.—Taking the cases as a whole, the prognosis of fatty degeneration is grave, as it is one of the commonest diseases in which sudden death occurs. The duration of life, however, may vary from a few months to many years. In considering the probable duration of life, among the points which should be considered are the following. When the affection supervenes upon fatty infiltration the patient may live for many years. In the acute forms, as, for example, when due to acute infective diseases or anemia, the im-

mediate prognosis is grave—especially if cardiac failure makes its appearance at an early stage of the disease—but the ultimate prognosis is not infrequently favourable; the outlook in diphtheritic cases is, however, uncertain. In the chronic forms, as, for example, in coronary disease, the immediate prognosis is more favourable, but the ultimate prognosis is not so good; and yet even in these cases life may be prolonged for some years, if the patient be able to live a carefully regulated life.

A fatal termination may result from gradual or rapid cardiac failure, or from sudden death, the latter occurring perhaps in a majority of cases, and may be due to syncope, angina pectoris, or rupture of the heart. Rupture of the heart is perhaps not so common in fatty as in fibroid degeneration.

Treatment.—The treatment of fatty degeneration is the same as that of chronic interstitial myocarditis.

CHRONIC INTERSTITIAL MYOCARDITIS

Definition.—By chronic interstitial myocarditis is meant an increase of the interstitial fibrous tissue of the cardiac wall, as a consequence of which atrophy and degeneration of the muscle-fibres result.

Ætiology.—Hereditry is certainly a factor, and the condition is more common in males in about the proportion of two to one, and during or after middle life. It is to be found in occupations involving prolonged muscular or mental strain. The condition may follow acute myocarditis. Disease of the ascending aorta involving the orifice of one or both of the coronary arteries and, still more frequently, disease of the coronary arteries themselves, constitute the commonest causes. They are fully described on page 860. Chemical poisons, conditions of defective metabolism, such as chronic gout, and increased peripheral resistance, as, for example, in arterial hypertrophy and granular kidney, also play a part in the ætiology of the disease. Among other causes are chronic venous congestion, due to mitral disease and those affections of the lungs which cause embarrassment of the pulmonary circulation; old standing valvular disease; the chronic adherent form of pericarditis; acute infective fevers; and perhaps altered states of the blood.

Pathology.—The affection may be general or local in its distribution, the latter being usually due to coronary disease. When the affection follows acute myocarditis, a more or less diffuse fibrosis, usually most marked beneath the pericardium and endocardium, is found. In both forms the auricles are little, if at all, affected, and the left side of the heart is much more commonly affected than the right, especially in the neighbourhood of the apex and the lower part of the interventricular septum. When the condition is the result of chronic venous congestion, however, it is more in evidence on the right side of the heart. There is an increase in the thickness of the cardiac wall—the so-called false hypertrophy—and ultimately dilatation occurs. White masses of fibrous tissue, varying in size from that of a pea to a five-shilling piece or even larger, and irregular in shape, are to be observed replacing portions of the cardiac wall or interventricular septum. When the condition has continued for some time and the increase of fibrous tissue is extreme, the affected muscle-fibres may be entirely replaced by dense scar-like tissue. When the coronary arteries are diseased, the aortic

cusps are not infrequently the seat of primary chronic endocarditis, and there may also be widespread atheroma and cirrhosis of the kidneys.

Symptoms.—The clinical picture of fibroid degeneration is a varied one; if the morbid condition be general or extensive, the disease may be difficult to distinguish from fatty degeneration, with which it often coexists. In very rare instances, the disease is latent during its whole course and is only discovered on post-mortem examination. The onset of the symptoms is gradual, and the clinical features are those of chronic heart failure. The most common symptoms are progressive dyspnoea on exertion, together with slight cyanosis of the face; there may also be a sense of oppression in the præcordium, and not infrequently pain on exertion, and slight œdema about the ankles, especially at night. There may be a sensation of fullness and throbbing in the head, noises in the ears, and flashes of light before the eyes. There may be symptoms of cerebral anæmia, as described on page 754. The urine is usually diminished in quantity and of high specific gravity, and may contain albumin, which is frequently present in the later stages of the disease. The patient may suffer from attacks of cardiac asthma, especially at night, and angina pectoris is of common occurrence. Cheyne-Stokes respiration is sometimes found. The usual indications of failure of the right side of the heart may supervene. Ultimately the patient is apt to suffer from marked dyspnoea on the slightest exertion, orthopnoea, and the most distressing cardiac asthma, while the quantity of urine steadily diminishes, and anasarca increases.

The pulse may be of normal rate, or increased in frequency, or bradycardia may be present, the last of these being relatively common. The character of the pulse varies considerably. It is usually fuller than normal, with heightened pressure, although the latter is not pronounced, unless cirrhosis of the kidney or some such affection exists; when cardiac failure is present, however, the pulse may present the opposite characteristics. The wall of the radial artery is usually thickened. When the affection is the result of chronic venous congestion or of chronic adhesive pericarditis, the pulse may be feeble, of subnormal pressure, with no evidence of thickening of the radial wall. The apex-beat is displaced downwards and to the left, its area and force are increased, the area, however, being proportionately greater and the force of the apex-beat proportionately less than in pure hypertrophy. The area of cardiac impairment is increased in all directions. When the affection is due to mitral disease or emphysema, the impulse is most obvious near the ensiform cartilage, and the increased area of impairment to the right of the sternum. On auscultation, the first sound is prolonged and muffled at the apex, with often a soft systolic murmur; the first sound is barely audible at the base, and may be entirely absent. The second sound in the aortic area may be accentuated and reduplicated; when due to mitral disease, however, the second sound in the pulmonary area may be accentuated, but at the same time is less ringing in character than in the earlier stages of valvular disease. A tricuspid systolic bruit is sometimes heard.

Diagnosis.—An absolute diagnosis of chronic interstitial myocarditis is not infrequently a matter of extreme difficulty. The differential diagnosis between this condition and fatty degeneration has been already dealt with on page 866. It is also necessary to distinguish the affection from the cardiac failure of valvular disease, as for example, relative mitral incompetence

occurring in fibroid degeneration from mitral incompetence due to primary organic disease of the valve—a problem of the utmost difficulty. In the former case there is no history of valvular disease, the subjective symptoms are frequently out of proportion to the physical signs, and angina pectoris, and syncopal and epileptiform attacks are of more frequent occurrence.

Prognosis.—The prognosis of the affection closely resembles that of fatty degeneration. Here also the duration of life may vary from a few months to many years. A fatal termination may take place as the result of gradual or sudden cardiac failure. In estimating the prognosis, among other things which should be taken into consideration are the presence or absence of the pulsus alternans, angina pectoris, and syncopal attacks.

Treatment.—It is of great importance that the patient should curtail his physical and mental activities so as not in any way to exceed the limited strength of the heart. His daily life should be considered with great care and in detail. Carefully regulated exercise in the fresh air is permissible, but violent and sudden efforts should be strictly forbidden. Such exercise as walking against a wind and cycling uphill are contra-indicated; on the other hand, quiet walking on the level, or even slow walking up an incline, quiet cycling, croquet, and even riding or golf may sometimes be allowed in suitable cases. In all cases, exertion should stop short of producing breathlessness, palpitation, fatigue, a sense of tightness across the chest, or præcordial pain or distress. If these precautions be not taken, there is real danger. High altitudes are better avoided. Only warm bathing should be allowed. The clothing should be warm. Particular care should be taken with regard to diet; it should be most carefully regulated on the lines previously laid down. Gastric and intestinal dyspepsia, especially with flatulence, should be avoided, or treated when present. What fluid is taken with meals should be taken *at the end*. Overloading the stomach should be avoided. Rest before and after food, and in the afternoon, should be enjoined. The state of the bowels should receive most careful attention. In these cases it is sometimes of advantage to diminish the body weight. If there be supernormal blood-pressure, it should be regulated by the methods described previously. If anæmia be the cause or an accompaniment of the condition, it should be adequately treated.

When there are indications of cardiac failure, rest, proportionate to the degree of failure present, is imperative; other therapeutic measures also, as previously described, should be adopted. The indications for one of the digitalis series of drugs have already been discussed.

HYPERTROPHY OF THE HEART

In cardiac hypertrophy there is an increase in the thickness of the walls of one or more of the cavities of the heart, due to an increase in the actual size, and possibly also in the number, of the muscle-fibres. The hypertrophy may include the muscoli papillares, columnæ carneæ, and muscoli pectinati.

It is customary to divide hypertrophy of the heart into three kinds, namely—(1) The concentric, in which with the increased thickness of the walls the cavities are diminished in size; (2) the simple, in which the cavities are normal in size; and (3) the excentric type, in which the cavities are increased in size—in other words, there is hypertrophy with dilatation.

In the opinion of some, the concentric variety only exists as a post-mortem change.

Ætiology.—Hypertrophy is apt to occur when the heart has been subjected to an excessive amount of work. It is more common, therefore, in men, on account of their greater exposure to long-continued excess of muscular effort and to mental strain. Among other causes are long-continued over-indulgence in food, alcohol, or tobacco, lithæmia, supernormal blood-pressure and arterial disease independent of kidney disease, nephritis—especially the chronic interstitial form, chronic valvular disease, congenital atresia of, or pressure upon, the aorta, chronic adhesive pericarditis, certain affections of the nervous system causing persistent increased cardiac rate, hyperthyroid secretion, chronic disease of the lungs—such as emphysema, cirrhosis, and chronic fibroid tuberculosis, chronic disease of the bronchi, and atheroma of the pulmonary artery. Drinking large quantities of beer, chronic interstitial nephritis, and aortic disease may give rise to enormous hypertrophy.

In the case of long-continued muscular effort and mental strain, long-continued over-indulgence in food, alcohol, or tobacco, affections of the nervous system, and hyperthyroid secretion, the hypertrophy is likely to be general; in supernormal blood-pressure and arterial disease, nephritis, and aortic valvular disease, the left ventricle is more especially affected; whereas in the chronic affections of the lungs or of the bronchi, and disease of the pulmonary artery, the right ventricle is principally involved.

Pathology.—Hypertrophy of the heart may be general or local. In the former, all the chambers of the heart are involved. The ventricles are more affected than the auricles, for the walls of the latter contain more fibrous tissue. When the condition is local, which is much the more common, while all the chambers are not affected, there is, as a rule, hypertrophy of more than one, though in varying degree. The following is the comparative order of frequency: left ventricle, right ventricle, left auricle, right auricle. When the left ventricle is affected, the apex of the heart is accentuated, and the whole organ is elongated and rather conical in form. When the right ventricle, on the other hand, is concerned, the apex is less pronounced, and the whole organ broader and somewhat quadrate in form. The excentric variety of hypertrophy may give rise to enormous enlargement of the organ, in which case the heart is often spoken of as a “beefy heart” or a “cor bovinum.” This is especially apt to occur in aortic valvular disease.

For the development of full hypertrophy, an adequate blood supply is necessary, and in this connection the state of the general nutrition, as well as the anatomical and physiological condition of the coronary arteries, is of considerable importance.

Symptoms.—The symptoms of the morbid condition which is the cause of the hypertrophy, whether of the left or right side of the heart, may be present. With regard to the hypertrophy itself, there may either be a complete absence of subjective symptoms, or, on account of increased tension in the cerebral circulation, a sensation of fullness and throbbing in the head, headache, usually in the occipital region, flushings, noises in the ears, flashes of light before the eyes, and giddiness. Sometimes patients complain of discomfort or even of actual pain in the præcordium, especially when lying on the left side, and this sensation is aggravated by exertion. Actual pain,

however, is not common, unless perhaps in the case of neurasthenics and of subjects of tobacco poisoning. Another symptom of which the patient may complain is palpitation. When cardiac failure supervenes, complaint may be made of dyspnoea on exertion and other symptoms.

Hypertrophy of the left ventricle is characterised by a full strong pulse, of prolonged duration, and by a blood-pressure above the normal. The pulse-rate, on the other hand, is apt to be rather lower than normal. There may be some bulging and widening of the intercostal spaces in the præcordial area to the left of the sternum, especially when the hypertrophy occurs during the growing period of life. The apex-beat is displaced downwards and outwards; it may be as low as the sixth, seventh, or even eighth intercostal space. Its extent and force are increased, and its character "heaving" or "thrusting," the beat being slower and longer than normal. *This heaving or thrusting of the apex-beat is the most characteristic feature of the condition.* The area of impairment is increased, both from above downwards and transversely; it may even extend downwards to the eighth interspace, and transversely to the anterior axillary line. On auscultation, the first sound in the mitral area is frequently long, low in pitch, and muffled; the short pause may be lengthened, and the long pause shortened, while the second sound in the aortic area is frequently accentuated. Sometimes the first sound is reduplicated, and then is usually best heard rather to the inner side of the apex-beat. The aortic second sound also is occasionally reduplicated.

When there is considerable dilatation with the hypertrophy, occurring either in the first instance or subsequently in association with cardiac failure, the pulse increases in frequency, the blood-pressure becomes lower, the apex-beat becomes more diffuse, weaker, abrupt and rapid, and is of a tapping character. The transverse area of impairment becomes enlarged, and the first sound may be accentuated, sharp, clear, high in pitch, and considerably shortened. Other indications of cardiac failure, such as œdema, may also supervene.

In hypertrophy of the right ventricle there may be, more especially in children, a certain amount of bulging in the region of the ensiform cartilage, while not infrequently there is pulsation in the epigastrium, diastolic in time. When the condition is marked, there may be a heaving impulse in the epigastrium, and over the lower sternum and costal cartilages, and in such cases even more marked than that of the left ventricle. The apex-beat is displaced chiefly to the left and only slightly downwards, and may be normal, diffuse and indefinite, or altogether invisible. When the right ventricle is much enlarged, that chamber may displace the left ventricle backwards, so that the clinical apex-beat is formed entirely by the right, instead of the left, ventricle; in these cases systolic recession over the lower part of the præcordium is sometimes observed. Systolic recession in the third, fourth and fifth intercostal spaces between the margin of the sternum and the parasternal line on the left side, or in the fourth and fifth intercostal spaces on the right side, may be present. The area of cardiac impairment is usually increased, especially to the right. The left border may also be displaced outwards, but rarely extends beyond the nipple line. The first sound in the tricuspid area is not infrequently louder than normal, and the second sound in the pulmonary area is usually accentuated and may be reduplicated. Later, the symptoms of tricuspid incompetence may supervene.

When hypertrophy of the auricles occurs, it is accompanied by dilatation. In hypertrophy of the left auricle, the area of impairment may be higher than normal. When the right auricle is affected, there may be an extension outwards of the area of impairment in the third and fourth right intercostal spaces.

Diagnosis.—A diagnosis of hypertrophy of any chamber or chambers of the heart should not be made merely from the presence of pulsation or percussion impairment in an abnormal area, for these may be due to causes other than hypertrophy, as, for example, morbid conditions of the lungs or pleuræ. The most reliable sign of hypertrophy of the heart is a heaving or thrusting impulse. It should be remembered that mere increase of force of the apex-beat is sometimes met with in nervous subjects, especially in the young whose chest-walls are thin; but in these cases there is no displacement of the apex-beat, the impulse is sharp and short, the area of impairment is not increased, and the sounds of the heart are not altered in the characteristic manner described. I have seen an incorrect diagnosis of hypertrophy of the left ventricle made in cases of retraction of the left lung; in these cases there is an increased area over which the healthy heart comes into direct contact with the chest-wall. The apex-beat, however, is displaced upwards, is not heaving or thrusting in character, and there are signs of a pulmonary lesion. Hypertrophy of the right ventricle can be diagnosed when the objective signs already mentioned are present. The diagnosis of hypertrophy of the left auricle is exceedingly difficult; hypertrophy of the right auricle is more easily detected.

Prognosis.—This depends upon, among other things, the cause, the degree of hypertrophy, the degree of dilatation present, the condition of the systemic and coronary arteries, and of the myocardium. With regard to the first, the prognosis depends very largely upon whether this is serious and irremediable, as when renal cirrhosis is present, in which case dilatation is apt to supervene; or whether it is merely transitory, as, for example, when the result of a period of excessive muscular strain, in which case it seems clearly established that hypertrophy may disappear when the cause no longer exists. Long-continued hypertrophy is apt to be followed by dilatation which adds to the gravity of the condition as a whole.

With regard to the condition of the coronary arteries, it need only be pointed out that anginal attacks in all probability point to the existence of coronary disease, in which case the supply of blood to the hypertrophied heart will be insufficient, with a resultant tendency to degeneration. With regard to the integrity of the myocardium, the importance of testing the cardiac response has already been fully considered.

Treatment.—The hypertrophy itself does not need treatment. It is always advisable, however, to consider the cause, and, in some cases, as, for example, when chronic Bright's disease, supernormal blood-pressure, or arterial disease is present, it should be suitably treated. In order to provide a good supply of food to the heart-muscle, we should see that the patient obtains plenty of fresh air, and an adequate supply of nutritious and easily digestible food, and any dyspepsia or anæmia present should receive attention. Undue physical or mental strain should be avoided. If cardiac failure supervene, it should be treated as described elsewhere.

DILATATION OF THE HEART

In cardiac dilatation there is an increase in the capacity of one or more of the cavities of the heart.

Looking at the condition from the pathological standpoint, the muscular walls of the chambers may be of normal thickness, which is not common; more usually they are either thinner or thicker than normal. The last is by far the most common, *i.e.* in the great majority of cases there is some hypertrophy with the dilatation: this is called excentric hypertrophy, and has already been described. It should be remembered that when dilatation has existed for a long time, the walls become thin, although, perhaps, in the first instance thickened.

Looking at the subject from the clinical standpoint, however, dilatation means an increase in the capacity of one or more of the cavities of the heart as the result of impairment of the function of tonicity; this form of dilatation is associated with cardiac failure. From this point of view, dilatation with hypertrophy is only included when the dilatation is in excess of the hypertrophy. Hypertrophy is apt to be followed by dilatation, and the latter, therefore, may be secondary to the former.

In dilatation a larger quantity of blood exists in the affected chamber than normal, while the propulsive power is diminished; the chamber, therefore, cannot empty itself. As the dilatation progresses, the contraction of the chamber becomes less effective, and the amount of residual blood progressively increases.

Ætiology.—Cardiac dilatation is more common in men, on account of their greater exposure to long-continued excess of muscular effort and to mental strain; this is especially so in certain occupations. General cardiac dilatation may occur in any of the following conditions: severe or prolonged pyrexia, more especially in the case of pneumonia, scarlet fever, typhoid or typhus fever; toxæmias, as influenza and diphtheria, alcoholism, tobacco poisoning, and overdosage by the salicylates; various forms of anæmia; cachectic conditions; myocardial degeneration; rheumatic carditis; and affections of the coronary arteries causing defective blood supply. In the case of toxæmia of influenza and diphtheria, as well as in the acute carditis of rheumatism, dilatation may be acute.

Dilatation may occur secondarily to hypertrophy, especially when the nutrition is defective. One of the most common causes of secondary dilatation is some form of mechanical obstruction, slowly produced, either in the blood vessels or in the valves. Some of the causes of hypertrophy may produce acute dilatation by acting quickly, before there is time for hypertrophy to occur; this is especially the case when the muscular fibres are already impaired. Thus, whereas prolonged and continued excess of muscular effort tends to produce hypertrophy, a sudden physical strain is apt to produce acute dilatation, especially if the individual be not in training (see primary cardiac overstrain); further, in cases of completely established hypertrophy, dilatation may be produced with apparent suddenness by a comparatively trivial ailment, such as bronchitis, influenza, or any febrile attack.

It should be particularly noted that a very common clinical condition in which acute cardiac dilatation occurs is the supervention of a new heart rhythm, such as auricular fibrillation.

In addition to disease of the pulmonary artery, and the chronic pulmonary affections enumerated in the ætiology of hypertrophy, acute dilatation of the right side of the heart may occur in pneumonia, œdema of the lungs, and in pleurisy with effusion.

Pathology.—Dilatation rarely affects one chamber alone, all of them being usually affected in some degree, although unequally so. The heart becomes larger, and when the condition is more or less general the organ approaches the globular form, particularly when the right side is affected. With the increase in the capacity of the ventricles, the dimensions of the auriculo-ventricular orifices also increase, and this results in what is known as *relative incompetence*. In dilatation of the auricles there is usually enlargement of the venous channels.

Symptoms.—The symptoms of the cause are sometimes to be noted, and in addition there is usually languor, and fatigue on physical exertion, while strain is liable to induce a sensation of faintness, or even actual syncope. Shortness of breath and palpitation on exertion are of common occurrence, while there may be an uncomfortable feeling, amounting to actual pain, in the præcordium. Some degree of cyanosis of the face may also be noted. The digestive functions are usually impaired, as shown by anorexia, drowsiness after meals, atonic dyspepsia with a tendency to flatulent distension of the stomach, torpidity of the functions of the liver and bowel, and occasionally gastro-intestinal catarrh. Cerebral symptoms, such as giddiness, lack of power of concentration, early fatigue on mental effort, a tendency to drowsiness, disagreeable dreams, nervousness, and even symptoms of mental derangement may be noticeable. Jaundice is not infrequently present, and also vomiting, hepatic enlargement, œdema of the feet, and sometimes splenic enlargement. The urine may be scanty, and contain albumin, and even blood and tube casts. There is a tendency to chronic congestion and œdema of the lungs, particularly of the bases, and ascites and pleural effusion are occasionally present. As the case progresses, dyspnœa may occur on the slightest exertion, and orthopnœa, cardiac asthma, anasarca, and a still further diminution in the amount of urine.

The pulse is usually found to be more frequent, of smaller amplitude, and weaker, while the blood-pressure is lower than normal. Distension and pulsation of the jugular veins may take place.

Sometimes, particularly in children, in dilatation of the right ventricle there is a certain amount of bulging of the præcordium in the region of the ensiform cartilage. The apex-beat is displaced chiefly outwards. It is diffuse and often difficult or even impossible to locate, but if it can be determined is found to be weaker than normal and tapping in character. In dilatation of the left ventricle a diffuse wavy impulse may be present in the anterior axillary line. In enlargement of the right ventricle the clinical apex-beat may be formed by the right, instead of the left, ventricle, in which case there may be a more diffuse systolic recession over the lower part of the præcordium, in place of the normal apex-beat; also systolic recession in the third, fourth and fifth intercostal spaces between the margin of the sternum and the parasternal line on the left side, or in the fourth and fifth intercostal spaces on the right side, may be present. The area of cardiac impairment is increased transversely, and is more marked to the left when the left ventricle is chiefly involved and to the right in the case of the right ventricle. In dilatation of the

left auricle the area of impairment may be higher than normal, and in dilatation of the right auricle it may extend outwards in the third and fourth right intercostal spaces. On auscultation, both cardiac sounds are found to be weaker; and, further, the first sound is short, sharp and clear, resembling the second sound in character. The long pause is often diminished, on account of acceleration of the rate of the heart, and sometimes the tic-tac heart-beat is present. Occasionally gallop rhythm is to be heard. A mitral, and in a still larger proportion of cases a tricuspid, systolic bruit may be present—on account of *relative* incompetency of these valves.

The physical signs of dilatation enumerated above may be modified by those of the cause of the condition, or of accompanying hypertrophy. In the case of valvular disease, the original murmurs may become weaker or even inaudible when dilatation occurs.

The symptoms of cardiac dilatation may come on rapidly in the acute forms or more gradually in the more chronic cases. In many of the cases associated with the onset of a new cardiac rhythm the dilatation takes place so rapidly that in the space of even a few hours there are urgent dyspnoea, extreme hyperæsthesia of the chest-wall, evidence of œdema of the lungs, and enlargement and pulsation of the liver. When dilatation is due to a sudden physical strain, faintness passing into actual syncope, together with vomiting, and even fatal syncope, may occur before the signs of venous stasis have had time to develop.

Diagnosis.—A diagnosis of cardiac dilatation can readily be made when the physical signs described are present. The diagnosis of dilatation from hypertrophy is easy on a comparison of the physical signs of the two conditions. When hypertrophy and dilatation coexist in the same individual, there is a blending of the signs of both. It is sometimes difficult to diagnose great dilatation, especially of the right ventricle, from pericardial effusion. The points relating to the differential diagnosis will be fully discussed under pericarditis. Cardiac dilatation must also be distinguished from those cases of mitral stenosis in which there is an absence of a presystolic murmur at the time of examination. It is, further, sometimes necessary to exclude a right-sided pleural effusion displacing the heart to the left, in which case signs of fluid in the right pleural sac will be found.

Prognosis.—The prognosis of cardiac dilatation depends, among other things, upon the cause, the degree of dilatation and whether this is out of proportion to the cause, the degree of any coexisting hypertrophy, the severity of the symptoms, the rate and force of the pulse, the vigour of the apex-beat or of the impulse of the right ventricle, and the size of the heart. Taking cases of cardiac dilatation as a whole, the prognosis is unfavourable.

In acute dilatation from temporary causes, such as sudden physical strain or acute disease, if immediate danger can be tided over, there is a prospect of complete recovery, provided an adequate period of rest is available. The same applies to those cases due to the inception of a new cardiac rhythm, if the rhythm return to the normal. In chronic dilatation from a permanent cause, *e.g.* chronic valvular disease, complete recovery is improbable; it may take place, however, in some instances under suitable treatment. The prognosis is very unfavourable when dilatation supervenes upon marked arterial disease or myocardial degeneration, and this applies also to cases of Bright's disease.

Treatment.—The first thing that requires consideration is the recognition of the cause of the condition, whatever its nature, and suitable therapeutic measures should be employed in this connection. Added to this is the treatment of the affection itself, which is that of cardiac failure, and consists of an adequate period of rest, dieting, perhaps the administration of cardiac tonics or stimulants, and symptomatic treatment. Rest is imperative, and in acute cases must be absolute. Graduated exercises may be of service in a small group of cases, as, for example, in fatty infiltration. With regard to the administration of cardiac tonics, such as digitalis, the reader is referred to the appropriate section for their indications, dosage, and method of administration. When dilatation is due to bacterial poisoning, digitalis appears to be ineffective. In acute cases, strychnine, alcohol, ether, and ammonia, by the mouth or subcutaneously, may be given. When venous engorgement and other indications of distension of the right chambers of the heart are present, purgatives, diuretics, and blood-letting by means of leeches or venesection, are indicated. The special indications for the practice of venesection in these cases, as well as the treatment of gastro-intestinal and other symptoms, have already been noted.

FREDERICK W. PRICE.

DISEASES OF THE PERICARDIUM

PERICARDITIS

The varieties of pericarditis which may be met with are the fibrinous or dry, sero-fibrinous, purulent, hæmorrhagic, and chronic adhesive, *i.e.* adherent pericardium. Some writers describe a chronic form of pericarditis; this, however, is practically synonymous with chronic adhesive pericarditis.

ACUTE PERICARDITIS

Ætiology.—It is questionable if pericarditis be ever primary or idiopathic. The affection is more common in children, especially those of the second decade, and in males. By far the commonest cause, especially in young people, is rheumatism, under which chorea is to be included, the pericardial inflammation usually appearing during the second half of the first week or the first part of the second week of the rheumatic attack. The relation between rheumatism and pericarditis has been already discussed. The terminal stages of Bright's disease, especially of the two chronic forms, and in particular the chronic interstitial variety, and pneumonia, more especially affecting the left side, are frequent causes of pericarditis; in pneumonia, infection may take place either by means of the blood stream or by extension. Other causes of pericarditis are scarlet fever, measles of severe type, small-pox, enteric fever, influenza, diphtheria, tuberculosis, gonorrhœa, and other acute infective conditions; constitutional diseases, such as gout and diabetes; disordered blood states, such as leucocythæmia, lymphadenoma, purpura, and scurvy; new-growths; affections of the neighbouring parts, as, for example, the pleuræ, lungs, mediastinum, ribs, vertebræ, and peritoneum; injuries to the chest-wall; and in conjunction with myocarditis.

When pericarditis is due to Bright's disease, there is a tendency to the purulent, hæmorrhagic, or chronic adhesive variety of the disease. The pericarditis which occurs in connection with malignant disease is usually of a chronic type, and is generally accompanied by the effusion of fluid, which is usually hæmorrhagic, but may be purulent or serous. Purulent pericarditis is usually due to pyæmia, septicæmia, as in the exanthematous fevers, or suppuration in the neighbourhood of the pericardium, as, for example, empyema, or the rupture of a pulmonary vomica. It may also occur in Bright's disease, and in tuberculous deposits in the pericardium. Among the micro-organisms which may be found are staphylococci, streptococci, pneumococci and gonococci. Hæmorrhagic pericarditis is more frequently met with in the aged, in Bright's disease, in acute infective conditions, such as small-pox, tuberculosis, scurvy and purpura, malignant disease, either by direct extension or secondary, wounds of the heart, and in leakage from an aneurysm.

Pathology.—Pericarditis may be general or local; if the latter, the base of the heart, close to the region of the great vessels, is, as a rule, principally affected.

In the fibrinous form, the free surface of the pericardium becomes more vascular and loses its smooth shiny appearance, owing to the transudation of lymph, which coagulates and forms a fibrinous exudate, which in the course of time may involve the entire surface, visceral and parietal, and may reach $\frac{1}{8}$ in. in thickness. In the majority of cases the exudate may easily be separated from the underlying surface, often leaving a honeycomb or reticulate appearance. In the fibrinous form there is little or no effusion of serum into the pericardial sac. In the sero-fibrinous form, on the other hand, complete resolution of the fibrin, and, in the latter case, absorption of the effusion, may take place, so that no trace of the inflammation is left. When, however, resolution of the fibrin and absorption of the fluid occur slowly, which is the rule in the sero-fibrinous form of the disease, organisation takes place. This may give rise to white patches of thickening ("milk spots") upon the pericardium, or may result in its two layers becoming adherent by permanent fibrous adhesions; in the latter case, chronic adhesive pericarditis or adherent pericardium is produced. In purulent pericarditis the pus rarely perforates the pericardium, and has been known to become absorbed, leaving behind a pultaceous mass.

It may be noted that some degree of myocarditis is always present with pericarditis.

Symptoms.—The symptoms of the primary affection are generally to be noted. The severity of the symptoms of the disease itself exhibits great variation, and there may be a complete absence of subjective symptoms throughout the whole course; on auscultation, however, pericardial friction is usually found.

If pyrexia be already present, there is usually a further slight rise of temperature, although this may not be noted, and, in the opinion of some, there may even be a slight fall. This applies equally where there has been no pre-existing pyrexia. When effusion has occurred, there is, as a rule, no increase of temperature, and, indeed, if the pyrexia have been marked, there is a tendency for it to become lower. Occasionally the onset of the disease is marked by a rigor.

The patient is usually pale, and sometimes cyanotic; when effusion has

occurred, these features become more pronounced, and he usually wears an anxious expression. Præcordial uneasiness, or even pain, is frequently present; the pain may be located in the epigastrium, the left scapular or interscapular region, instead of in the præcordium, and varies greatly in severity and character. It may be constant and dull, or recurring, sharp and stabbing; anginal attacks are rarely to be noted. When pain is present, there is usually accompanying hyperæsthesia. Sometimes palpitation and breathlessness are complained of, and there may be faintness. The respiratory rate may be increased, and there may be even cardiac asthma or Cheyne-Stokes respiration. Interference with the respiratory functions is more pronounced when effusion has occurred, and may be greatly aggravated unless the effusion of fluid is gradual. Not infrequently a dry cough is present. Dysphagia is of uncommon occurrence, being more marked in cases of effusion and when the patient is in the recumbent posture. When the recurrent laryngeal nerve is implicated, the voice becomes affected, while if the phrenic nerve be involved the patient may suffer from hiccough.

There may be headache, restlessness, insomnia, convulsions, mild nocturnal delirium, or, less frequently, noisy delirium, stupor, and even coma. Hepatic enlargement is of comparatively common occurrence. A certain amount of œdema may become evident; it is usually general and is more marked in the dependent parts. Not infrequently pulmonary œdema occurs. The urine may become scanty and albuminous.

The pulse is more frequent in rate and smaller in volume than normal. After a shorter or longer period, the blood-pressure becomes lower. At first the apex-beat may be excited and its force considerably increased; later it becomes diminished in force, sometimes tapping in character and displaced outwards. Friction-fremitus can sometimes be noted in fibrinous pericarditis. Its area of maximum intensity does not absolutely correspond with that of a thrill due to valvular disease. As a rule, friction-fremitus accompanies ventricular systole and diastole, having a to-and-fro character, but sometimes it is only systolic; in any case it is not exactly synchronous with either systole or diastole. It gives the impression to the hand of being superficial. After a shorter or longer period, the area of deep cardiac impairment may become enlarged to the left, upwards, and to the right. Auscultation reveals the most characteristic and reliable physical sign, namely, that of pericardial friction. It may accompany every phase of the cardiac cycle. As a rule, it accompanies ventricular systole and diastole, is of a to-and-fro character, with usually a short pause between the two portions. Sometimes it is only ventriculo-systolic, while at other times, when the inflammation involves the auricle, it accompanies auricular systole, ventricular systole, and ventricular diastole, giving rise to a triple rhythm. In any case, the different portions of the friction sounds do not absolutely coincide either in rhythm or duration with any period of the cardiac cycle, being rather later than any of them and usually heard during portions of more than one period. The sound is usually first audible over the base of the heart, but later on may become audible over the whole præcordium. The area of maximum intensity does not absolutely correspond with that of any of the valvular areas. A characteristic feature is that, as a rule, the sound is either not at all or only slightly conducted, and there is no definite selective direction of propagation. It is of a rubbing quality, either fine and creaking or coarse and grating, and is superficial, giving the

impression of being produced immediately beneath the stethoscope, while moderate additional pressure with the stethoscope usually causes an increase in its intensity. The friction may not be so well heard when the patient is lying down as when he is sitting up, and its loudness may be also influenced by respiration, being, as a rule, louder during inspiration—in contra-distinction to pleural friction.

The heart sounds are usually audible. There may be doubling of the first sound, giving rise to a triple rhythm, while a mitral systolic murmur is not infrequently present, due either to coexisting endocarditis or to cardiac dilatation.

As the exudate is absorbed the friction gradually disappears, but it usually remains, unless the quantity of fluid is great, and even then it may persist—this being in marked contrast with friction occurring as the result of pleuritis. If the friction persist, it occupies a higher level than before. When pericarditis is secondary to pleurisy or pneumonia, there is often pleuro-pericardial friction along the left border of the heart, where the pleura lies in front of the pericardium. This also occurs in cases of pericarditis in which the outer surface of the pericardium and the opposing pleural surface become involved.

The early physical signs of sero-fibrinous pericarditis are those of the fibrinous variety. The pulse becomes still more frequent, smaller in volume, and the blood-pressure lower. At times the pulse is somewhat collapsing in type. The pulsus paradoxus may be present. Not infrequently there is prominence of the præcordium, and, if so, the intercostal spaces may be widened or even bulge, as well as the ribs, and there may also be prominence of the epigastrium. The apex-beat is often displaced upwards, and is usually found in the fourth, but sometimes in the third, interspace, in which case it is not the normal apex of the heart, but a point nearer to the base-line, and the impulse is more diffuse than normal; it may be to the left of the nipple line, and sometimes is more mobile than normal. It is diffuse and its force is diminished. It is more distinct in the recumbent posture than when the patient sits upright, on account of the tendency of the fluid to gravitate backwards when lying down, and forwards when sitting up. As the amount of effusion increases, the apex-beat becomes less and less distinctly felt, until it may be quite imperceptible. Friction-fremitus may be present, but not in the same degree as in the fibrinous variety. The most characteristic physical signs are those obtained by percussion. The areas of superficial and deep cardiac impairment are increased, in some cases considerably; this increase takes place in all directions, and is progressive. Some observers believe that in the early stage of pericardial effusion, impairment of the percussion note may be found in the fifth right intercostal space, between the costal cartilages, where the right margin of the heart forms an angle with the liver (Roch's sign). When the effusion is considerable, the form of increased area of cardiac impairment is characteristic, its outline, as a rule, closely resembling that of a pear hanging downwards by its stalk. The area of relative impairment often extends well to the left of the apex-beat; it may be almost to the left mid-axillary line. The right border may be found considerably to the right of the sternum. The extension upwards may be as high as the left clavicle, the upper lobe of the left lung being compressed. The lower limit may reach the lower margin of the sixth rib. In the recumbent posture the area is smaller

than when the patient sits upright, on account of the tendency of the fluid to gravitate backwards in the one case and forwards in the other. The degree of impairment is absolute.

On auscultation, the heart sounds are found to become progressively indistinct and muffled, and may be lost, though sometimes, even when the quantity of fluid is large, they may persist, especially at the base; this also holds good with regard to friction. The pressure of the effusion upon the lungs may result in the production of dullness and diminished breath sounds at the extreme left base close to the spinal column; as well as skodaic resonance, tubular breathing, and ægophony, not only over a patch in the neighbourhood of the angle of the left scapula, but also over the borders of the lungs anteriorly; the upper limit of the area of impairment posteriorly may shift on change of position. The liver and spleen also may be pushed downwards. The extent of the effusion, as well as the displacement of the organs, can be recognised by X-ray examination. Finally, physical signs of tricuspid incompetence, including enlargement of the liver, may supervene.

As the fluid becomes absorbed, the area of cardiac impairment diminishes, the heart sounds gradually return to the normal, and, as the two surfaces of the pericardium come once more into contact, friction may reappear.

The symptoms of purulent pericarditis are those of the sero-fibrinous variety, except that rigors, a high and fluctuating temperature, profuse perspirations, great wasting, pallor, rapid prostration, marked rapidity of the pulse-rate, a subnormal blood-pressure, a smaller area of cardiac impairment, and an absence of pericardial friction, are more likely to occur. It should be noted, however, that the temperature may be almost normal, and cases have been reported in which it was even subnormal; there may also be little alteration in the frequency of the pulse or respiration. Sweatings may occur without the existence of rigors. An examination of the blood usually reveals a leucocytosis. When pus is present from the first, the subjective symptoms may be obscured by those of the associated condition, and only the physical signs of pericarditis with effusion may be noted; though even then there may be no increased area of impairment, and an absence of friction.

Diagnosis.—It has been pointed out elsewhere that it is extremely important to be on the look-out for an insidious or masked attack of pericarditis.

The diagnosis of the fibrinous variety of pericarditis is not, as a rule, difficult, and rests not upon subjective symptoms, but upon physical signs. Of these the most characteristic sign is the presence of friction sounds of the type already described. This is pathognomonic of fibrinous pericarditis, or of tuberculous, cancerous, or gummatous deposits, and should be differentiated from an endocardial murmur (especially if the friction sound be single), and from pleuro-pericardial friction. With regard to the first, in endocardial sounds, whether due to pericardial friction or to pleuro-pericardial friction, the different portions of the friction sounds do not absolutely coincide either in rhythm or duration with any period of the cardiac cycle, being rather later than any of them and usually heard during portions of more than one period; the area of maximum intensity does not absolutely correspond with that of any of the valvular areas; the friction sounds are, as a rule, conducted either not at all or only to a slight extent, and there is no definite

selective direction of propagation; they are of a rubbing quality; they give the impression of being produced immediately beneath the stethoscope, while additional pressure with the stethoscope usually causes an increase in their intensity; and, further, their position, intensity and character may alter in a few hours. With regard to the second, the friction is either much reduced or ceases when the patient stops breathing, while it is increased by respiration. Further, pleuritic friction usually disappears with the effusion of fluid, whereas in pericarditis with effusion, friction is not abolished unless the quantity of fluid is great, and even then it may persist.

Sero-fibrinous pericarditis can be diagnosed from the physical signs described, such as a progressive enlargement of the area of cardiac impairment, synchronous with a progressive muffling of the cardiac sounds.

In the diagnosis of sero-fibrinous pericarditis, we should be careful to exclude dilatation of the heart, hydro-pericardium, left localised pleural effusion, pulmonary consolidation, thoracic aneurysm, new-growth, enlarged glands and abscess of the mediastinum. In each case the causation, mode of onset and physical signs should be considered.

It is sometimes difficult to diagnose pericardial effusion from great dilatation of the heart, especially of the right ventricle. In pericardial effusion there is often bulging of the præcordium, with obliteration of the intercostal spaces; the apex-beat is internal to the left margin of percussion impairment, and may be displaced upwards to the fourth or even third interspace; the area of cardiac impairment may extend to the second left costal cartilage, the extension often coming on rapidly, and in form is pear-shaped, instead of increased transversely; the angle formed by the heart and liver impairment is obtuse, whereas in the case of an enlarged right heart it is acute or is at most a right angle; the percussion note is absolutely dull and the sense of resistance greatly increased; and there may be evidence of displacement of the liver and spleen. On auscultation, the heart sounds are muffled, whereas in cardiac dilatation the characteristic physical signs already described are present.

Hydro-pericardium may be detected by noting the cause, the absence of friction during any period of the illness, and the presence of general anasarca, ascites, or pleural effusion.

A positive diagnosis of purulent pericarditis may be made by an exploratory puncture.

Prognosis.—In most cases the immediate prognosis of pericarditis is not unfavourable. The prognosis is more unfavourable at the extremes of life, and with a history of alcoholism. When the affection is due to rheumatism, the immediate prognosis is favourable in the great majority of cases; a fatal termination, however, sometimes occurs at the extremes of life. When due to Bright's disease, pneumonia, tuberculosis, acute infective conditions, and new-growth, the prognosis is unfavourable. A severe degree of dyspnoea, or of cyanosis, or pronounced mental symptoms are of unfavourable omen.

If the effusion be serous and moderate in degree, recovery is the rule, although adhesions result; if, on the other hand, the amount of fluid be large, the termination may be fatal, and this usually occurs during the second or third week. When the effusion is purulent, the prognosis is grave, especially if the pus be putrid, and a fatal termination may occur

within a few days. The outlook is likewise grave when the effusion is hæmorrhagic in character. Death may be due to asphyxia, sudden syncope, especially on exertion while in bed, and more rarely asthenia.

With regard to the ultimate prognosis of pericarditis, time is necessary to determine whether adhesions have resulted, and, if so, their site and degree, and whether the myocardium has been permanently damaged and to what extent.

Treatment.—The primary condition should be treated, and if rheumatism be the cause, the procedure suggested on page 823 should be carried out. If the pyrexia continue notwithstanding the administration of salicylates, the best way of reducing the temperature is by tepid sponging of the body: if drugs be employed, the best of these is quinine, although some place reliance upon antipyrin, phenacetin, and antifebrin, but they are not advisable except for occasional use. In septic cases, the sulphocarbolates and quinine may be administered.

In all cases, whatever the cause, absolute rest in bed is essential; excitement and worry of every kind should be avoided. The diet should be light, and during the acute stage it may be advisable to restrict it only to milk. An aperient should be administered at the outset, and during the illness strict attention should be paid to the state of the bowels. The internal administration of iodides is recommended by some. If there be much exhaustion, dyspnœa, cyanosis, or an unduly rapid pulse, alcohol may be given and oxygen employed, the quantity of alcohol varying with the individual requirement. Other diffusible stimulants, such as ether and ammonia, may be administered, especially in cases of sudden collapse. Strychnine may be tried when there is great exhaustion: it is better withheld, however, in the early stages of the illness when the cardiac action is excited.

For præcordial pain and distress, a hot linseed poultice or hot fomentations may be applied to the præcordium, or, if these fail, the continuous application of an ice-bag may be of service; other remedies, such as dry or wet cupping, mustard leaves, the application of the Paquelin cautery, or leeches to the præcordium, are recommended. In some of these cases there may be indications for the use of venesection; this has been referred to on page 772. Internally, Dover's powder (grs. x to xv), or, if necessary, morphine, may be administered. In the less acute cases, a fly blister is not infrequently efficacious. If insomnia or other symptoms be present, they should be treated on the lines previously laid down.

In cases of moderate effusion, the former treatment should be continued. If, however, the effusion become considerable, counter-irritation, the administration of iodide of potassium, purgatives, and diuretics, and limitation in the amount of fluid taken, are indicated. If the amount of effusion do not diminish, or if there be marked dyspnœa, cyanosis and a small rapid pulse, paracentesis pericardii should be performed. The site chosen for this procedure varies. It may be performed in the fifth left intercostal space just inside the mammary line; or quite near the margin of the sternum in the same space; or in the angle between the ensiform cartilage and the left costal margin of the sternum, near the lower end of the body of the sternum, and passing upwards and inwards behind it into the pericardial sac. Formerly a trochar and cannula, or a fine aspirating needle, was employed, but the use of an aspirator is now found to be preferable.

The stage of convalescence requires careful management, on the same lines as those of acute endocarditis.

The treatment of purulent or hæmorrhagic pericarditis consists in free incision and drainage of the pericardial sac, unless the state of the patient is too grave to allow of it—in which case paracentesis may be performed, and, if improvement occur, incision and drainage may be subsequently permissible—or unless the condition is associated with a hopeless primary cause.

CHRONIC ADHESIVE PERICARDITIS OR ADHERENT PERICARDIUM

In this form of pericarditis the two layers of the pericardium are bound together by permanent fibrous adhesions.

Ætiology.—The condition usually results from a previous attack of acute pericarditis, especially if accompanied by effusion, or it may follow a primary chronic inflammation; the latter may be due to an extension of inflammatory processes from the neighbouring parts.

Pathology.—The degree of chronic adhesive pericarditis varies. It may amount to only a few fine bands, most commonly situated at the base of the heart close to the great vessels, crossing the pericardial sac; or, in more severe cases, it may result in the formation of a layer of connective tissue, occasionally of considerable thickness, which more or less completely unites the two layers of the pericardium. The formation of partial synechiæ, however, is a much more common result than obliteration of the sac. Sometimes extra-pericardial adhesions exist. In this way adhesions may form between the pericardium anteriorly and the anterior chest-wall; laterally with the pleuræ and lungs; posteriorly with the aorta, œsophagus, or vertebral column; and below with the diaphragm. In rare instances, extra-pericardial adhesions are found in the absence of adhesions between the two layers of the pericardium. In advanced cases, pericardial adhesions may become more or less completely calcified, owing to the deposition of lime salts.

In a large proportion of cases, cardiac, especially ventricular, hypertrophy, usually accompanied by dilatation, exists, even in the absence of coexisting valvular disease. The degree of cardiac enlargement varies with the position and nature of the adhesions: it may be small or altogether absent, even when the sac is completely obliterated, provided the sac is not thickened and there is an absence of extra-pericardial adhesions; whereas it may be very great if the reverse be the case. Fatty or fibroid degeneration of the myocardium may occur.

The openings of the large vessels entering and leaving the heart may be constricted, and thus may interfere with the influx and egress of blood.

Symptoms.—The condition may be latent throughout its whole course. If symptoms be present, they may exhibit considerable variation in different cases. Dragging pain in the præcordium, sometimes extending considerably beyond it, is not an uncommon symptom, and anginal attacks have been known to occur. There may be also palpitation, dyspnœa, and cyanosis. Edema is present in a certain proportion of cases; ascites and hydro-thorax are occasionally to be noted, as also hepatic and splenic enlargement, and scanty and even albuminous urine. The pulse may exhibit the characteristics of pulsus paradoxus. The præcordium may be prominent; less commonly there is flattening. The apex-beat is usually displaced, and

its position does not vary with change of posture—a fact which also applies to the area of cardiac impairment. The area of pulsation is usually greatly increased, and may even extend from the second to the sixth intercostal space, and almost from the right parasternal line beyond the left mammillary line; it may be wave-like and undulatory in character. If adhesions between the pericardium and chest-wall exist, indrawing of the apex-beat may occur, also with systolic recession of the intercostal spaces on either side of the sternum, of the lower end of the sternum and adjacent costal cartilages, and in the epigastrium; while systolic retraction of the lateral and posterior walls of the left side of the chest, upon the latter of which Broadbent has laid great stress as indicating adhesion between the pericardium and diaphragm, is occasionally to be noted. A diastolic rebound or shock, after the systolic retraction, is rarely present at the apex-beat, or over a larger area of the præcordium, or even over the left lateral or posterior aspect of the chest; this is supposed to be pathognomonic of the affection. The position of the apex-beat and the area of cardiac impairment may be unaltered on deep respiration. Diminished expansion of the left side of the chest, and incomplete descent of the left half of the diaphragm during inspiration, as shown by diminished movement of the upper part of the abdominal wall on the left side, may be noted. Collapse of the veins of the neck during diastole—Friedreich's sign—may occasionally be observed.

The area of cardiac impairment is usually much increased, both to the right and to the left. Bruits indicative of relative incompetence both of the mitral and tricuspid areas may be present. Some authorities are of opinion that a rumbling mitral presystolic bruit is sometimes heard in adherent pericardium in children; this bruit, however, is not rough or vibratory in character, nor does it terminate abruptly in the first sound, as in the case of mitral stenosis. Lastly, there may be physical signs of coexisting heart disease.

Diagnosis.—The diagnosis may be a matter of considerable difficulty. A positive diagnosis should not be made from the presence of one sign only, except when diastolic shock or rebound exists, and perhaps also in those cases in which systolic recession of the sternum itself is present. It should be noted that the pulsus paradoxus, indrawing of the apex-beat, and systolic recession in the intercostal spaces on either side of the sternum, or in the epigastrium, or even of the lateral or posterior walls of the left side of the chest, do not necessarily indicate the existence of chronic adhesive pericarditis, and, further, that an absence of alteration of the position of the apex-beat and of the area of cardiac impairment with change of posture or deep respiration may also be present in pleural adhesions. When, however, several or all of the physical signs of the affection are present a positive diagnosis is warranted, especially if there be indications of right-sided cardiac enlargement or failure in the absence of mitral or pulmonary disease. A history of acute pericarditis or of acute rheumatic infection is of additional assistance, although, on the other hand, it should be remembered that the affection may be chronic from the beginning.

Prognosis.—This depends upon the situation, extent, and nature of the adhesions, the size of the heart, the existence or otherwise of valvular disease, the degree of integrity of the myocardium, and the degree of cardiac failure which may be present. The prognosis may be good, and, indeed, the

patient's longevity may not be affected ; or, on the other hand, it may be grave, especially in early life.

Treatment.—The treatment of the condition consists in counter-irritation externally, and the internal administration of iodide of potassium during the later stage of the attack of acute pericarditis as a prophylactic. When adhesions have formed, detailed instructions should be given to the patient to curtail his physical and mental activities so as not in any way to exceed the limited strength of the heart. When cardiac failure supervenes, it should be treated on the lines previously laid down.

It may be necessary to consider the advisability of performing the operation of "cardiolysis" in some cases of severe adhesions between the pericardium and the chest-wall. This operation was introduced by Brauer in 1902, and is indicated when there is also evidence of cardiac failure and ordinary treatment has failed ; but the operation should not be unduly delayed. It is usually not necessary during childhood or adolescence, because of the flexibility of the chest-wall. The operation consists in the resection of the fourth, fifth and sixth ribs on the left side, and, where possible, freeing the adhesions.

CHRONIC PERICARDITIS

It has been already noted that some writers describe a chronic form of pericarditis. This, however, is practically synonymous with chronic adhesive pericarditis or adherent pericardium, although it sometimes happens that in acute pericarditis with effusion, especially when due to tuberculosis, the effusion may persist for an indefinite period and the condition become a chronic pericarditis, resulting in considerable thickening of both layers of the pericardium. Further, but less frequently, pericarditis may be chronic from the first, especially in the aged, in alcoholism, and in nephritis.

When the result of acute pericarditis, the symptoms are those of that stage of the disease at which it became chronic. When chronic from the first, the affection is not infrequently latent throughout its whole course ; there may, however, be dyspnoea, a sense of oppression, and rarely pain, in the præcordium, an increase in the area of cardiac impairment, feeble cardiac sounds, and sometimes pericardial friction.

TUBERCULOSIS OF THE PERICARDIUM

Tuberculosis of the pericardium may be primary, or part of an acute general tuberculosis, or secondary to that of the lungs, the pleuræ, the mediastinal or bronchial glands. It may give rise to—(1) Tuberculous pericarditis, in which the effusion may be clear, purulent or bloodstained, and in which tuberculous nodules with giant cells are sometimes found in the fibrous tissue consequent upon organisation ; (2) miliary tubercles, which may be seen along the course of the small blood vessels in the epicardium, especially in the sulci ; and (3) larger tubercular masses in the epicardium, situated particularly at the base of the heart, and presenting a yellow caseating centre. The two latter conditions are much less common than the first. There is a greater tendency to the chronic type of pericarditis in

the case of tuberculosis than when due to other causes, the condition persisting for several weeks or even months, and not infrequently giving rise to a layer of connective tissue of considerable thickness, more or less completely uniting the two layers of the pericardium; there may or may not be fluid, which is frequently bloodstained, and is occasionally purulent.

Symptoms.—The affection (1) may be entirely latent throughout its whole course; (2) may present the symptoms of acute pericarditis, with, in addition, loss of weight and strength, a fluctuating temperature, a tendency to chronicity, and ending in effusion of fluid or the formation of adhesions; (3) may be a chronic adhesive pericarditis, with consequent hypertrophy and dilatation, and ultimately indications of cardiac failure; or (4) may present the symptoms of acute tuberculosis.

Diagnosis.—This can be made from an absence of any history of rheumatism or other cause of pericarditis, and, further, there may be evidence of tuberculosis elsewhere.

Prognosis.—This is very grave.

Treatment.—The treatment is that of pericarditis due to other causes, together with that indicated in ordinary tuberculosis, such as an abundance of fresh air, a generous diet, and the administration of cod-liver oil.

HYDRO-PERICARDIUM

Definition.—A certain amount of fluid is usually found in the pericardium after death; in hydro-pericardium, or dropsy of the pericardial sac, this is in excess. The fluid is clear, pale amber in colour, and has a specific gravity of about 1015.

Ætiology.—The condition is always secondary. It may occur along with ascites, hydro-thorax, and general anasarca, in valvular or myocardial disease, or in nephritis. Or it may occur alone, as the result of pressure upon the veins of the pericardium or of the heart by aneurysm, enlarged glands, or new-growth of the heart, pericardium, or mediastinum; from constriction of the veins by adhesions; and in various cachectic conditions, scarlet fever, and some purpuric conditions.

Symptoms.—The symptoms of the primary affection are usually to be noted. The condition in itself does not give rise to pyrexia or precordial pain. There may, however, be a sense of oppression in the chest, dyspnoea, cyanosis, attacks of faintness or even unconsciousness, œdema, hepatic enlargement, and scanty urine. In some cases there is drowsiness or mild muttering delirium. The pulse is soft, and of subnormal pressure. On examination of the heart, the physical signs are found to be those of pericarditis with effusion, except that there is an absence of friction on auscultation.

Diagnosis.—A diagnosis may be arrived at by a consideration of the cause, signs of fluid in the pericardial sac, and an absence of friction.

Prognosis.—The prognosis is that of the primary affection.

Treatment.—This is based upon the causal condition, and, in addition, a lessened intake of fluid, together with the use of purgatives and diuretics, are indicated. If urgent symptoms appear to demand it, paracentesis may be performed; this, however, is rarely necessary.

PNEUMO-PERICARDIUM

Definition.—By pneumo-pericardium is meant the presence of air in the pericardial sac. It is a very rare condition. Pericarditis is always present, with serous (pneumo-hydropericardium), purulent (pneumo-pyopericardium), or hemorrhagic (pneumo-hæmopericardium) effusion.

Ætiology.—The affection may be due to wounds through the chest-wall, or the result of communication with an air-containing cavity, such as occurs in abscess or gangrene of the lung, malignant disease of the œsophagus, gastric ulcer, and hepatic abscess. It is further believed by some that gas may be spontaneously generated within the pericardial sac *intra vitam*.

Symptoms.—Breathlessness, præcordial discomfort or even pain, faintness and cyanosis are the most constant symptoms. There may be a certain amount of bulging of the præcordium, and the apex-beat is diminished in force or even absent. On percussion, a tympanitic note is to be observed, the area of which changes with an alteration of posture. In the recumbent position it may be heard over most of the præcordium, while if the patient be sitting upright the lower part of the præcordium becomes impaired and the upper part hyper-resonant. On auscultation, metallic and splashing sounds, resembling those produced by a water-wheel or a churn, synchronous with the movements of the heart, are audible; these sometimes become more pronounced on shaking the patient, and occasionally may be heard at a considerable distance. Pericardial friction is sometimes also to be noted.

Diagnosis.—The diagnosis is not difficult when the physical signs enumerated are present. Care, however, should be taken to exclude a large pulmonary vomica in the neighbourhood of the heart, a left-sided pneumothorax, and dilatation of the stomach.

Prognosis.—The majority of cases die within the course of a few days. Traumatic cases, however, have been known to recover; the wound may heal and the air be absorbed.

Treatment.—In traumatic cases, paracentesis of the pericardial sac, with free incision and drainage if the fluid be purulent, is advisable. In other cases, treatment is usually only palliative.

HÆMO-PERICARDIUM

Definition.—By this is meant the presence of blood in the pericardial sac, occurring apart from pericarditis.

Ætiology.—It may be due to punctured wounds, perforation of the œsophagus by a dental plate, rupture of the aorta, of one of the coronary arteries, or of the heart, or as the result of purpura or scurvy.

Symptoms.—Death may take place suddenly, or there may be sudden collapse, marked pallor, perspiration, or syncope, with a rapidly fatal termination. On examination, the pulse will be found to be feeble, and of low tension, with, perhaps, increased area of cardiac impairment.

Prognosis.—Except in some traumatic cases, where surgical interference is possible, the outlook is always hopeless.

Treatment.—This is limited to immediate surgical operation in certain cases.

OTHER DISEASES OF THE HEART AND PERICARDIUM

SYPHILITIC AFFECTIONS OF THE AORTA, THE HEART, AND THE PERICARDIUM

This subject is one of great importance, and also of great difficulty, more especially with regard to the relative frequency and the diagnosis of the condition, for these are intimately bound up with ætiological and pathological considerations. I shall confine my remarks to the acquired form of the disease.

Pathology and Relative Frequency.—Acquired syphilis may attack the aorta, the cardiac valves, the coronary arteries, the myocardium, the auriculo-ventricular junctional tissues, and the pericardium. With regard to the aorta, Professor H. M. Turnbull found that in 288 necropsies at the London Hospital in which lesions of acquired syphilis were present, the most common syphilitic lesion was *mesaortitis*. This affection is the result of inflammation of the *vasa vasorum* and their terminations in the external and middle coats of the aorta. Its pathology is described on pages 860–861. It should be noted that while syphilis is not a cause of primary atheroma of the aorta, in the later stages atheroma usually occurs in the thickened intima over the areas of inflammation; also that syphilitic *mesaortitis* and primary atheroma may coexist, especially in later life. The ascending part of the aorta is the most commonly affected. The disease process in the aorta may involve the aortic valve, and occasionally it extends to the base of the aortic cusp of the mitral valve. In the case of the aortic valve, it results in incompetence and occasionally in stenosis. Syphilitic *mesaortitis* may also give rise to narrowing or complete occlusion of the orifice of one or both of the coronary arteries. Syphilis may also affect the terminal branches of the coronary arteries. In syphilis of the coronary arteries the aorta is usually affected at the same time. The results of coronary disease have been described on pages 860–862. Gummatus deposits, with secondary fibrosis, also occur in the cardiac wall, but they are of comparatively rare occurrence. It will thus be seen that in syphilis, fibrosis of the myocardium may be the result of syphilis of the aorta or of the terminal branches of the coronary arteries, or of gummata in the cardiac wall. Any of these lesions may involve the auriculo-ventricular junctional tissues, and give rise to auriculo-ventricular heart-block. Syphilis of the pericardium is of rare occurrence. The disease more commonly attacks in the form of an infiltration, with consequent formation of fibrous tissue, resulting in adhesions between the two layers of the pericardium, while in some cases there is effusion of fluid into the pericardial sac. Gummata are of rare occurrence.

The foregoing is a brief summary of the lesions which it is generally agreed syphilis may produce. But this does not by any means exhaust this part of the subject. Thus, in addition to the fact that syphilitic *mesaortitis* may

involve the aortic valve and the base of the aortic cusp of the mitral valve, is syphilis among the causes of primary chronic endocarditis of one or more of the cardiac valves? There is no evidence that it is. Again, apart from inducing secondary fibrosis in the manner described, may syphilis give rise to fibrosis of the myocardium independently—in other words, is it among the causes of primary chronic myocarditis, i.e. a true inflammation? There is no doubt that syphilis may give rise to a primary chronic inflammation elsewhere; and it would appear that congenital syphilis does so in the case of the myocardium. Some authorities are of opinion that acquired syphilis may cause a patchy or a diffuse fine fibrosis independently of the coronary arteries, while others are not. In any case, the histological diagnosis is very difficult even in the early stage, and is perhaps impossible in the later stage, so that it is probable that many of the cases of fibrosis of the myocardium in elderly people which are thought to be the result of syphilis are not so. Syphilis is the cause of a large proportion of all cases of aortic incompetence, and also an important aetiological factor of angina, especially under the age of 40. But, in considering the relative frequency of syphilis in affections of the heart and aorta, there is now a danger of going to the other extreme. Thus, statements to the effect that syphilis is responsible for a quarter to a third of the total number of cases of organic disease of the heart, for about three-quarters of all cases of aortic regurgitation, and almost invariably for cases of aortic incompetence in which there is an absence of a definite history of acute rheumatism, should be accepted with the greatest reserve.

Symptoms.—In aortitis pain is the most frequent and characteristic symptom, and it is exceedingly important to recognise its characteristic features. It is situated behind the upper part of the sternum, and is generally localised there, but it may radiate to the arms and neck. It may vary from slight discomfort or a sensation of pressure to an intense pain. It may be more or less constant, or intermittent. Occasionally there are paroxysms of pain, accompanied by a feeling of suffocation. The pain may come on spontaneously—that is, apart from physical exertion, especially when lying down—or it may occur only on exertion; it is usually aggravated by exertion; it may not completely disappear on cessation of exertion. There may be hyperæsthesia over the painful area. Occasionally severe attacks of suffocation occur, and tachycardia may often be noted. The pain may disappear after a few months or weeks, either spontaneously or as a result of treatment. It may be followed by angina pectoris. Some observers are of opinion that sometimes, during the early stage, rubbing sounds along the right border of the sternum may be noted, especially when the patient leans forward; personally I have never been able to detect this. At a later stage there may be indications of fusiform dilatation of the aorta. There may be pulsation in the neck, particularly in the suprasternal notch, and in the first and second intercostal spaces on either side of the sternum; impairment of percussion over the manubrium sterni and on either side of it; a systolic murmur over the aortic area; while the second sound may exhibit a musical, bell-like, or clanging quality. With the X-rays the aorta may show diminished translucency and an increased diameter. Alteration in the voice and tracheal tugging are occasionally to be noted.

Later, the clinical picture of aortic incompetence or of myocarditis or saccular aneurysm may develop. With regard to the first, shortness of

breath on exertion is probably the most frequent symptom of all. The largest group presents symptoms of systemic anæmia. Cardiac asthma is comparatively frequent. Indications of chronic venous congestion supervene in a comparatively small proportion of cases. General œdema is only occasionally met with. I would emphasise the great importance of an early and most careful search for the presence of a diastolic murmur over the base of the heart, over and on either side of the sternum, and at the apex—in fact, over the whole precordial area. There is less tendency for the systolic blood-pressure to rise, and still more so for physical signs of left ventricular hypertrophy to develop, than in the case of aortic incompetence due to other causes. Involvement of the myocardium may reveal itself on polygraphic, and, more frequently, on electro-cardiographic examination, by the presence of the first or second grade of auriculo-ventricular block, and rarely by bundle-branch or intra-ventricular block, and in one case of my experience by transient attacks of auricular fibrillation. Subacute bacterial endocarditis may supervene. Sudden death may occur, and may be due to complete and abrupt closure of a coronary artery, or rupture of the heart, fatal syncope, or angina pectoris.

The foregoing description covers the great majority of cases. It is necessary to add the following: Relative, and even complete, recovery—either the result of specific treatment or spontaneous—may occur at any period. There may be exacerbations of the disease all through life. Sometimes aortitis escapes notice altogether, and the clinical picture is that of aortic incompetence developing insidiously. The clinical picture may be that of acute general cardiac failure, it may be proceeding to rapid dissolution. Sometimes the condition is only discovered post mortem.

In the early stages the Wassermann reaction is almost invariably positive, but as the disease becomes more chronic it is increasingly negative, although I have been surprised at the frequency with which a positive Wassermann persists even in the case of patients who, from a clinical point of view, have done well.

Diagnosis.—This is sometimes comparatively easy, but it may be very difficult. In its consideration the following points, among others, require consideration: The age, the previous history, the history of the present illness, the subjective symptoms, the results of physical and instrumental examination, the Wassermann reaction, the presence or otherwise of syphilitic stigmata, and the course of the disease. With regard to the previous history, it is very easy to overlook a rheumatic infection in childhood. There may also be a history of rheumatic and syphilitic, and even other, infection in the same patient. There may be a combined lesion. I would emphasise the importance of pain behind the upper part of the sternum, presenting the characteristic features described. If it has been possible to obtain a full and accurate history, it will be found that in the vast majority of cases it has been present in the early stages. The pain differs from that of angina pectoris in that it is less paroxysmal, its location is higher, it has a far less tendency to radiate to a distance, and it is more likely to come on spontaneously and not to cease completely after exertion is over. The presence of a systolic murmur over the aortic area, an altered second sound in the manner described, and the result of an examination with the X-rays, are of considerable diagnostic importance. It is necessary to exclude aortitis due to infection by pyogenic

organisms of a subacute or chronic type, by the tubercle bacillus and other organisms, aneurysm, and atheroma. The last-named when limited to the aorta, however, does not cause pain presenting the characteristic features described. A cardiac lesion coming on in middle life, if antecedent rheumatic infection can undoubtedly be excluded, is strongly suggestive of syphilis, as also is angina pectoris occurring before the age of forty. A combination of aortic and mitral valvular disease, especially before thirty years of age, is strongly suggestive of being of rheumatic origin. Atheroma much more frequently causes aortic stenosis than incompetence. A Wassermann test should be done in all doubtful cases, and in all cases of aortic disease, even if there is a history of acute rheumatism. A negative Wassermann is not so valuable as a positive reaction, a single negative reaction does not exclude syphilis, and in some cases it may be advisable to employ a provocative dose of salvarsan or one of the other organic arsenical preparations. We should, on the other hand, be careful not to place too much reliance on the result of the Wassermann reaction; it should be considered in conjunction with other clinical data. A positive Wassermann does not indicate that the malady from which the patient is suffering is necessarily syphilitic; the same applies to the coexistence of other specific stigmata. There may also be a double lesion.

Prognosis.—This depends largely upon early diagnosis and the kind of treatment adopted. Taking cases as a whole, the prognosis is very unfavourable, due, no doubt, to the fact that a correct diagnosis is not often made until the later stages of the disease. When untreated, the lesion is usually progressive, it may be rapidly so, and the mortality is high. If, on the other hand, a diagnosis is made early, and treatment is prompt and adequate, especially when the patient has not received specific treatment previously, there is a reasonable prospect of relative recovery, and occasionally recovery is even complete. Naturally the prognosis is much more favourable in the absence of aortic incompetence, involvement of the coronary arteries and of the myocardium, angina pectoris, and aneurysm. Prompt and adequate treatment of aortitis may prevent the aortic valve, coronary arteries, and the myocardium becoming involved, and the formation of a saccular aneurysm. Even in the absence of angina pectoris and aneurysm, in aortic regurgitation the prognosis is usually very unfavourable, death often taking place within two or three years after the onset of subjective symptoms. Two important points in all cases are the degree of cardiac failure present, and its rate of advance. Help is sometimes obtained from the results of polygraphic and, still more frequently, of electro-cardiographic examination. Thus, the presence of pulsus alternans in the absence of a severe grade of tachycardia is an indication of extreme exhaustion of the heart muscle; the occurrence of partial heart-block is a sign of myocardial involvement; persistent heart-block of mild degree is also indicative of myocardial damage; bundle-branch block is usually of very unfavourable significance; and intra-ventricular block is usually of grave import. A few cases of complete auriculo-ventricular block have been recorded in which energetic specific treatment appears to have been rewarded with recovery, but as far as my experience is concerned anti-specific treatment is of no avail at this stage. Lastly, in all types of cases, marked and surprising improvement is occasionally met with when adequate specific treatment is adopted.

Treatment.—The various measures which may be applicable to any form of cardiac disorder should be considered in detail. Apart from these, the indication is for anti-specific treatment. This should be adopted in every case in which a definite diagnosis of syphilis of the heart and aorta is arrived at, even if the Wassermann reaction is negative; and in every case of disease of the heart and aorta in which there is a positive Wassermann or other manifestations of active syphilis, even in the absence of clinical evidence that the lesions of the heart and aorta are of specific origin. Cardiac failure is not a contraindication. It is impossible to exaggerate the importance of the adoption of this method of treatment *promptly*. It should also be *prolonged*. I am a firm believer in the employment of the arsenical preparations—but only under certain conditions. Their indiscriminate use is attended with danger, even of grave degree; they may result in further swelling of the intima of the small vessels, and thus increase the risk of thrombosis. I always recommend a preliminary course, of three weeks duration, of mercurial inunction and of iodide of potassium by the mouth—10 grains thrice daily during the first week, increased to 15 grains during the second week, and to 20 grains during the third. This to be followed by one of the arsenical compounds administered cautiously, commencing with small doses and only gradually increasing the dosage. The scheme I advise is the result of two or three conversations I have had the privilege of having with Colonel L. W. Harrison, to whom I desire gratefully to acknowledge my indebtedness. This consists of a series of courses of one of the sulpharsenobenzene preparations (kharsulphan, myosalvarsan, sulfarsenol, or sulphostab), injected deep subcutaneously, with mercury injected intramuscularly. The first course makes a cautious start with 10 centigrammes of sulpharsenobenzene, and the dosage is increased, in bi-weekly injections, to 24 centigrammes, the total amount given in the first 54 days being 2.76 grammes in sixteen injections, with 8 grains of mercury in eight injections. The reason that the dosage of sulfarsenol in the first course is cautious is that patients with syphilis of the heart or aorta seem easily to be upset at first by arsenobenzene preparations. After the foregoing course of injections, potassium iodide is given for three weeks, to be followed three weeks later by a course of five injections of sulfarsenol and mercury. This time it may be possible to proceed more boldly with the sulfarsenol—three injections of 48 centigrammes and two of 60 centigrammes. Thereafter the treatment is continued with courses of ten injections totalling 5.8 grammes sulfarsenol and 10 grains of mercury at intervals increasing from two to five months, with potassium iodide for a month at a time between the courses. In place of mercury, one of the bismuth preparations may be injected deep subcutaneously or intramuscularly. In this event, the individual dose should contain from 20 to 30 centigrammes of metallic bismuth. The treatment is continued on these lines for two years. After the completion of this scheme, I suggest a three weeks' course of potassium iodide every two or three months during the rest of the patient's life. It may be advisable to continue anti-syphilitic treatment as long as the Wassermann is positive, even in the absence of other manifestations of active syphilis, for there is a risk of exacerbations all through life, and the small vessels around the principal lesions may become involved.

ANEURYSM OF THE HEART

Aneurysm of the heart may occur in its valves or walls, or in the coronary arteries.

Acute aneurysm of the valves may occur in malignant endocarditis, the semilunar being more commonly affected than the auriculo-ventricular valves. The aneurysm bulges in the direction of the blood current; rupture may take place, giving rise to perforation and valvular incompetence.

Acute aneurysm of the walls of the heart may take place in acute mural malignant endocarditis, usually in the interventricular septum, in the neighbourhood of the undefended space. A diagnosis of this affection is scarcely possible.

Chronic aneurysm of the walls of the heart occurs as the result of fibroid degeneration, and is more frequent in males. In the majority of cases it arises in the left ventricle near its apex. The aneurysm consists of a sac or localised depression, communicating with one or more chambers of the heart. It is lined by thickened endocardium, and the wall is formed of fibrous tissue and muscle-cells, in varying proportion, according to the length of time it has been in existence. Occasionally a certain amount of calcareous matter is present. The visceral layer of the pericardium may be thickened, and its parietal layer also involved. The aneurysm generally contains laminated fibrinous coagulum, and its size may vary from that of a small marble to an orange or even larger. The symptoms are those of general heart failure. The area of cardiac impairment may be increased, and occasionally a tumour in the region of the apex may be detected. Sudden death is not of uncommon occurrence, although rupture is comparatively rare.

Aneurysm of the heart may also result from a stab.

Aneurysm of a coronary artery occurs rarely, and is usually due to atheroma.

WOUNDS OF HEART

Wounds of the heart are not of very uncommon occurrence. They may be the result of stabbing, bullet wounds, or the passage of foreign bodies from the œsophagus. Recovery occurs in a fair proportion of cases, especially when due to stabbing.

Treatment of these cases is purely surgical.

RUPTURE OF THE HEART

Rupture of the heart is a rare event, and is usually due to fatty degeneration or infiltration of the myocardium. It is occasionally the result of abscess or aneurysm of the myocardium, or of traumatism. The left ventricle is most commonly involved, usually its anterior wall. Rupture of the heart occurs nearly always during physical exertion. It may result in sudden death, or its occurrence may be indicated by sudden agonising pain, intense dyspnoea, pallor, and collapse; in the latter case, the patient may live for some hours or even days.

NEW-GROWTHS OF THE HEART AND PERICARDIUM

Neoplasms may arise from the walls of the heart or from the valves. They, as well as tuberculous deposits, are usually secondary. Primary carcinoma and sarcoma of the pericardium are extremely rare, and secondary deposits are also of unusual occurrence; in the latter case they may be secondary to those of the œsophagus, mediastinal glands, lungs, or pleuræ; more rarely from distant parts. Instances of hydatid cysts and actinomycosis of the myocardium and pericardium have occasionally been noted post-mortem; they are not diagnosable during life.

The symptoms of new-growths of the pericardium are those of pericarditis, especially of the chronic type, together with the cachexia characteristic of the primary cause. The diagnosis rests upon the recognition of these features, with possibly evidence of malignant disease elsewhere. The prognosis is hopeless, and treatment at the best is only palliative.

FREDERICK W. PRICE.

CONGENITAL HEART DISEASE

Ætiology and Pathology.—Congenital heart disease is more common in males than in females. It may be the result of some developmental defect, or of fetal endocarditis—due to rheumatism or one of the other causes of acute endocarditis affecting the mother during pregnancy. Syphilis is said to be a causal factor. Both developmental defects and fetal endocarditis are more common on the right than on the left side of the heart, as the result of a relatively higher pressure. The pulmonary orifice is more commonly affected than the tricuspid. The lesion of congenital heart disease may give rise to stenosis, or incompetence, or both. The endocarditis is usually of the sclerotic type, although vegetations may occur. It may be noted that there is a predisposition to endocarditis in the fœtus the subject of some developmental error, and this increases the primary malformation; endocarditis may also occur after birth.

VARIETIES.—There are many varieties of this condition, and I shall not attempt to deal with them all. *As a rule, several lesions coexist, a single lesion being uncommon.*

In *ectopia cordis* the heart is situated outside the thoracic cavity; it may lie in the neck (*ectopia cervicalis*), or outside the chest-wall (*ectopia pectoralis*), or in the abdominal cavity (*ectopia abdominalis*). In *mesocardia* the heart occupies the mesial position of the thoracic cavity, the apex-beat being in the epigastrium. In *dextro-cardia* or *dextro-cardia*, the heart lies on the right side of the thoracic cavity; this variety of congenital heart disease is usually associated with transposition of the viscera. More or less complete absence of the pericardium is rarely found.

The development of the heart may become arrested at the stage when only an auricle, a ventricle, and a bulbus arteriosus exist, a comparatively rare condition, to which the term “bilocular” heart has been applied. Another comparatively rare form is complete absence of the interventricular

septum, in which case the heart consists of two auricles and one ventricle, and is said to be "trilocular." The tricuspid and mitral orifices are usually present, and the bulbus arteriosus is usually divided into a pulmonary artery and an aorta. Another rare condition is complete absence of the inter-auricular septum, in which case the heart consists of an auricle and two ventricles. One of the most frequent forms of congenital heart disease is an incomplete septum ventriculorum, due to an arrest of development; it is a much commoner condition than complete absence of the septum. The aperture of communication between the two ventricles is usually situated in the region of the pars membranacea. This condition is frequently associated with pulmonary stenosis or atresia, and hypertrophy of the right ventricle; less frequently with other defects. When coexisting with pulmonary stenosis or atresia, the blood can pass from the right to the left ventricle. When not so associated, the aerated blood after birth passes from the left to the right ventricle, and the walls of both chambers undergo hypertrophy. There may be complete absence of the septum of the ductus arteriosus, or this may be incomplete, with resultant communication between the pulmonary artery and the aorta; in these cases, the right ventricle is generally hypertrophied.

The septum between the auricles may be incomplete, due to arrest of development, and is much commoner than complete absence of the septum. The defect is usually situated at the foramen ovale, due to mal-development of the membrane of the fossa ovalis. It should be noted that the absence of an absolute closure of the foramen ovale is not pathological. The majority of cases of patent foramen ovale are associated with pulmonary stenosis, or a defect in the ventricular septum, or some other congenital defect. Some writers believe that in the larger number of cases a patent foramen ovale results from pulmonary stenosis, while others hold a different view. Whichever view be correct, pulmonary or tricuspid lesions are often found associated with it, and occasionally lesions at the aortic or mitral orifice. In the case of a patent foramen ovale, the blood passes from the right to the left auricle, instead of into the right ventricle and thence to the lungs.

Pulmonary stenosis is perhaps the commonest form of congenital heart disease. A patent interventricular septum is present in the great majority of cases, and a patent foramen ovale is of not infrequent occurrence, while the ductus arteriosus may remain patent. Further, owing to increased pressure in the cavity of the right ventricle, there is sometimes a deviation of the interventricular septum to the left; in this case, the right ventricular cavity is enlarged, and the aorta takes its origin, either completely or partially, from this chamber, the left ventricle being small and atrophied, and communicating with the right ventricular cavity. In pulmonary stenosis the blood accumulates within the right ventricle, and is compelled to take a new channel. If the defect have occurred before the ventricular septum is completed, the septum remains incomplete, and blood passes through the opening and thence to the aorta, the right ventricle being the chief agent in carrying on the systemic circulation. Owing to the increase in pressure in the right heart, the right ventricle and auricle hypertrophy. If the lesion be severe, much of the blood to the lungs must reach them from the aorta through the ductus arteriosus, which does not, therefore, close after birth. If the interventricular septum have completely closed before pulmonary

stenosis takes place, the pressure in the right auricle becomes increased; if the foramen ovale be patent, the blood passes from the right to the left auricle, and in this way a patent foramen ovale is not infrequently found. The right auricle is small and atrophied, and the tricuspid orifice becomes smaller. The cavity of the left ventricle enlarges, and its walls hypertrophy, as it carries on both the systemic and pulmonary circulation. In almost all these cases the blood is carried to the lungs by the patent ductus arteriosus. It will thus be seen that the circulation in cases of pulmonary stenosis depends upon the patency of the foramen ovale or interventricular septum, and of the ductus arteriosus. Pulmonary atresia or obliteration of the pulmonary artery is much less common. When complete, and the interventricular septum is closed, the right ventricle is small and atrophied, the right auriculo-ventricular opening ultimately closes, and the heart becomes trilocular.

Stenosis and atresia of the aorta are of much less common occurrence than of the pulmonary artery. Stenosis may exist at one of the following sites: (1) at the orifice, (2) above the entrance of the ductus arteriosus, and (3) just below the entrance of the duct. In the first of these, the ventricular and auricular septa do not close, and the left ventricle remains undeveloped. Most of the systemic circulation is carried on by the pulmonary artery through the ductus arteriosus. The second, or new-born type, is often associated with other malformations, as, for example, pulmonary stenosis. The ductus arteriosus remains open, and most of the systemic circulation is carried on by the right ventricle, through the duct. The third or adult type of stenosis is more common. By coarctation of the aorta is meant stenosis of the aorta at or just below the junction of the ductus arteriosus with the aorta, *i.e.* in the region of the aortic "isthmus." The condition is more common in males than in females. The ductus arteriosus may remain patent or may close. When the condition is present in adults and in children who have survived the period of infancy, it is supposed to have arisen gradually after birth, in association with the closure of the ductus arteriosus. Usually in such cases an elaborate system of collateral arterial circulation has developed, so that the arterial blood from the upper part of the body—that is to say, from the great arteries given off by the aorta above the site of the obstruction—can pass by enlarged anastomosing branches to the lower part of the trunk and the lower extremities. Hypoplasia of the aorta, or narrowing of the lumen of the vessel throughout its whole extent, with diminished size of the heart, was first described by Virchow, and there is sometimes accompanying chlorosis. Other malformations of the heart are occasionally also present. The condition known as double aorta is a form of congenital heart disease very rarely found.

Persistence of the ductus arteriosus occurring alone is also a rare condition. It is a common accompaniment of pulmonary stenosis or atresia, when a patent inter-ventricular septum is also present; it may also accompany aortic stenosis or atresia, and congenital disease of the auriculo-ventricular valves. Premature closure of the ductus arteriosus and of the foramen ovale is of rare occurrence.

Transposition of the pulmonary artery and the aorta may be found, the aorta arising from the right ventricle and the pulmonary artery from the left. Among other lesions which may be present are a patent foramen ovale, a

patent septum ventriculorum, and a patent ductus arteriosus. Other forms of malposition of the pulmonary artery and of the aorta have been recorded, such as both trunks taking their origin from the left ventricle. A communication between the pulmonary artery and the aorta has been known to occur.

Supernumerary or defective cusps of the cardiac valves have been noted; the number of cusps may be increased or decreased, and in the latter case incompetence of the valves may result.

Congenital lesions of the auriculo-ventricular valves may occur. Stenosis or atresia of the tricuspid or mitral orifice is much less frequent than of the pulmonary artery or of the aorta. A considerable proportion of cases of tricuspid stenosis are congenital. Tricuspid incompetence is rarely congenital; it may be associated with pulmonary atresia. Congenital lesions of the mitral orifice are of much rarer occurrence than those of the tricuspid orifice.

Symptoms.—The subjective symptoms of congenital heart disease vary in their intensity according to the site and degree of the lesion. It may be laid down as a broad principle that septal defects have a less disturbing effect upon the circulation than stenosis or atresia; indeed, in some of the former cases there may be a complete absence of subjective symptoms throughout the whole course, and the affection is only discovered on physical examination or post mortem. The results of physical examination also show variation.

Cyanosis and dyspnœa on exertion are the two chief symptoms. The former may be present within a few weeks of birth, or may only make its appearance after some years. It is a more conspicuous feature of this form of cardiac disease than of any other, the term "morbis cœruleus" being, indeed, frequently used for congenital heart disease. This is most marked in the lips, nose, the malar region, and the fingers and toes, being especially noticeable in the nails, and may be confined to these localities, or may be more general. The degree of cyanosis varies up to a deep purple, and is increased by exertion. The lips and nostrils may exhibit thickening, and clubbing of the ungual phalanges of the fingers and toes is usually present, due to chronic venous engorgement. There may be an absence of dyspnœa while at rest, but it may make its appearance on exertion, while in some cases paroxysmal dyspnœa occurs.

While the temperature taken in the mouth or rectum is usually normal, the skin temperature is usually subnormal. The subject of congenital heart disease often complains of feeling cold, is very susceptible to any fall of temperature, and is liable to attacks of bronchitis. On examination the blood is found to have an increased viscosity, and its specific gravity may be as high as 1070. There is a large increase in the number of the erythrocytes, which may even reach 9,000,000 per c.mm., the hæmoglobin is increased, and may be as high as 160 per cent., while the leucocyte count may show an average of 15,000 per c.mm. There is usually retardation of growth, and in some cases wasting; the mental condition is backward, and the patient is frequently dull and lethargic. There may be syncopal attacks, even resulting in prolonged unconsciousness, while epileptiform attacks may also occur. In certain instances there is a tendency to hæmorrhage from the nose, gums, and less frequently from the lungs. Œdema is sometimes present, which at

a later stage may become general, and hæmoptysis, hepatic enlargement, albuminuria, and transudation of fluid into the serous sacs may also occur. Not infrequently other bodily malformations are to be noted.

The veins of the retina are almost always dilated and tortuous, the lumina appearing in some places to be unduly wide, and in others abnormally narrow; both arteries and veins are much darker than normal.

The pulse is usually quickened in rate. There is usually evidence of cardiac enlargement, although perhaps not of severe grade, the right side of the heart being particularly affected. Distension or pulsation of the jugular veins may also be present. Sometimes a thrill and frequently a murmur, usually systolic in time, are to be noted. The point of maximum intensity may be over the pulmonary area, but it may be difficult or impossible to define. The murmur is usually rough and grating, and, perhaps, extremely loud; on the other hand, it is sometimes very faint. The pulmonary second sound may be normal, diminished, or loud and ringing.

The subject of congenital heart disease may ultimately die from gradual cardiac failure—the clinical picture resembling that of mitral disease, or infective endocarditis, bronchitis, broncho-pneumonia, pulmonary tuberculosis, one of the acute infective diseases, cerebral thrombosis or abscess, or convulsions, while instances of sudden death have been known to occur.

Passing now to a consideration of the symptomatology of the individual lesions, in dextro-cardia the apex-beat is on the right side of the thorax, and the point of maximum intensity of the aortic second sound is on the left, instead of the right side. For the result of electro-cardiographic examination, see page 922. When patency of the interventricular septum exists alone, the subjective symptoms are usually slight. A certain amount of dyspnœa and cyanosis on exertion may occur, but cyanosis is not a prominent feature, and there is usually no clubbing of the ungual phalanges of the fingers and toes. There may be evidence of enlargement of the right side of the heart. In some instances a systolic thrill and a loud and harsh murmur over the præcordium are present. Writers also differ in regard to their point of maximum intensity; according to some, e.g. Roger, it is in the median line in the upper third of the præcordium, while in the opinion of others it is near to the left margin of the sternum in the third left interspace, or even as low down as the xiphisternum. There is a diversity of opinion also in respect of the question of the direction of selective propagation of the bruit, some believing that there is none, and that the bruit is not audible over the carotid artery, whereas others affirm the opposite. Some writers say that the second sound in the pulmonary area is accentuated. When patency of the interventricular septum is secondary to other lesions, the symptoms of the primary affection predominate.

When patency of the inter-auricular septum exists alone, there is not infrequently an absence of subjective symptoms, and the condition, therefore, may not be discovered during life. In other cases, however, they are present, the results of physical examination then exhibiting considerable variation. A murmur or murmurs may be present over the præcordium, being in some cases systolic, in others diastolic, or, according to some writers, even characteristically presystolic, and having the point of maximum intensity over the base of the heart.

In congenital pulmonary stenosis, cyanosis occurs in the vast majority

of cases, and usually within a few weeks of birth, but in rare instances it only makes its appearance after some years. Clubbing of the fingers and other symptoms of congenital heart disease are usually present. The pulse may present no special peculiarity, or it may be small and empty. Sometimes a thrill, systolic in time, and with its point of maximum intensity over the pulmonary area, is present. On percussion the left border of the heart is often, and the right border is almost always, found to be displaced outwards. The most characteristic physical sign is to be found on auscultation; this is a murmur, with its point of maximum intensity in the pulmonary area, systolic in time, usually rough and grating, and, it may be, extremely loud. The murmur may be heard over a considerable area of the chest; occasionally it is quite distinct as high as the first rib; sometimes, indeed, all over the chest. As a rule, it has no direction of selective propagation, and in the vast majority of cases is not audible over the vessels of the neck. The pulmonary second sound is usually diminished or even absent; sometimes there is a pulmonary diastolic bruit present, owing to incompetence of the valve.

The physical signs of congenital stenosis at the aortic orifice are the same as those of the acquired form of the disease. In stenosis above the entrance of the ductus arteriosus, cyanosis is usually present, but the physical signs are indefinite; systolic and diastolic bruits may be audible over the front and back of the thorax. In typical cases of the "adult" type of coarctation of the aorta, a number of thickened tortuous arteries can be both seen and felt pulsating beneath the skin of the back and front of the trunk.

When a patent ductus arteriosus occurs alone, there may be no subjective symptoms, or they may be only slight, such as slight cyanosis and dyspnoea on exertion. The area of cardiac impairment is usually displaced to the right, also sometimes to the left, and other evidence of enlargement of the right heart, such as systolic retraction, may also be present. There is sometimes a certain amount of fullness, a thrill, and a murmur, having their point of maximum intensity in the second left intercostal space at least 2 inches from the middle line. The murmur is prolonged, and occupies both systole and diastole; it commences shortly after the beginning of the first sound, and extends into a considerable part of the diastole; indeed, it may persist almost throughout the whole cardiac cycle. It is not propagated to the vessels of the neck. The second sound in the pulmonary area may be accentuated. Other writers have noted the presence of systolic pulsation, a small area of impairment of percussion note, and a shadow on skiagraphic examination.

In congenital lesions at the tricuspid orifice, cyanosis, dyspnoea and clubbing are not conspicuous features, and the latter is not infrequently entirely absent. The physical signs are the same as those of the acquired form of the disease.

Diagnosis.—While it is usually not difficult to say that congenital heart disease exists, it is a much more difficult task to diagnose the form of the disease, and, further, it should be remembered that several lesions often coexist. In considering the question of diagnosis, the history of the case, the subjective symptoms, the existence or otherwise of evidence of enlargement of the right side of the heart, and the time of occurrence, the point of

maximum intensity, and direction of selective propagation of any existing murmur, are all points which should be taken into account.

With regard to the diagnostic value of the various symptoms, it may be remarked that cyanosis, even of marked degree, may be present during an attack of acute bronchitis in infancy and early childhood, especially in anæmic and rickety subjects, and also in cretinism; and that clubbing of the fingers may exist in the acquired form of heart disease, more especially in mitral stenosis, while it may be absent in the slighter forms of congenital disease. It is also necessary to point out that in some cases of congenital heart disease the right side of the heart may be only slightly enlarged. The murmurs are usually systolic in time and loud, and their point of maximum intensity and direction of selective propagation are not so typical as those of the acquired form of heart disease. In cases of a non-functional systolic murmur having its point of maximum intensity over the pulmonary area, we should think of the possibility of congenital heart disease. It may, however, be exceedingly difficult, and indeed impossible, to distinguish functional basic murmurs from those of congenital heart disease during infancy and childhood by means of auscultation alone. It should be noted that a prolonged thrill and murmur occupying both systole and diastole may also be met with in arterio-venous aneurysm.

In those subjects of heart disease who have attained to adult life, and even in the case of young children, it is difficult to say whether the lesion is congenital or acquired. If there be a history of marked cyanosis soon after birth, and there have been known to be clubbing of the fingers, evidence of enlargement of the right side of the heart, and a systolic thrill and murmur whose point of maximum intensity and direction of selective propagation are not so typical as those of the acquired form of heart disease present in early life, a positive diagnosis of the congenital form of heart disease is not difficult.

Prognosis.—The prognosis of congenital heart disease exhibits wide variation. If the defect be slight, as, for example, a patent foramen ovale or a small opening in the interventricular septum, a considerable proportion of cases live to an advanced age without experiencing subjective symptoms; whereas if the defect be serious, the duration of life is brief in a large proportion of cases, and, indeed, the individual may die within a few hours. The degree of cyanosis is not absolutely reliable. The occurrence of paroxysms of dyspnoea, syncopal attacks, and convulsions is a very unfavourable omen.

Meso-cardia, dextro-cardia, and absence of the pericardium are conditions compatible with long life. On the other hand, life cannot exist with a bilocular heart. Trilocular heart is compatible with life for some years, and, indeed, instances have been recorded in which individuals have lived to adult age; usually, however, the period of life is short. Persons suffering from septal defects not infrequently live to an advanced age. When patency of the interventricular septum occurs alone and the opening is not large, the individual may live to past middle life; when, however, it occurs in association with other lesions, the prognosis depends upon the latter. The prognosis of an individual suffering from pulmonary stenosis depends upon, besides those points already mentioned, whether there is a patent interventricular septum to afford relief to the over-distended right heart. Death may occur,

on the one hand, within a few hours after birth, while on the other, in the case of lesions of slighter grade, life may be prolonged for 5, 10 or 20 years, and occasionally even to middle life; indeed, if a patent interventricular septum be present in these slighter lesions, cases have been recorded in which patients have lived to the age of 60. Taking cases of pulmonary stenosis as a whole, however, most of the patients die at an early period of life. Pulmonary atresia is a much more serious condition, and life is prolonged for only a brief period. Cases of stenosis at the aortic orifice do not survive birth, and in those in which stenosis exists above the entrance of the ductus arteriosus life is prolonged at the outside for a few months only, but when just below the entrance of the duct it may be prolonged till middle age. Persistence of the ductus arteriosus is not infrequently compatible with adult life, and individuals have been known to have lived even to old age. Cases of transposition of the pulmonary artery and the aorta do not, as a rule, survive infancy, but instances have been recorded in which these patients have lived to middle age.

Treatment.—The general measures previously laid down are applicable also to this affection. It is particularly important that the patient should be kept warm, and it is imperative that careful and detailed measures should be adopted for the prevention of bronchitis; if bronchitis should occur, adequate treatment should be adopted without delay. When cardiac failure supervenes, it should be treated on the lines previously laid down.

PRIMARY CARDIAC OVERSTRAIN

Definition.—By primary cardiac overstrain is meant a cardiac disorder which is the immediate result of excessive physical exertion in an individual whose heart has been sound, or in whom the heart has been already somewhat impaired. It formerly included the condition known as "soldier's heart" or the "irritable heart of soldiers," which I shall describe separately.

Ætiology.—The affection is the direct result of excessive physical exertion, and is most frequently met with in persons of athletic habits and in soldiers. It is more apt to occur in those who undergo excessive physical exertion while not in training; indeed, it is questioned by some whether the affection can occur in persons with previously sound hearts who have been properly trained. It is also more likely to occur in older persons, and where there is a history of rheumatism or of some other acute infection, in anæmia, and in those who have indulged in excesses of any kind.

Symptoms.—When the malady is due to sudden physical strain, as in boat-racing or Alpine climbing, there may be lividity or cyanosis of the face, giddiness, faintness, passing into actual syncope, together with vomiting and even fatal syncope, and possibly evidence of acute dilatation of the right heart. Later on, there may be collapse, cyanosis, coldness of the skin, præcordial uneasiness and even actual pain, quick and shallow respiration, and a quickened, small and thready pulse; while later, in severe cases, there may be evidence of œdema of the lungs. These acute symptoms may be followed by general lassitude, impaired digestive functions, an increase of rectal temperature, and a pulse of subnormal pressure, although at the same

time the apex-beat may be forcible and tumultuous; tachycardia, and a forcible and tumultuous apex-beat being especially noticeable on the least exertion. For some weeks, dyspnœa and an increase of cardiac rate from 30 to 40 per minute above the normal on even slight physical exertion, nervousness, languor, and a sense of fatigue on mental exertion are apt to occur.

In the chronic form of the affection, among the symptoms are palpitation, even of severe degree, a feeling of oppression or of constriction of the chest, and sometimes actual pain over the præcordium, extending to the left shoulder, and occasionally down the arm; as a rule there is no sense of impending death. Among other symptoms which may be noted are dyspnœa and faintness on exertion, tremors, nervousness, insomnia, noises in the ears, flashes of light before the eyes, vertigo, a dull headache, hebetude, and languor, while the digestive functions are often impaired. There may be some degree of cyanosis. These symptoms may pass away with rest, only to reappear on exertion. The pulse-rate is usually increased, but is rarely over 120 per minute while at rest, although exertion causes a further increase—up to as much as 140 or 150. The pulse is usually small, weak, and of subnormal pressure, while the apex-beat may be diffuse and diminished in force or even absent, but on exertion may become unduly forcible and tumultuous. The area of cardiac impairment is usually increased to the left, and not infrequently also to the right. The cardiac sounds may be feeble, or short and sharp, and may be reduplicated, or a mitral or tricuspid systolic murmur may be audible, while the second sound in the pulmonary area may be accentuated.

Diagnosis.—The diagnosis in large measure resolves itself into the question whether the case is one of primary cardiac overstrain, or whether the heart has been previously damaged; in the latter case, excessive physical exertion is merely the exciting cause. In considering this problem, the presence or absence of a previous history of one of the acute infections and the state of the general health, and whether there is evidence or otherwise of myocardial, valvular, or arterial disease, are points of material importance.

Prognosis.—The prognosis of primary cardiac overstrain exhibits a wide variation, ranging from a slight illness on the one hand to a severe and even irremediable affection on the other. In the less severe degree of acute cases occurring in the young and previously sound and vigorous, recovery is the rule; the patient may be well in a few days or weeks, although, on the other hand, progress may be slow, and a long time may elapse before the individual is capable of an ordinary amount of work. If tricuspid regurgitation be present, this, unlike mitral regurgitation, usually passes off quickly. But if the heart have been previously affected by rheumatism or by some other infection, and in the case of older persons, the prognosis is serious; recovery may be long delayed, or the patient may be always compelled to lead a sedentary life, and, in some cases, even a fatal termination may result. In all cases of primary cardiac overstrain a diminishing increase of pulse-rate on exertion is of favourable omen.

Treatment.—In the acute cases, a very hot bath is to be commended, the patient being lifted out of it in a blanket, or a hot pack, together with the administration of one or two 15-grain doses of diuretin. A strictly limited amount of food, both solid and liquid, is indicated in the early stages,

and no tea, coffee, alcohol, or tobacco. Oxygen may be required in some cases; morphine and strychnine are rarely necessary. Later on, tea and coffee may be allowed in limited quantities, but the patient should still abstain from alcohol and tobacco. The bromides are often extremely useful in persons who suffer from an unduly excitable nervous system or from insomnia. When the patient is able to get up, extreme caution should be enjoined as to the amount and character of any exertion. The use of electricity is contra-indicated. Warm baths, followed by a cold douche, may in individual cases be tried, if followed by a reaction. Such general tonics as iron, arsenic, and quinine may be indicated.

In the more severe or chronic cases, prolonged physical and mental rest may be necessary, although **massage** may be employed at an early stage with advantage, provided it is at first very gentle and at all times stops short of causing fatigue. The diet should be small in quantity, nutritious, and easily digestible, and if atonic dyspepsia be present it should be treated.

SOLDIER'S HEART

Synonyms.—The Irritable Heart of Soldiers; Disordered Action of the Heart (D.A.H.); Effort Syndrome.

This condition was first fully described by Da Costa in 1862 and later, and by Myers in 1870. It is necessary to point out, however, that in the light of recent discoveries some of the cases described by these writers were in all probability cases of auricular fibrillation, the onset of the latter condition having in many cases been associated with undue physical exertion. Since the Great War much attention has been paid to the subject, owing to the large number of cases which have arisen, apparently as a result of the conditions attendant upon the life of the soldier in modern warfare.

Ætiology and Pathology.—The affection is more common in those of sedentary occupation, and there is frequently a history of acute rheumatism.

The prevailing view prior to the Great War was that the malady was due either to the accoutrements of the soldier, such as tight belts and closely fitting uniforms, or to over-exertion, such as "setting-up drill." It may be pointed out, however, that in a discussion reported in the *Journal of the Royal Army Medical Corps*, 1910, R. J. S. Simpson pointed out that the method of training can only be subsidiary as a cause, and expressed the belief that the affection is congenital, or at least developmental; while W. Bezley Thorne put forward the view that it depends upon toxæmia, and recommended the removal of this condition as part of the treatment. Speaking broadly, investigations conducted during and after the Great War appear to show that in a large proportion of the cases of soldiers invalidated home for so-called soldier's heart affections, the heart is not the *fons et origo* of the malady, and that the circulatory symptoms are but a manifestation of the general state. On inquiry, it has been found that in many of the cases there has been a history of some slight illness, such as diarrhœa, or a febrile attack pointing to some infection.

Among the hypotheses which have been advanced in explanation of the condition are the following:

1. *Glandular*.—The glands blamed are the thyroid and the suprarenals. Some consider that the condition is one of hyperthyroidism, and state that enlargement of the thyroid is present in nearly every case. But as Lewis found this in only 4 per cent. of the cases, and other observers have scarcely ever noticed it or other signs of hyperthyroidism, this theory cannot be said to be proved. The irritation of the sympathetic, with its concomitant results, noted in the condition, has led some to blame the suprarenals; but it is difficult to believe that this is the true cause, especially as the administration of adrenalin appears to aggravate the condition.

2. *Nervous system*.—All the symptoms point to the nervous system as bearing the full force of the blow; it is not, however, the primary but the secondary factor, the exciting cause falling chiefly on this system.

3. *Myocardial factor*.—It has been suggested that, as a history of rheumatic fever is so frequent, the myocardium is chiefly to blame. Rather does it seem that the myocardium is affected secondarily by the exciting cause.

4. *Bacteræmia*.—At one time this was thought to be the cause of the disease, but the failure of Dimond and Briscoe to find the presence of any bacteria in the blood has disposed of this claim.

5. *Poisoning following some microbic invasion*.—Numerous authorities subscribe to this view, as in 50 to 60 per cent. of cases the symptoms have been first noted after an infection. I do not consider, however, that a case has been made out in support of this view. It may be asked, for example, what about the other 40 per cent. in whom there is no such history, and why should infection cause soldier's heart in one case and not in another?

Personally, I consider that the view of Simpson and others, namely, that the malady is congenital, or at least developmental, has much to commend it. One person is constitutionally not so strong as another (called by some "constitutional inferiority"), the reason of which cannot be discovered. This view would explain why alteration of accoutrements and avoidance of over-exertion do not obviate the condition. I incline to the view that numerous factors play a part in the production of the malady, and that the following may explain the pathology: As in the case of civilians, one soldier is constitutionally not so strong as another, as a result of congenital or developmental weakness, and any evil effect weakening the system by infection, fright, shock, or emotion of any kind, overstrain, or other concomitants of warfare, will in those soldiers less able to bear these produce the symptoms of soldier's heart, while their stronger brethren will escape; especially will this be the case in those who before enlistment have been employed in sedentary occupations. During the pre-war period the condition may have remained latent, as there had not been a sufficient excitement to make it evident; but directly this is increased by the conditions of warfare the system breaks down.

It may be added that soldier's heart in no way differs from what may be met with in civilian life.

Symptoms.—Thanks to Lewis and other workers, the individual symptoms have received thorough investigation, but nothing of any importance has been added to the symptomatology since the classic description given by Da Costa. Among the commonest symptoms complained of are invariably breathlessness; almost always a sense of exhaustion after effort, physical or mental, giddiness and headache; frequently palpitation, præ

cordial discomfort or pain, depression of spirits, and irritability of temper ; and less commonly fainting attacks, nervousness, loss of emotional control, lack of power of concentration, impairment of memory, sleeplessness, disagreeable dreams, tremors of the hands, and vasomotor symptoms, such as flushing, and numbness, coldness, and pallor or lividity of the extremities. Shortness of breath is usually related to exertion or emotion, being out of proportion to either, and the respiratory rate may rise to 40 or even 70 per minute. The respiratory rate is always normal while asleep, and usually so apart from physical exertion and emotion. The sense of exhaustion after effort may be extreme. Giddiness is associated with physical exertion or with change of posture, especially the latter ; as also are fainting attacks, which may be accompanied by loss of consciousness. Headache usually occurs after exertion, and may be severe, throbbing and localised in the frontal region. Palpitation is generally induced by physical exertion or emotion, but it may be nocturnal, and occasionally occurs apart from these. Pain is usually related to exertion, less frequently to emotion, and is occasionally nocturnal. It is commonly limited to the præcordium, but sometimes radiates to the back, to the neck, or down the left arm. The cardiac rate is increased, and also the increase in rate on physical exertion, emotion, and the assumption of the upright posture after lying down is in excess of the normal, as is also the time which elapses before the pulse-rate returns to its rate prior to exertion. The blood-pressure is usually not increased, but the increase on physical exertion and as a result of emotion is exaggerated. The apex-beat is often unduly visible and palpable, but it is not heaving in character. On X-ray examination, the heart is not found to be enlarged. Not infrequently the first sound is shortened and sharp, and the second sound at the apex accentuated. A systolic murmur is sometimes audible, often having its point of maximum intensity in the pulmonary area. There is nothing abnormal revealed on electro-cardiographic examination. The deep reflexes are usually exaggerated. There is a moderate leucocytosis, the lymphocytes being relatively increased in number.

Diagnosis.—There are certain fundamental distinctions between primary cardiac overstrain and "soldier's heart." In the latter, the sense of exhaustion after effort is more prominent ; giddiness and fainting attacks are more associated with change of posture and less with physical exertion ; and there is much more likely to be depression of spirits and other nervous symptoms, as well as vasomotor symptoms. It is necessary to diagnose the condition from cardiac hypertrophy ; in the latter, the apex-thrust is slower and longer than normal, and the first sound is long, low in pitch, and muffled.

Prognosis.—This is, generally speaking, not good, from the point of view of complete recovery, a majority not being able to return to their occupation.

Treatment.—*Prophylactic.*—Slow and carefully graduated training is especially advisable in recruits whose occupations have been sedentary.

Curative.—Investigations should be conducted for septic infection, especially from the teeth, the fauces, and the colon. Efforts should be directed towards the restoration of the patient's general bodily and mental health. To this end, fresh air and graduated exercises, especially in the form of games to begin with, are enjoined. It is of great importance to secure an ample amount of sleep, and for this, as well as for excitability or irritability of the

nervous system, bromides, at first in the usual dosage and continued in smaller dosage, are frequently of value. Digitalis is of no avail. Those cases in which there are indications of a slack vasomotor system are sometimes greatly relieved by wearing a belt to act as a general support for the abdomen.

ANGINA PECTORIS

Definition.—The term angina pectoris is usually employed to denote a paroxysmal attack of pain, usually in the retrosternal region, with a tendency to radiate in certain directions, and often accompanied by a feeling of constriction within the chest, and sometimes by a sense of impending death. I wish to emphasise at the outset, however, that *there are many grades and modified forms of the affection.*

Ætiology.—Heredity is a factor, for it is well known that certain families are more prone to degenerative processes of the arterial system and of the heart than others. The affection is much more frequent in males than in females, and is found more particularly in those who are passing from middle into elderly life. It is much more prevalent in those classes of society who are subject to excessive mental wear-and-tear, whether from overwork, worry, or anxiety, and is commoner in those who have been subjected to long-continued physical overstrain. The other important predisposing causes are gout, syphilis, rheumatism, some of the acute infective diseases, especially influenza and enteric fever, and toxic chemical substances, such as alcohol, and perhaps tea, coffee and tobacco. *In persons under 40, syphilis is an important causal factor.* Arterial disease, from whatever cause, predisposes to the disease and is present in the majority of cases, and in many there is in addition supernormal blood-pressure.

Among the exciting causes which induce attacks, the most common is physical exertion, such as walking uphill or hurrying to catch a train, especially after meals and against a cold wind; sometimes even the effort of dressing, or stooping to lace the boots, is sufficient to precipitate an attack. Other exciting causes may be cold in the sense of getting chilled from whatever cause, emotional excitement, less frequently mental effort, and dyspepsia—particularly those forms attended with flatulent distension of the stomach or colon. It must be remembered, however, that flatulent distension is also a frequent concomitant of the paroxysm. Only rarely do attacks occur apart from some exciting cause; occasionally the attack comes on whilst the patient is in bed, but this happens usually at the end of a fatiguing day.

Pathology.—The commonest structural changes found in angina pectoris are narrowing or occlusion of one or both coronary arteries, acute or chronic aortitis, fibroid or fatty degeneration of the myocardium, chronic disease of the aortic and much less frequently of the mitral valves, fusiform dilatation of the aorta, sacculated aneurysm, fatty infiltration, adherent pericardium, and arterial disease.

The hypotheses which have been advanced in explanation of the attacks are numerous, and include the following: (1) That angina pectoris consists in the distension of an enfeebled ventricle; (2) that it is of the nature of a cramp, or spasm, of the heart, analogous to cramp of a voluntary muscle; (3) that it is an "intermittent claudication"; (4) that it consists in a myo-

cardial ischæmia, generally due to an affection of the coronary arteries (atheroma, functional constriction, thrombosis, etc), this ischæmia being the direct cause of the pain; (5) that it is "neural" in origin—a neuritis, a neurosis, a neuralgia, a vasomotor storm, local or general. The third hypothesis is based upon the analogous phenomena sometimes met with in the legs in partial occlusion of the arteries. In this condition, a cramp-like pain and loss of function of the muscles are experienced on quick or prolonged walking. It is supposed that the circulation is sufficient for rest or quiet and limited exertion, but not for active or prolonged exertion. But, in the opinion of the late Sir Clifford Allbutt, the heart does not "claudicate" in angina pectoris. He himself regarded the phenomena as generally, but not always, due to tension of the first part of the aorta, which is the seat of some inflammatory or degenerative lesion; sudden death, when it occurs, being due not directly to the aortic lesion, but being the result of "vagus inhibition," the shock of the paroxysm causing asystole. He described certain rarer cases in which the morbid stress falls on the pericardium. The late Sir James Mackenzie's view was the following: That angina pectoris is "an expression of cardiac exhaustion and also an expression of a susceptible nervous system." The pain is a viscerosensory reflex; the sense of constriction a visceromotor reflex, giving rise to spasm of the intercostal muscles.

Symptoms.—As has been already stated, angina pectoris is characterised by a paroxysmal attack of pain, usually in the retrosternal region, with a tendency to radiate in certain directions, and often accompanied by a feeling of constriction within the chest, and sometimes by a sense of impending death.

Pain is the cardinal feature. It is felt *most commonly in the retrosternal region*, next most frequently across the front of the chest, and occasionally in the præcordium, the epigastrium, or over a wide area of the back of the chest. The severity of the pain varies from slight discomfort to intense anguish. In some cases it attains its maximum with extraordinary suddenness, while in others this happens gradually. The pain, as stated, has a tendency to radiate in certain directions. It frequently spreads to the left shoulder and armpit; occasionally to both sides; in many cases down the arm, generally on the ulnar side, usually not beyond the elbow, although it may reach as far as the finger tips. It sometimes strikes through to near the angle of the scapula, on one or both sides, or to a wide area on the back of the chest. Occasionally it extends to the neck and occiput, or to the jaw, and rarely it radiates in a downward direction, being felt even in the lower part of the trunk and lower limbs. The pain may begin in the left arm, in the jaw, the left pectoral muscle, the left leg, or in the abdomen—the so-called *angina abdominis*—and remain localised.

The feeling of constriction in the chest already referred to is described in different terms by different individuals; in some cases the sensation is as if the chest were held in a vice, in others as though a heavy weight were pressing on the chest. When the sensation of impending death is present, this overshadows the most severe pain. It may be present without the pain—the "*angina sine dolore*" of Gairdner.

When an attack occurs, the patient, if in motion, stops short and rests. The expression of the face is often anxious or even one of intense anguish. The skin is often pallid, or even cadaveric in hue, and there is frequently a

clammy sweat. The breathing is shallow, and the patient is afraid to make an effort to breathe normally. There may be a sensation of numbness, more particularly of the arm; this may be present only during a paroxysm, while in other cases it is a constant symptom. Among other subjective phenomena which may be present are tingling and giddiness, while hyperæsthesia over the painful area may often be noted. In almost every grave case the patient complains of a sensation of sinking, and of a feeling as if the heart were stopping, but rarely loses consciousness, unless fatal syncope occurs. The pulse-rate seems to vary in different cases; in some it is increased, while in others it is diminished. Very considerable changes are frequently found in the character of the pulse in different cases; at times it appears to be quite unaffected; at others it may become irregular, and different forms of irregularity have been observed, but there does not seem to be anything definitely known on the subject. The blood-pressure is often considerably increased at the crisis of the attack, but it should be remembered that this is not by any means a universal rule. The patient may yawn continuously, and there may be hiccough, flatulence, retching, or vomiting. The attack, as a rule, passes off gradually, but sometimes ceases suddenly; as it subsides the patient may belch up a large quantity of air, and it is often followed by the passage of abundant pale urine. After the attack the patient may be much exhausted, and may feel ill for some days. Death may occur at the height of an attack, and this may take place even in the first.

The attack may last for a few seconds, a few minutes, or longer; so frequently may they recur that for hours or even days the patient appears to be suffering from one continuous attack—*status anginosus*.

The above description is that of a typical and severe attack, but *there are many grades and modified forms*. For example, there may be on physical exertion or emotion only a little discomfort or pain felt over the sternum, radiating to the arm and neck, and accompanied by a feeling of uneasiness and distress, which may at first disappear as soon as the existing cause ceases, but at a later stage may continue for some minutes after its cessation.

Diagnosis.—Angina pectoris is not infrequently missed altogether. A diagnosis is practically always possible if full advantage be taken of all the avenues of investigation in each case. The age, sex, and previous history of the patient, the site of the pain, its paroxysmal character, its severity, its tendency to radiate in certain directions, the fact that *it is usually first noticed during or after exertion*, that it is often accompanied by a feeling of constriction within the chest and a sense of impending death, and evidence of cardio-vascular disease, together go to form a typical clinical picture.

Among the conditions which should be excluded are pseudo-angina, aneurysm, pleurodynia, acute pleurisy, cervico-brachial neuritis, and colic, whether of intestinal, hepatic or renal origin. The differential diagnosis between the true form of angina pectoris and pseudo-angina will be discussed later.

Prognosis.—This is very difficult. While the proportion of cases in which the immediate outlook is grave is not large, and while the great majority of other cases respond to treatment to a very considerable extent, the prognosis is usually serious, the occurrence of sudden death being not uncommon. In trying to forecast the future, it is necessary to consider—(1) The nature and severity of the underlying cause; and (2) the frequency

and severity of the attacks. With regard to the first, naturally the outlook is much better when the disorder is due to fatty infiltration than when associated with coronary disease, fatty or fibroid degeneration of the myocardium, or general arterial disease. When there is no doubt that the case should be placed in the latter group, the outlook is usually grave, and is still more so if in addition there be aortic incompetence or chronic renal disease. A point of great importance is to ascertain how far the patient is able to modify his life so as to bring it within the limits of the heart's strength, and also the response the patient makes to treatment.

Secondly, it is obvious that the more frequent and severe the attacks, and if provoked by slight exciting causes, the worse the prognosis. Very rarely is the disease fatal in the first attack. Apparently there is a tendency for the paroxysms to become less frequent and less severe if dilatation of the heart supervene.

Treatment.—The treatment resolves itself into two parts—(1) Prevention, if possible, of the recurrence of the paroxysm; and (2) an endeavour to relieve it.

With regard to the first of these, we should try to improve the general health, more especially the circulatory and nervous systems; and since the disease occurs usually in association with exhaustion of the cardiac muscle, a cardinal indication is to try to remedy this condition, and to prevent its recurrence. In this connection it is advisable first of all to review the ætiology, and to endeavour to find out the cause of this exhaustion; and for this purpose it will be necessary to inquire in detail into the past and present life of the patient.

In all cases the clear indication is to enjoin rest, proportionate to the degree of cardiac failure, and with this object in view it may be necessary to order complete rest in bed for some time, and even to give sedatives, such as chloral or opium. Morphine in most cases of this kind is more useful than opium. After a period of rest, explicit instructions should be given that in future the patient should live within the limits of the heart's strength, the daily life, physical and mental, being carefully regulated. He should avoid exertion which produces symptoms of cardiac distress; as well as hurry, sudden effort, walking or hurrying against a cold wind, and cold in the sense of getting chilled. Cold sheets at night, and a cold bath in the morning, should be prohibited. It should not be forgotten that the nervous system may be a factor in the production of angina pectoris, and when there is reason to believe that this is the case, appropriate measures should be employed. When the patient has suffered from a period of mental strain or sleeplessness, and, indeed, whenever there is any excitability or irritability of the nervous system, the administration of bromide of ammonium in doses of 10–20 grains three times a day, is often of great value. Emotional excitement, gastro-intestinal dyspepsia—particularly that form which is accompanied by flatulent distension—constipation, and all other possible exciting causes of an attack should be carefully treated. Over-indulgence in food, alcohol, or tobacco should be avoided. Flannel should be worn next to the skin, both summer and winter. When there is reason to believe that syphilis is the cause, appropriate and energetic anti-syphilitic treatment should be employed. Similarly, if high tension be present, this should be treated on the lines previously laid down. In fact, we should review the

whole of the causes of angina pectoris, predisposing and exciting, with a view to treatment.

Of drugs which may be given with the hope of preventing an attack, the most hopeful are iodide of potassium and nitro-glycerine. The former is probably in most respects the best, and is particularly indicated when arterial disease is present, more especially if there be a history of syphilis. In some cases 5-grain doses are sufficient, while in others the drug should be pushed. Sometimes syrup of hydriodic acid, in doses of from $\frac{1}{2}$ to 2 drachms, well diluted with water, is better tolerated. Nitro-glycerine may be given in the form of tablets, or the 1 per cent. solution of trinitrin. The usual dose is $\frac{1}{100}$ th grain; this may be given three or four times a day, and gradually increased to $\frac{1}{20}$ th grain or even $\frac{1}{10}$ th grain. Either drug should be given intermittently for 2 or 3 weeks at a time, while in some cases it is good to alternate them. Sodium nitrite, erythrol tetranitrate, mannitol nitrate, and nitrite of potash are other drugs which may occasionally be employed. Taken altogether, the nitrites are not so valuable as the iodides.

Within recent years, diathermy and radiotherapy have been advocated. Operative treatment has also been resorted to. T. Jonnesco, in 1916, removed the last two cervical ganglia and the first thoracic ganglion of the sympathetic on the left side. Four years afterwards the patient had remained completely free from an attack, and the pulse-rate had increased from 44-52 to 72-74. He explained the beneficial effects as due to suppression of the centripetal path between the cardio-aortic apparatus and the nerve centres following resection of the cervico-thoracic sympathetic, the aortic reflexes to the nervous centres and the reaction of these centres which would result being thus eliminated, it having been found that ascending sensory nerves pass from the cardio-aortic plexus into the cervico-thoracic sympathetic, and terminate in centres in the brain and medulla. Daniélopoulou and Hristide are of opinion that Jonnesco's method should be supplanted by resection of the posterior roots corresponding to the sensory nerves of the heart; and if this operation be too serious, resection of the left corresponding spinal nerves. V. Pleth has published four successful cases of cervical sympathectomy.

For the paroxysm, the most efficacious remedy in most cases is the inhalation of nitrite of amyl; the action of the drug is almost immediate, and the relief is usually complete, this being particularly the case with widespread arterial constriction. It is best administered in the form of the glass capsules or perles, each containing from 2 to 5 minims, which the patient should carry about with him. This dose may have to be repeated. A similar effect may be obtained by nitro-glycerine, but its action is not so rapid, although its effect is more prolonged. The patient may nibble one or more of the tabellæ nitro-glycerini until the pain disappears; or the liquor trinitrini may be given, beginning with one, and increasing, if necessary, to 5-minim doses, in a little water. If flatulent distension be present, a draught of carminative mixture, or, if this be not available, some very hot water with a little essence of peppermint or brandy, sipped slowly, may be given with the amyl inhalation or the nitro-glycerine drops. In cases in which there is pronounced heart failure, brandy or ether, preferably the latter, in doses of 20 to 60 minims, in which 1 to 2 minims of a 1 per cent. solution of trinitrin may be dissolved, may be injected subcutaneously. Erythrol tetranitrate and sodium nitrite are not so suitable.

If the drugs enumerated fail, chloral by the mouth, hypodermic injections of morphine, or inhalations of chloroform, should be employed. Twenty grains of chloral hydrate may be tried. As a rule it is necessary to give morphine in large doses— $\frac{1}{4}$ th to $\frac{1}{3}$ rd grain. Nitro-glycerine may be combined with the morphine. The nitrites and chloroform are not of such value when there is no decided arterial spasm as in cases in which it is present. Where there is cyanosis or asthma, oxygen inhalations may be tried, particularly when morphine is found necessary.

If the drugs enumerated are not at hand, hot drinks, water containing whisky, brandy, capsicum or spirits of chloroform, or a carminative mixture, may do good by the relief of flatulence.

PSEUDO-ANGINA

Definition.—The term pseudo-angina is used by some writers to denote a paroxysmal attack of pain in the region of the heart, independent of cardiovascular lesions. While, however, this is the case, it should be remembered that it may be met with in individuals who are the subjects of valvular disease.

Ætiology.—The malady is much more frequent in females than in males, and while it is found more particularly between the ages of 25 and 50, it may occur at any age. It is not infrequently associated with hysteria, neurasthenia, or toxic causes. While the exciting causes are the same as those of the true form of angina pectoris, physical exertion does not play such an important part; cold, emotional excitement, and perhaps dyspepsia, are, on the other hand, more important factors.

Symptoms.—The pain is usually less severe than in the true form of angina, and is usually accompanied by a feeling of distension instead of constriction. The patient may complain of shortness of breath, palpitation, and a feeling of faintness. The pulse is small, and its frequency is usually increased. The attack sometimes lasts for an hour or longer, and may be followed by the passage of abundant pale urine, the patient often complaining also of a sense of fatigue.

Pseudo-angina includes at least two groups of cases, namely—(1) the neurotic; and (2) the vasomotor or toxic. The first group includes the hysterical and neurasthenic cases, while the toxic group includes cases which are due to the excessive use of tobacco, and perhaps tea or coffee, and those which follow the acute infections—particularly influenza.

In the neurotic cases the attacks are not infrequently periodic and nocturnal, and induced by emotional excitement. Instead of becoming or remaining immobile, in a number of cases the patient moves about in an agitated manner, even rushing to the window for air. Associated nervous symptoms may be present; in hysterical subjects there may be points of hyperæsthesia and anæsthetic areas. The paroxysms show a tendency to recur for some hours, or even days, following the attack.

In the vasomotor or toxic variety, the individuals are not infrequently the subjects of vasomotor disturbances, such as numbness, coldness and pallor or lividity of the extremities; while in those cases associated with the excessive use of tobacco, symptoms of nicotine poisoning, such as tobacco amblyopia, may be present.

Diagnosis.—The differential diagnosis between true and pseudo-angina is, as a rule, not difficult. In its consideration, the age, the sex, the previous history, the presence or absence of evidence of cardio-vascular lesions, the exciting cause and character of the attack, its response to treatment, as well as the other distinguishing features already described, should all be taken into account.

Prognosis.—The prognosis with regard to life is good, the attack never proving fatal, and usually having little effect on the duration of life. Further, with suitable management and treatment, there is a good chance of complete cure; the neurotic forms, however, tend to recur. In those cases of toxic origin, it is essential that the causal factor should be removed. When abuse of tobacco is responsible, however, the complaint often persists for a long time.

Treatment.—Our first duty is to reassure the patient. We should review the ætiology of the malady, and measures appropriate to each case—as, for example, when the condition is associated with hysteria, neurasthenia, or the excessive use of tobacco—should be adopted. Further, all possible exciting causes should be prevented or treated. Anti-neuralgic therapeutical agencies are more likely to be efficacious than the use of vaso-dilators.

For the paroxysm, very hot water, sipped slowly, may be tried; while, if this be not successful, diffusible stimulants may be employed, although their frequent use is not to be encouraged. If these be of no avail, use may have to be made of morphine. It may be of service for the patient to carry about with him a carminative mixture, a dose of which may be taken when an attack is threatened.

FREDERICK W. PRICE.

CLINICAL ELECTRO-CARDIOGRAPHY ¹

By means of the electro-cardiograph we are able to obtain records of the movements of both the auricles and ventricles, to measure the function of conductivity of the auriculo-ventricular bundle not only above, but also below, its division into two branches—that is, after its entrance into the ventricular muscle, and to make out the time-relations of the contraction of the auricles and ventricles. In addition, it tells us the point of origin and path of conduction of the stimulus for contraction. It is the most precise means at our disposal of investigating the state of the myocardium.

It has been known for a considerable time that changes in electric potential take place in muscle when it contracts, and, further, that a record of these changes may be obtained by connecting the muscle with a sensitive galvanometer by means of electrodes.

A. D. Waller, in 1887, employed a capillary electrometer to register the changes in electric potential in the human heart during contraction. He demonstrated that these changes were distributed through the body, and he used the moist skin surfaces of the arms and legs as leads, connecting them with a galvanometer.

Einthoven employed the string galvanometer to register the changes

¹ Horizontal lines : 1 cm. = 1000 volt.

Vertical lines : thick = $\frac{1}{2}$ th second, thin = $\frac{1}{2}$ th second.

In most of the figures, the lead is marked in the upper left-hand corner.

in electric potential in the human heart. He modified this instrument, the Einthoven string galvanometer being now generally employed in physiological and clinical investigations.¹ In the Einthoven galvanometer there is an exceedingly fine silvered glass fibre, which is suspended in a box and placed vertically between the poles of a powerful electro-magnet. When a current passes through this fibre, minute movements of the fibre take place. The shadow of the oscillating fibre is magnified, and projected on to a photographic screen, and in this way a photograph of these movements is obtained. The sensitiveness of the fibre can be adjusted by altering the tension, the standard generally adopted being that of Einthoven, *i.e.* that when a difference of potential of one millivolt is passed through the fibre, this gives a deflection on the plate of 1 cm. in amplitude.

Following Einthoven, the common practice is to accept three leads and the following nomenclature, *i.e.* lead I, or the transverse, a lead from the right and left hands; lead II, or the axial, from the right hand and left foot; lead III, or the left lateral, from the left hand and left foot.

Oscillations may result from tremor of the somatic muscles, and may somewhat resemble those due to auricular fibrillation; the differential diagnosis will be discussed later.

The record of the changes in electric potential which take place in the heart during contraction is called an electro-cardiogram.

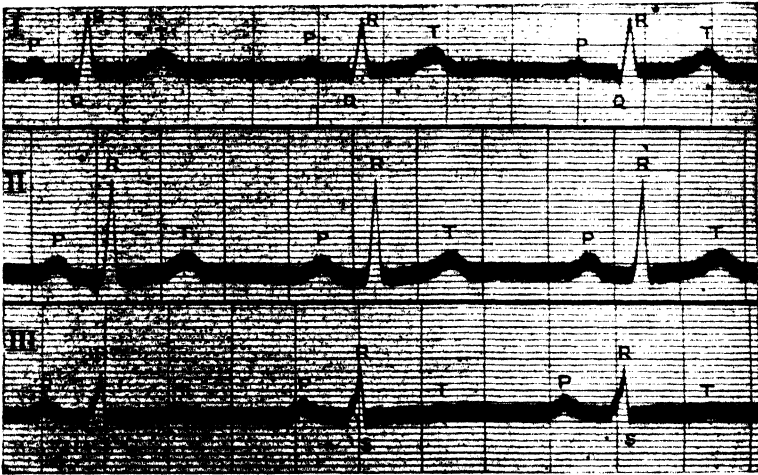

FIG. 68.—Electro-cardiogram of a normal subject. The first deflection, *P*, is due to the contraction of the auricles; the others are the result of the contraction of the ventricles, and are termed *Q*, *R*, *S*, and *T*. In normal subjects the amplitude of all the deflections is usually greatest in lead II, especially the deflection *R*.

If a normal electro-cardiogram be studied, certain upward and downward deflections are seen in each cardiac cycle, the former being the more important (Figs. 68 and 69). These deflections may exhibit considerable

¹ The electro-cardiograph supplied by the Cambridge Scientific Instrument Co. Ltd. is, in my opinion, the most satisfactory.

variations in amplitude and form. Following Einthoven, the deflections are called *P*, *Q*, *R*, *S*, and *T*, in some instances *T* being followed by *U* during the early part of diastole. That portion of the electro-cardiogram from the beginning of *P* to the commencement of *Q* is called the auricular complex.

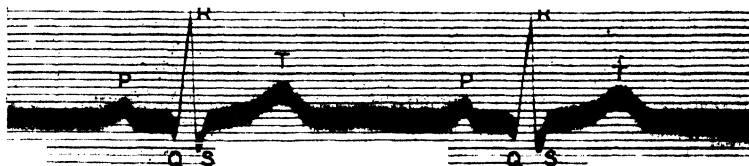

FIG. 69.—A normal electro-cardiogram.

and that portion between the commencement of *Q* to the end of *T* is called the ventricular complex. The interval between *T* and the following *P* represents diastole.

The first deflection, *P*, is due to the contraction of the auricles. *Q*, *R*, *S* and *T* are due to the contraction of the ventricles. *P* is a small, blunt and rounded, upward deflection. Following *P* the string either remains at zero,

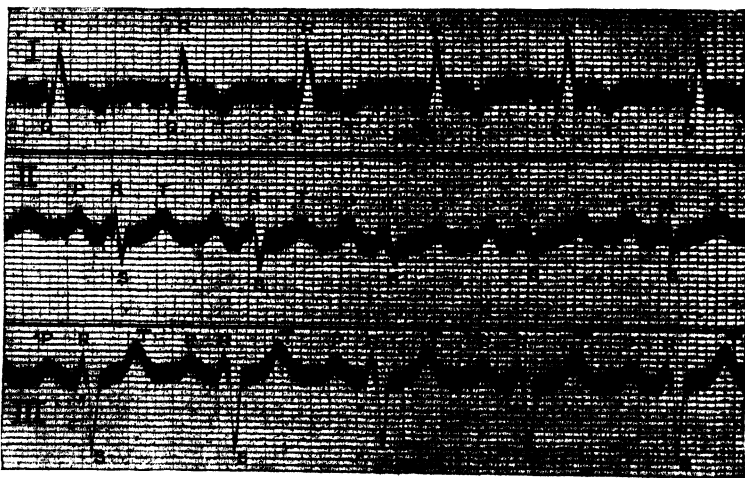

FIG. 70.—Electro-cardiogram showing inversion of *T* in lead I. There is also left-sided preponderance.

or descends somewhat. *Q* and *S* are downward, steep deflections, usually of small amplitude. *Q* passes at once into *R*, which is an upward sharp spike, and of greater amplitude than any of the other deflections. *S* follows immediately upon *R*. During the interval between *S* and *T* the string remains

at zero. *T* is a prominent, broad, blunt deflection. It is an upward deflection in lead II; it is almost always an upward deflection, but may be inverted in lead I (Fig. 70); and is not infrequently inverted in lead III

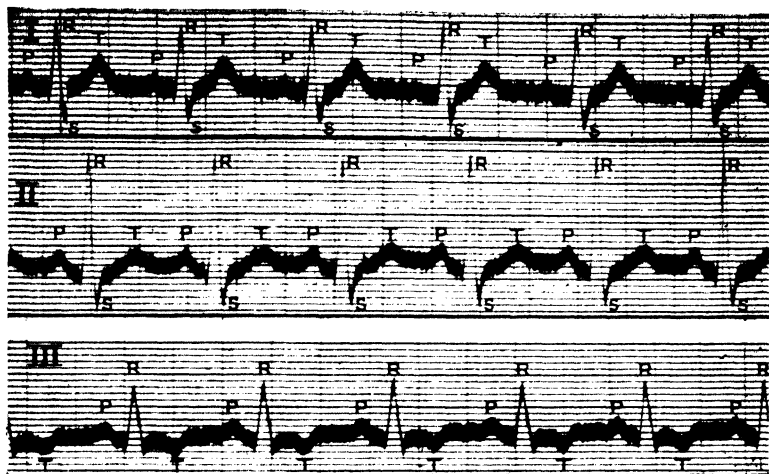

FIG. 71. Electro-cardiogram showing inversion of *T* in lead III.

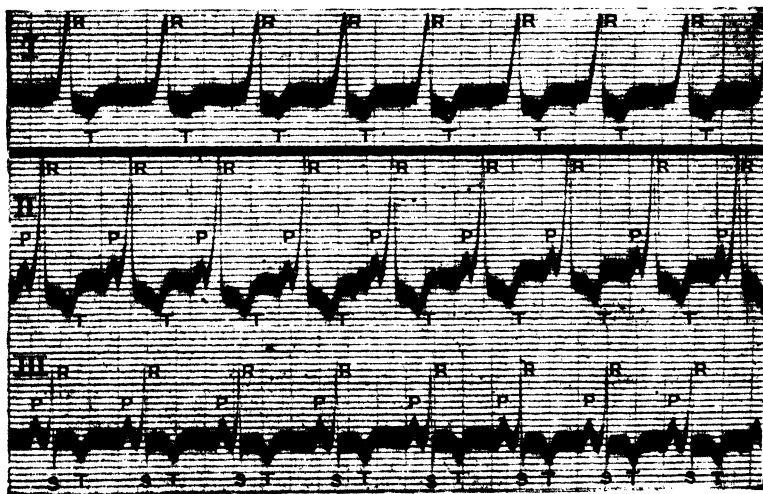

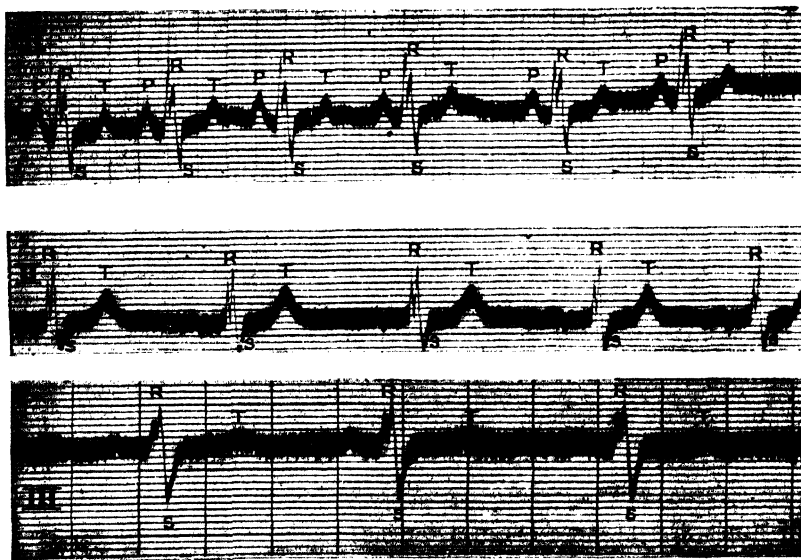

FIG. 72.—Electro-cardiogram showing inversion of *T* in all the leads.

(Fig. 71). It is said that inversion of *T* in lead II is always pathological, and in lead I nearly always so. If *P* (Fig. 73) or *R* be a downward deflection in lead I, II or III it is abnormal. Bifurcation of *R* (Figs. 74, 75 and 76) and

Fig. 73.—Electro-cardiogram showing inversion of *P* in lead III. There is also right-sided preponderance.

Figs. 74, 75 and 76.—Electro-cardiograms from three different subjects, showing bifurcation of R

S is occasionally found in normal individuals, and of *P* (Fig. 77) more rarely. Bizarre types of the *Q*, *R*, *S* group of deflections are occasionally to be noted (Figs. 78, 79 and 80).

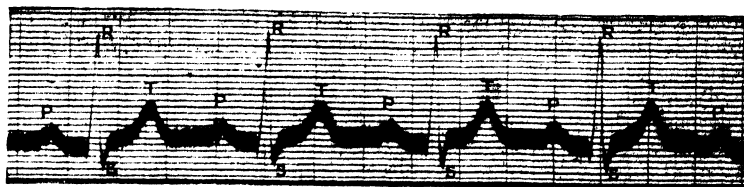

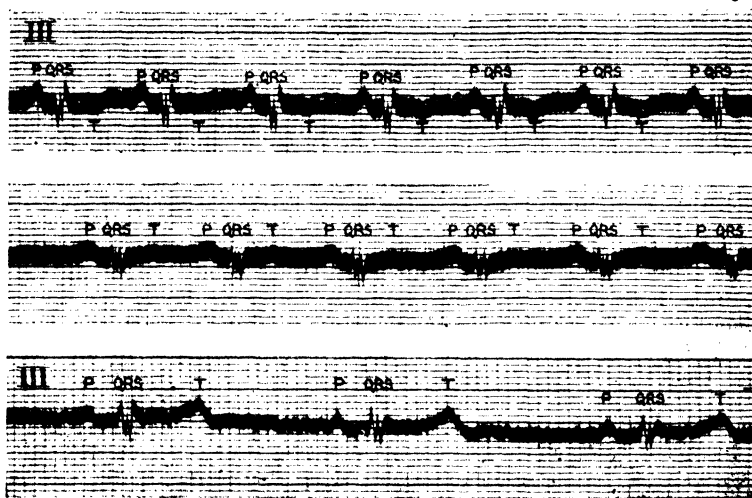

FIG. 77. Electro-cardiogram showing bifurcation of *P*.

R and *T* are the most constant deflections, the former more especially so; *Q* and *S* are not infrequently absent; while the *U* deflection is of very uncommon occurrence.

In normal subjects the amplitude of all the deflections is usually greater in lead II, especially the deflection *R*, while the deflections in lead III are not infrequently of small amplitude.

The time-distance between the beginning of *P* and the commencement of *Q*, or between *P* and *R*, as the case may be, is an index of the *As-Vs* interval,

FIGS. 78, 79 and 80.—Electro-cardiograms from three different subjects, showing bizarre types of *QRS* group of deflections.

that is, the interval separating the commencement of auricular and ventricular contraction, and is a measure of the function of conductivity of the auriculo-ventricular bundle above its division into two branches; it is called the *P-Q* or *P-R* interval. The rule is to employ the *P-R* interval, on account

of the frequent absence of the *Q* deflection. In normally acting hearts this interval does not measure more than 0.18 second (Figs. 68 and 69). If it exceeds this (Fig. 99), we may conclude that there is delay in the conduction of the stimulus from auricle to ventricle: this means that the function of conductivity is depressed, and that probably there is some affection of the auriculo-ventricular bundle. The *P-R* interval is a more reliable indication of the rate of conduction of the stimulus for contraction than the *a-c* interval in a polygraphic tracing, because the presphygmie interval and the period between the opening of the aortic valves and the carotid pulse are not included. The period of time occupied by the ventricular complex is approximately that of the ventricular systole. The initial group of ventricular deflections (*Q, R, S*) corresponds to the initial events of ventricular systole—in other words, to the spread of the wave of excitation in the ventricular muscle. The period of time occupied by this group is of great importance, being a measure of the time during which the various parts of the ventricular muscle are passing into activity. It is normally not more than one-tenth second. If it is increased, it indicates a delay in the conduction of the wave of excitation through the ventricular muscle. The period of time between the *S* and *T* corresponds with the time during which the mass of the ventricular

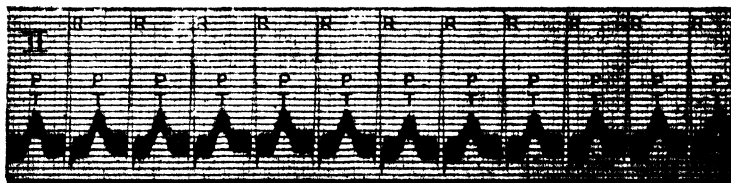

FIG. 81.—Electro-cardiogram in which *P* and *T* coincide and superimpose.

muscle is in contraction. The *Q T*, or *R T*, interval occupies about 0.32 second. When the cardiac rate is unusually frequent the duration of the diastolic interval is shortened, so that the deflection *T* approaches more and more to the following *P*, and *P* and *T* may even coincide and superimpose (Fig. 81).

The form of electro-cardiographic curves depends upon the point of origin and paths of conduction of the stimulus for contraction; any departure from the normal in respect of either of these will, therefore, result in a corresponding alteration in the form of the electro-cardiogram. A normal *P* signifies that the stimulus for contraction arises in the remains of the sinus venosus at the orifices of the great veins, and that from this point the stimulus spreads over the whole of the auricles along the normal paths. When *P* is abnormal, as, for instance, inverted, it is believed that the stimulus for contraction arises at some site other than the sino-auricular node, or that the paths of conduction are abnormal. Similarly, a normal ventricular complex signifies that the ventricles have contracted in response to a stimulus which has arisen above the level of the division of the auriculo-ventricular bundle into its two main branches, and that from this point the stimulus proceeds along the normal paths; and an abnormal ventricular complex signifies either that the stimulus for contraction has arisen at some point below

the level of the division of the auriculo-ventricular bundle, or that, when supra-ventricular in origin, the paths of conduction are abnormal.

Electro-cardiograms of a number of healthy persons all present different features, but the curve in each case will present individual characteristics which are constant. The form of electro-cardiogram is modified by age, and by displacement of the heart from whatever cause. Diminution in the amplitude of *T* occurs with advancing age. (*not Conduct. Clin.*)

CARDIAC HYPERTROPHY.—It has been previously pointed out that in cardiac hypertrophy, while both ventricles are more often affected than one alone, one ventricle is frequently involved to a greater degree than the other. This predominant hypertrophy or preponderance of either ventricle is revealed by the electro-cardiograph. If in cardiac hypertrophy an electro-cardiogram does not indicate either right- or left-sided preponderance, we

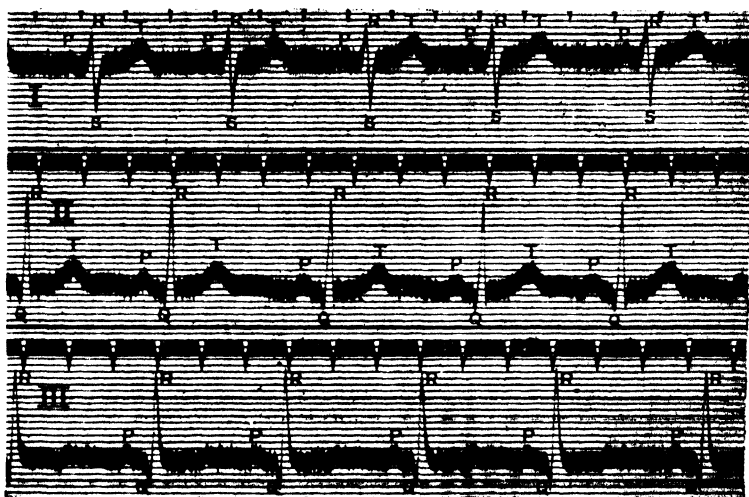

FIG. 82.—Electro-cardiogram showing predominant hypertrophy of the right ventricle.

may assume that the hypertrophy involves both ventricles approximately equally. Displacement of the heart should be excluded.

In predominant hypertrophy of the right ventricle, in lead I, *R* is small or absent, and *S* is large and may be very large; in lead III, *R* is large and may be very large, and *S* is small or absent; and *Q* is most pronounced in lead III (Fig. 82). The deflections of greatest amplitude in leads I and III, therefore, point towards each other. In predominant hypertrophy of the left ventricle, the electro-cardiogram is the reverse of that of the right ventricle. In lead I, *R* is large and may be very large, and *S* is small or absent; in lead III, *R* is small or absent, and *S* is large and may be very large; and *Q* is most pronounced in lead I (Fig. 83). The deflections of greatest amplitude in leads I and III, therefore, point away from each other. In extreme preponderance of either ventricle, the period of time occupied by the *Q, R, S* group of deflections may be increased, exceeding one-tenth of a

second. It is necessary to distinguish between predominant hypertrophy of the right or left ventricle and a lesion of the left or right main branch of the auriculo-ventricular bundle respectively. This will be referred to later.

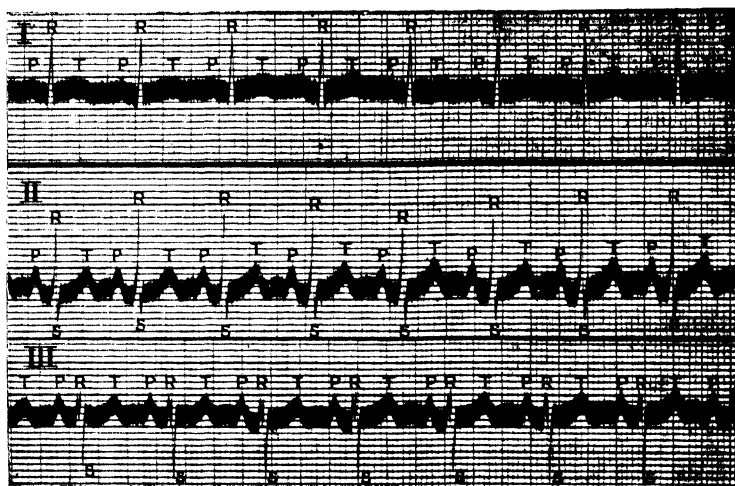

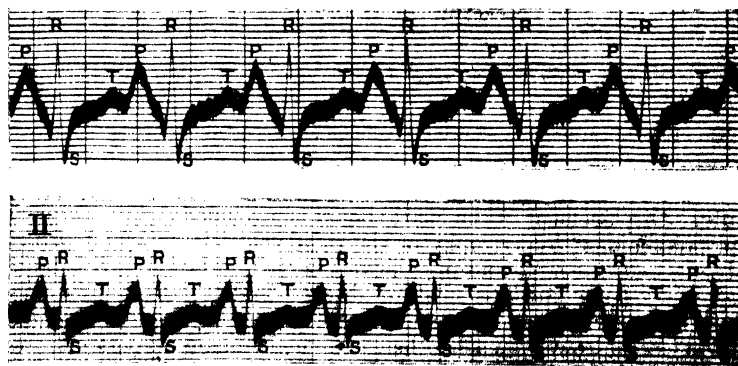

FIG. 83.—Electro-cardiogram showing predominant hypertrophy of the left ventricle.

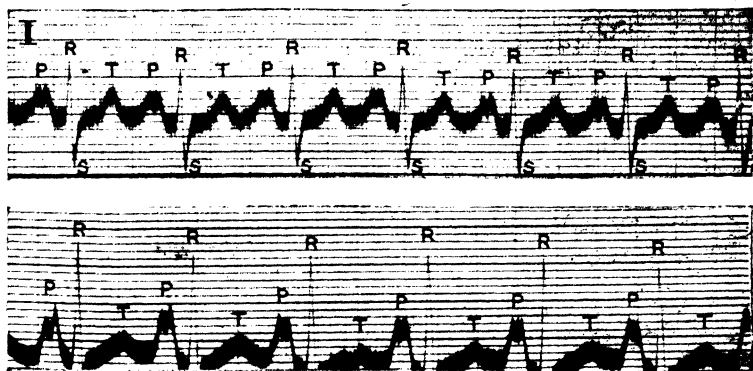

It is said that the amplitude of *P* is increased (Figs. 84 and 85), or even doubled, in hypertrophy of the auricles. Some writers, however, state that this is occasionally to be met with in normal hearts.

FIGS. 84 and 85.—Electro-cardiograms from two different subjects, showing increased amplitude of the deflection *P*.

CHRONIC VALVULAR DISEASE.—In many cases of aortic incompetence the ventricular complexes are the same as those of predominant hypertrophy of the left ventricle. In mitral stenosis the amplitude of the deflection *P* is often markedly increased, and not infrequently it is also broad, has a flat

top, and is bifurcate (Figs. 86 and 87). These features, when present, are of diagnostic value. While a marked increase in the amplitude of the deflection *P* is especially found in mitral stenosis in which there is hypertrophy

FIGS. 86 and 87. — Electro-cardiograms from two different cases of mitral stenosis. The deflection *P* is increased in amplitude, and is also broad, has a flat top, and is bifurcate.

of the auricles, in my opinion it is not justifiable to diagnose the lesion from this alone. In many cases of mitral stenosis the ventricular complexes are the same as those of predominant hypertrophy of the right ventricle. When auricular fibrillation supervenes in mitral stenosis, the curves will present

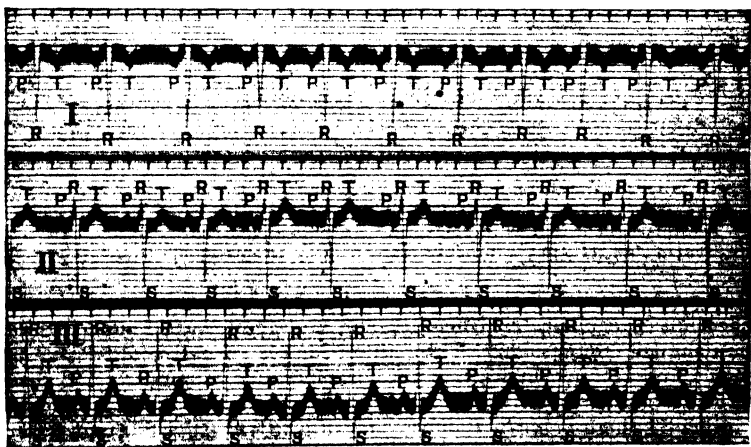

FIG. 88. Electro-cardiogram from a case of transposition of the heart. All the deflections in lead I are inverted.

features characteristic of that condition. In many cases of aortic incompetence, the ventricular complexes are the same as those of predominant hypertrophy of the left ventricle.

CONGENITAL HEART DISEASE.—It is said that an increase in the amplitude of the deflections is often found in congenital heart disease.

TRANSPOSITION OF THE HEART.—In this condition all the deflections of a curve from lead I are inverted (Fig. 88). It is believed that this form of electro-cardiogram is found in no other condition.

INFARCTION OF THE HEART.—As stated on page 861, electro-cardiograms of this morbid affection are usually characteristic, and are of great diagnostic value. They were first described by Pardee and others, and later in greater detail by Parkinson and Bedford,¹ and are as follows: There is usually an alteration in the *R-T* interval or in the *S-T* interval. This portion of the curve commences from the *R* or *S* deflection either above or below the zero

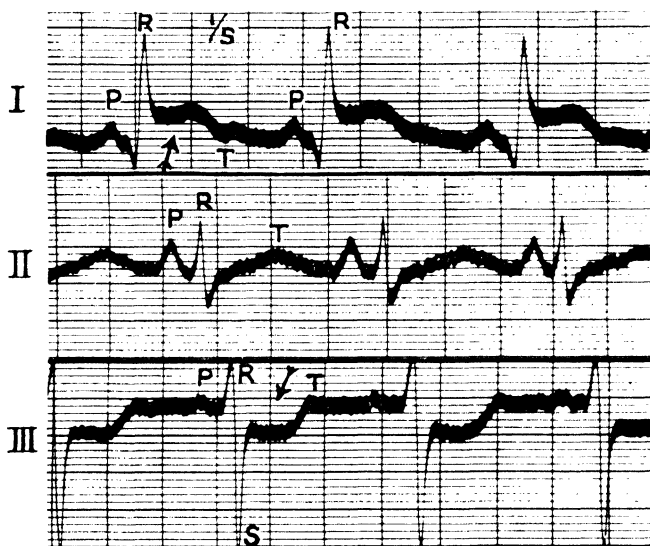

FIG. 89.—After Parkinson and Bedford (*The Lancet*). Electro-cardiogram from a case of infarction of the heart. Taken four days after the onset of symptoms. The *R-T* interval in lead I is in the form of a plateau-shaped elevation, and the *S-T* interval in lead III is in the form of a plateau-shaped depression, as indicated by arrows.

level, and afterwards proceeds in a more or less horizontal direction until the *T* deflection is reached, resulting either in a plateau-shaped elevation or in a plateau-shaped depression. This alteration is usually most noticeable in leads I and III, in which event the corresponding portions of the curves in these leads point away from each other—thus, when there is an *R-T* elevation in lead I there is an *S-T* depression in lead III (Fig. 89), and *vice versa*. Sometimes, however, it is best observed in leads I and II, or in leads II and III, and in either case the corresponding portions of the curves point in the same direction; or the alteration may be present in one lead only. The foregoing features are perhaps pathognomonic of the condition. From a few days to a few weeks later, the *R-T* or the *S-T* portion of the curve returns

¹ *Heart*, 1988, vol. xiv. No. 3.

to the zero level. Usually characteristic changes in the *T* deflections in one or more leads, generally the latter, are also to be noted (Figs. 90 and 91). If more than one lead is implicated, perhaps most frequently leads III and II, and next most commonly leads I and II; while if only one lead, either lead III or I. The *T* deflections become inverted, their form is usually that of a sharp spike, and their amplitude is often large. The *T* deflections point in the opposite direction to that of the previous deviation of the *R-T* or the *S-T* intervals respectively. The *R T*, or the *S T*, interval preceding an

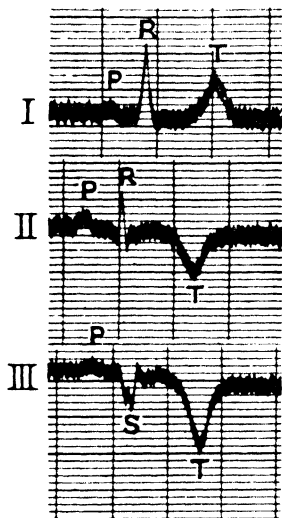

FIG. 90. After Parkinson and Bedford (*The Lancet*). Electro-cardiogram from a case of infarction of the heart. Taken two and a half weeks after the onset of symptoms. The *T* deflections in all leads are spiked and of large amplitude, and those in leads II and III are also inverted.

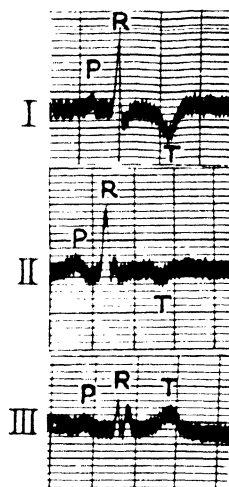

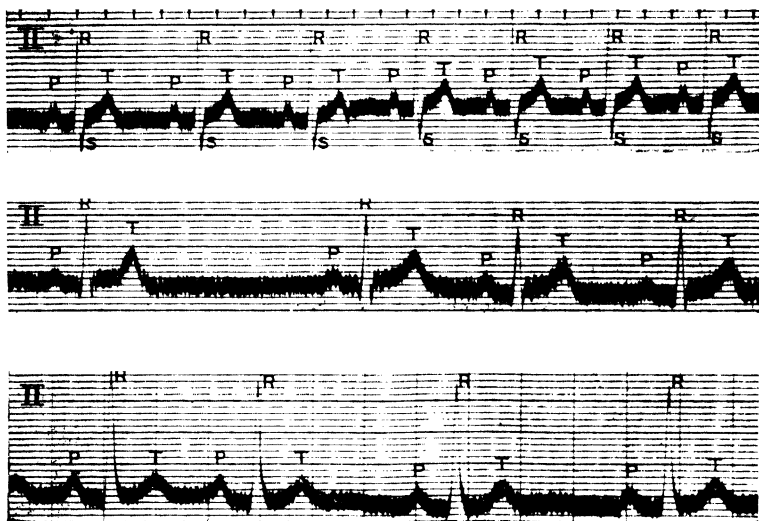

FIG. 91. After Parkinson and Bedford (*The Lancet*). Electro-cardiograms from a case of infarction of the heart. Taken three weeks after the onset of symptoms. The *T* deflections in lead I are inverted; their form is that of a sharp spike, and their amplitude is rather large. The *T* deflections in lead II are inverted.

inverted *T* deflection often exhibits upward convexity. These features are not so characteristic as are those of the first stage, but taken together with the clinical features, they afford strong corroborative evidence of the disease. In both the foregoing stages, the initial group of ventricular deflections (*Q, R, S*) usually exhibits diminished amplitude, the period of time occupied by the complex is often increased, and the latter is usually associated with notching or splintering. Some changes in the *T* deflections towards the normal generally supervene within a few weeks or months, and ultimately the *T* deflections in all leads may become normal, but sometimes those in one lead remain inverted and sharply spiked, and even these changes are very suspicious.

SINUS IRREGULARITY.—The electro-cardiogram of this rhythm may readily be identified (Figs. 92, 93 and 94). As the stimulus for contraction takes its origin at the physiological site, and from this point pursues a normal course, the auricular and ventricular complexes are of normal form, and the ventricular complexes follow the *P* deflections after a normal interval. As, however, there is a variation in the length of the diastolic intervals, variations are found in the length of the interval between *T* and *P*.

FIGS. 92, 93 and 94.—Electro-cardiograms from three different subjects, showing sinus irregularity. The auricular and ventricular deflections are of normal form, but there are variations in the length of the interval between *T* and *P*.

EXTRA-SYSTOLES.—Extra-systoles may be readily recognised by means of the electro-cardiograph, and usually their site of origin.

In the ventricular variety (Figs. 95 and 96) the auricle maintains its usual rhythm and contracts as the result of the normal stimulus from the sinus. When an extra-systole occurs, the ventricular complex occurs earlier than the anticipated time, and, as the point of origin of the stimulus for contraction is below the division of the auriculo-ventricular bundle into its two branches, it is abnormal in form; it is of larger amplitude and is diphasic. It is of the same duration as that of the rhythmic ventricular contraction. The corresponding *P* deflection appears at the anticipated time, and is normal in form; but it is usually embedded in the diphasic variation, although it may be detected in this part of the electro-cardiographic curve in some cases, and occasionally is nearly separate.

There are two main varieties of ventricular extra-systoles, and it is possible to differentiate between them by means of the electro-cardiograph. One variety has its origin in the basal or right portion of the ventricle, in which case the ventricular complex consists of an upward, tall, and pointed

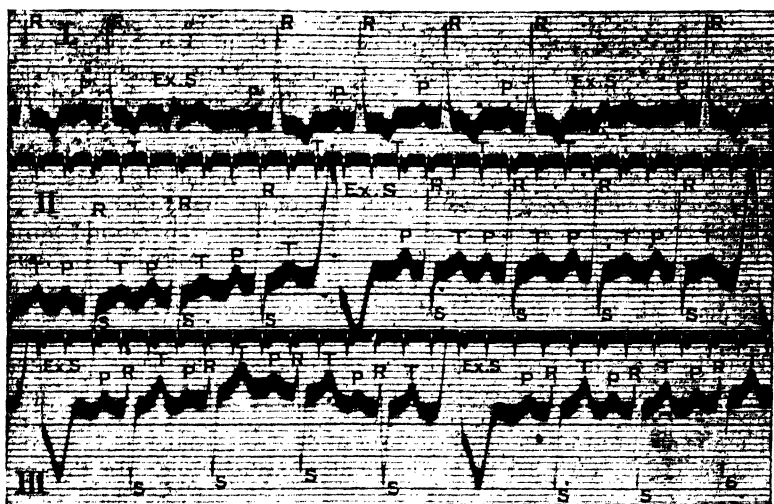

FIG. 95.—Electro-cardiogram showing extra-systoles, marked *Ex.S*, which arise in the right or basal portion of the ventricle. The direction of the deflections is the same in leads II and III, but is reversed in lead I. The corresponding *P* deflections are embedded in the diphasic variations. There is also inversion of *T* in lead I, and left-sided preponderance.

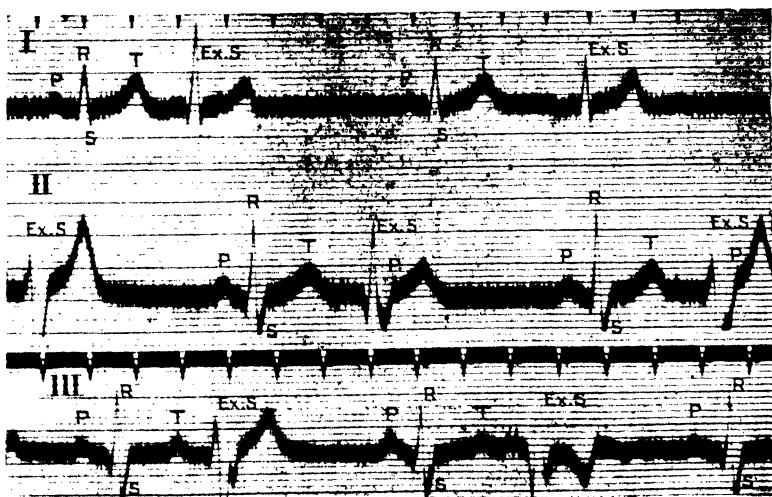

FIG. 96.—Electro-cardiogram showing ventricular extra-systoles. The first and third in lead II and the first in lead III arise in the left or apical portion of the ventricle. The second in lead II, the second in lead III, and those in lead I arise in the right or basal portion of the ventricle, probably high up near the auriculo-ventricular node.

deflection, and then of a downward and broader deflection; and in the other in the apical or left portion of the ventricle, in which case the ventricular complex consists of a downward, deep, and pointed deflection, and then of an upward and broader deflection. It should be noted that in any given case, while the direction of the deflections is usually the same in leads II and III, it is generally reversed in lead I; this means that lead I of the first variety usually gives the same form of electro-cardiogram as leads II and III of the second variety, and that lead I of the second variety presents the same form of electro-cardiogram as leads II and III of the first variety.

If the ventricular extra-systole take place after the normal auricular contraction, and the wave of contraction from the auricle have reached the ventricle and met that of the premature ventricular contraction in the ventricular wall, the ventricular complex of the premature contraction of the ventricle will present both normal and abnormal features.

The site of origin of an extra-systole may occasionally be at one time the basal or right portion of the ventricle, and at another the apical or left portion, in the same subject.

The departure from the normal form of electro-cardiogram is not nearly so pronounced in auricular as in ventricular extra-systole. In this variety

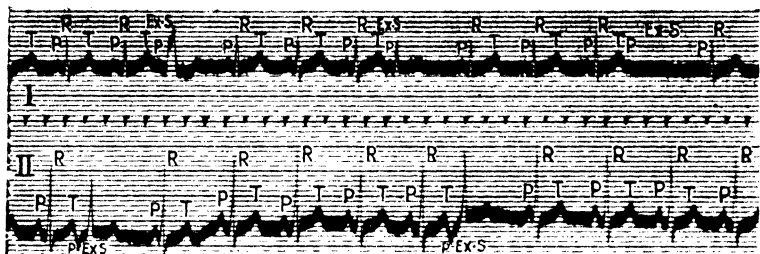

FIG. 97.—Electro-cardiogram showing auricular extra-systoles, marked *Ex.S.* The premature *P* deflections are of normal form in lead I, and of abnormal form—being inverted—in lead II. The premature ventricular complexes are of abnormal form. The third extra-systole in lead I is blocked.

(Fig. 97), when an extra-systole occurs, the *P* deflection takes place before the anticipated time. As the point of origin of the stimulus for contraction is abnormal, it is usually abnormal in form, often being inverted (lead II). Sometimes, however, the premature *P* deflection is of normal form (lead I). The *P* deflection is usually followed by a premature ventricular complex. This is usually of normal form, since the stimulus for contraction is supra-ventricular in origin and thence travels along the usual paths. Sometimes, however, the premature ventricular complex is of abnormal form (Fig. 97), due to the stimulus for contraction from the premature contraction of the auricle not reaching the various portions of the ventricular muscle in the normal manner. It may be even diagnosed as arising below the division of the auriculo-ventricular bundle into two branches. Abnormal ventricular complexes are almost always found only when there is diminished conduction along the auriculo-ventricular junctional tissues; and in some cases the

stimulus for contraction does not reach the ventricle at all, in which case the premature contraction of the auricle is not followed by a premature contraction of the ventricle—"blocked auricular extra-systole" (third extra-systole in lead I of Fig. 97). In auricular extra-systole, the premature contraction of the auricle may take place so early as to coincide with the ventricular contraction of the preceding cycle, in which case *P* and *T* superimpose.

In the auriculo-ventricular variety (Fig. 98), when an extra-systole occurs, there is prematurity of the *P* deflection, and also of the ventricular complex. The ventricular complex is of normal form, as its stimulus for

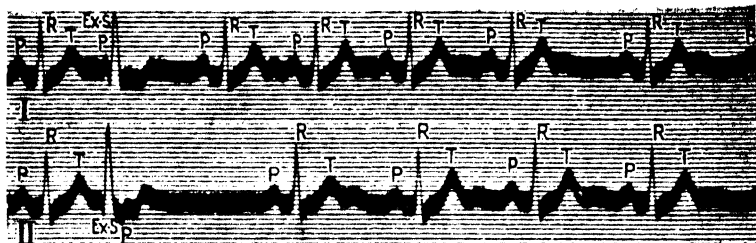

FIG. 98.—Electro-cardiogram showing auriculo-ventricular extra-systoles, marked *Ex.S.* In that of lead I the premature *P* deflection occurs before that of the ventricular complex, while that in lead II is embedded in the ventricular complex.

contraction is supra-ventricular in origin and thence travels along the normal paths. In cases in which the premature contraction of the chambers is absolutely synchronous, the *P* deflection is embedded in the ventricular complex (in lead II). When, on the other hand, the auricular contraction occurs before that of the ventricle, the *P* deflection is of abnormal form, often being inverted, and the *P-R* interval is diminished (in lead I).

Occasionally the beat immediately following an extra-systole arises from the same site as that of the premature contraction.

SINO-AURICULAR BLOCK.—In this condition there is an absence of both the auricular and ventricular complexes during the abnormally long pause.

AURICULO-VENTRICULAR BLOCK.—In the first degree of depressed conductivity (leads I and III of Fig. 99) there is merely an increase of the *P-R* interval, it exceeding 0.18 second. In the second degree, the *P* deflections are found at regular intervals and are normal in form, but more frequent than the ventricular complexes—even twice (lead II of Fig. 99), three times or more, according to the degree of block: in other words, sometimes the *P* deflections are not followed by ventricular complexes. But, unlike complete heart-block, on each occasion the ventricular complex is preceded by a *P* deflection. In complete heart-block (Fig. 100), the *P* deflections are found at regular intervals and are normal in form, and besides being more frequent than the ventricular complexes, the time-relation between the *P* deflections and the ventricular complexes is a constantly varying one—the *P* deflection at one time preceding, at another following, and sometimes again coinciding with the ventricular complexes. The ventricular complexes are of normal

form, as the point of origin of the stimulus for contraction is above the division of the auriculo-ventricular bundle into its two branches.

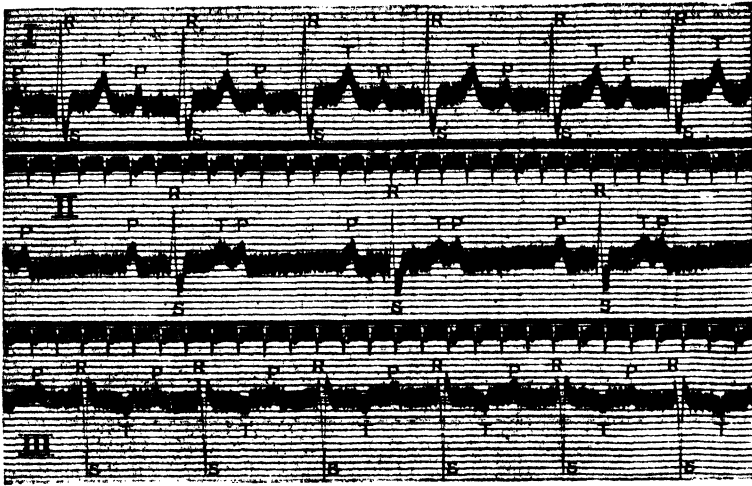

FIG. 99.—Electro-cardiogram showing partial heart-block. In each lead there is an increase of the *P-R* interval, and in lead II there is also continuous 2 : 1 rhythm, every other stimulus from the auricle failing to reach the ventricle. There is also inversion of *T* in lead III and left-sided preponderance.

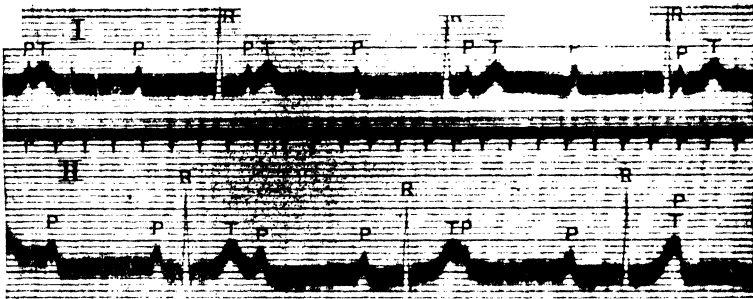

FIG. 100.—Electro-cardiogram of leads I and II, showing complete heart-block, or disassociation of the auriculo-ventricular rhythm, the auricles and ventricles beating independently of each other.

BUNDLE-BRANCH BLOCK.—A lesion of either the right or the left main branch of the auriculo-ventricular bundle may be recognised by means of the electro-cardiograph. When the right branch is involved, the stimulus for contraction from the auricle travels to both ventricles along the left branch alone; and when the left branch is involved, the stimulus travels along the right branch alone. Each ventricular complex is preceded by a

P deflection of normal form, but the ventricular complexes are abnormal. The ventricular complex is of increased amplitude and is diphasic. The

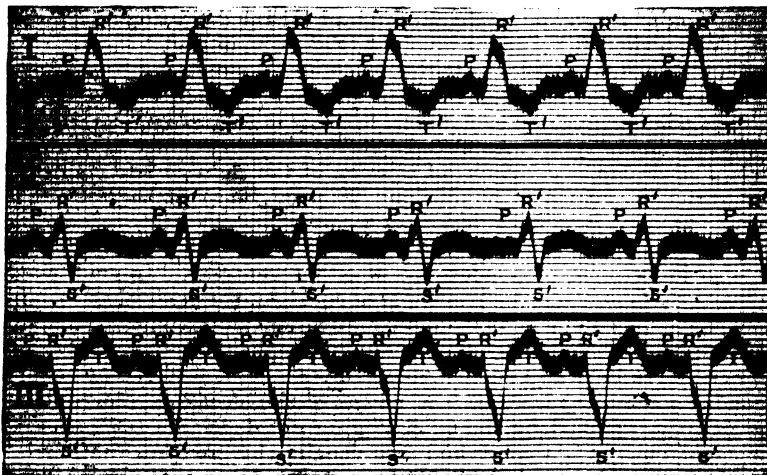

FIG. 101. - Electro-cardiogram showing a lesion of the right main branch of the auriculo-ventricular bundle.

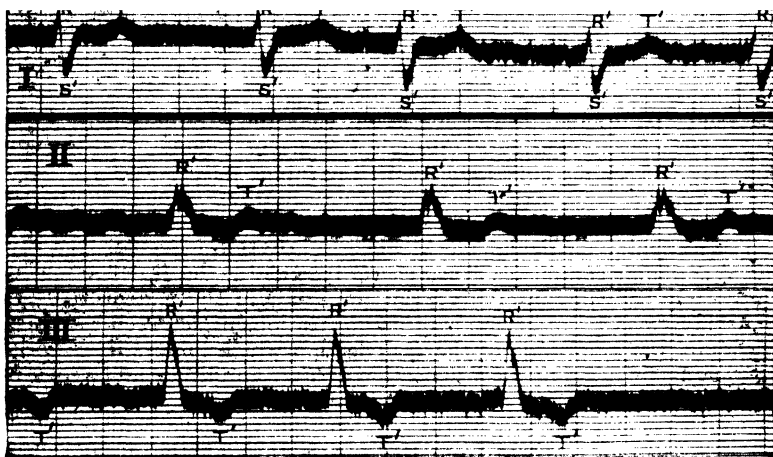

FIG. 102. - Electro-cardiogram showing a lesion of left main branch of the auriculo-ventricular bundle. There is also auricular fibrillation.

initial part is formed by the *Q, R, S* group, and the terminal part by *T*. The period of time occupied by the *Q, R, S* group is increased, exceeding one-tenth of a second, and usually more than a third of that of the whole ventricular complex. The terminal part, *T'*, points in the opposite direction to the

initial part in the same lead. The diphasic form of the ventricular complex is most evident in leads I and III, and the amplitude of the deflection *P* is increased in lead II. When the right branch is involved (Fig. 101), in lead I the deflection *R'* is tall and broad, and in lead III the deflection *S'* is deep and broad. When the left branch is involved (Fig. 102), in lead I the deflection *S'* is deep and broad, and in lead III the deflection *R'* is tall and broad. It will thus be seen that when the right branch in involved the deflections of largest amplitude point away from each other, whereas in the case of the left branch the opposite holds good. As already stated, it is necessary to distinguish between the electro-cardiograms of a lesion of the right or left main branch of the auriculo-ventricular bundle and preponderance of the left or right ventricle respectively. In a lesion of a main branch, the period of time occupied by the *Q, R, S* group of deflections is always increased. This may occur also in extreme preponderance of either ventricle. In such event, a differential diagnosis may be readily arrived at by the facts that in bundle-branch block *T'* points in the opposite direction to the initial part of the ventricular complex in the same lead, and its amplitude is increased.

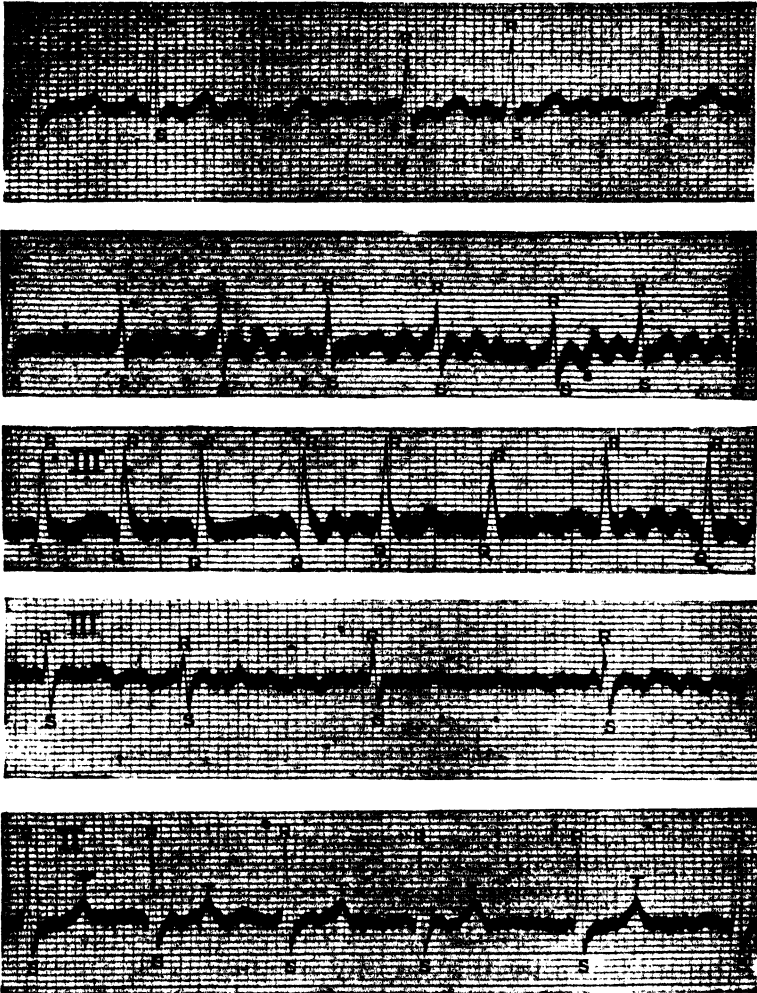

INTRA-VENTRICULAR (ARBORISATION) BLOCK.—It is believed by some that this condition may be recognised by means of the electro-cardiograph. The period of time occupied by the *Q, R, S* group of deflection is increased, exceeding one-tenth of a second, and also usually the group exhibits irregular notching or splintering. It has just been pointed out that the former may be found also in extreme preponderance of either ventricle.

ALTERNATION OF THE HEART.—This may be sometimes recognised by means of the electro-cardiograph, by an alternation in the amplitude of the deflections due to the contraction of the ventricle (Fig. 111). Both the *R* and *T* waves may be affected, or one more than the other. It should be noted that alternation of the heart is sometimes shown in a sphygmogram without any corresponding evidence in an electro-cardiogram, while rarely the opposite holds good. It should be further noted that the alternation in a sphygmogram and electro-cardiogram do not always correspond; i.e. the smaller ventricular deflections correspond with the larger pulse-wave.

AURICULAR FIBRILLATION.—In auricular fibrillation the electro-cardiogram is characteristic (Figs. 103–107). Apart from the very rare cases of complete auriculo-ventricular block, when the rhythm is regular, the rhythm of the ventricular complexes is completely irregular; the *R* deflections occur at irregularly irregular intervals; the amplitude of the *R* deflections varies from cycle to cycle; and there is often no relationship between the length of a pause and the amplitude of the *R* deflection which follows it—i.e. a short pause may be followed by an *R* deflection of large amplitude and a long pause by one of small amplitude. When the ventricular rate is slow or very rapid, the irregularity may be only slight. When the ventricle contracts only in response to stimuli received from the auricle through the normal channel, all the ventricular complexes are of normal form. Such, however, is not the case when there are superadded ventricular extra-systoles, or when there is also a lesion of either main branch of the auriculo-ventricular bundle (Fig. 102).

There is an absence of *P* deflections; these cannot be present because the auricle does not contract. There are, on the other hand, oscillations during diastole caused by the fibrillating auricle, occurring at the rate of about 450 per minute, and irregular in time and form. These are most evident in

cases of slow cardiac action, whereas if the action be frequent it is often difficult to detect them. Their size varies, being sometimes very minute and sometimes of considerable size. They may coincide with the *T* deflections, in which case the outline of the latter is altered.

FIGS. 103-107.—Electro-cardiograms from cases of auricular fibrillation.

These oscillations should be distinguished from those which occur as a result of tremor of the somatic muscles. These are of frequent occurrence in the subjects of Graves' disease, and may be of considerable size. Oscillations due to auricular fibrillation may be distinguished from those re-

sulting from tremor of the somatic muscles by the fact that in the latter case they are of more frequent occurrence—about 50 per second—and occur at regular intervals, the deflection *P* or some indication of it may be noted, and the ventricular complexes do not occur at irregularly irregular intervals.

It is further necessary to distinguish electro-cardiograms of auricular fibrillation from those of auricular flutter. This will be referred to later.

AURICULAR FLUTTER.—In this condition it is of especial importance to analyse the three leads (Figs. 108–110). The *P* deflections may range from 180 to 380, perhaps being usually between 280 and 300 per minute. In all leads they occur at regular intervals, and are of abnormal form, often being inverted, and in each lead of any given case they are almost invariably of constant form. In lead I their amplitude is comparatively small, while in

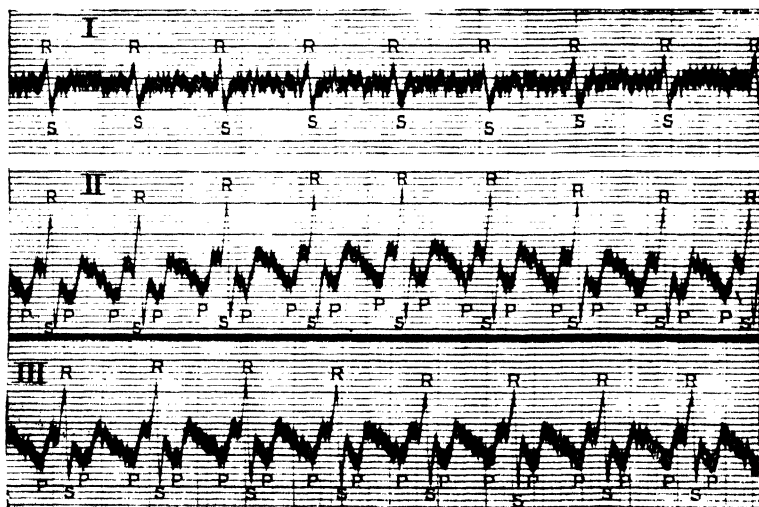

FIG. 108.—Electro-cardiogram from a case of auricular flutter, with 2 : 1 heart-block. The rate of the auricle is between 320 and 330 per minute.

leads II and III their amplitude is greater. Almost invariably there are two or more *P* deflections to each ventricular complex. The latter usually occur at regular intervals, and are of normal form, being of supra-ventricular origin. The ventricular complexes are superimposed, modifying the outline of some, or very rarely all, of the *P* deflections. In some instances *T* may be detected.

As has just been noted, it is necessary to distinguish the electro-cardiograms of auricular flutter from those of auricular fibrillation. In the case of the latter, the *R* deflections occur at irregularly irregular intervals; the amplitude of the *R* deflections varies from cycle to cycle; and there is often no relation between the length of a pause and the amplitude of the deflection *R* which follows it, i.e. a short pause may be followed by an *R* deflection of large amplitude, and a long pause by one of small amplitude. In the case of auricular flutter, it will be found that these features are not present, even

though the ventricular rhythm is markedly irregular. Further, the deflections due to auricular systole in cases of auricular flutter may be distinguished from the oscillations found in auricular fibrillation. In the case of the former,

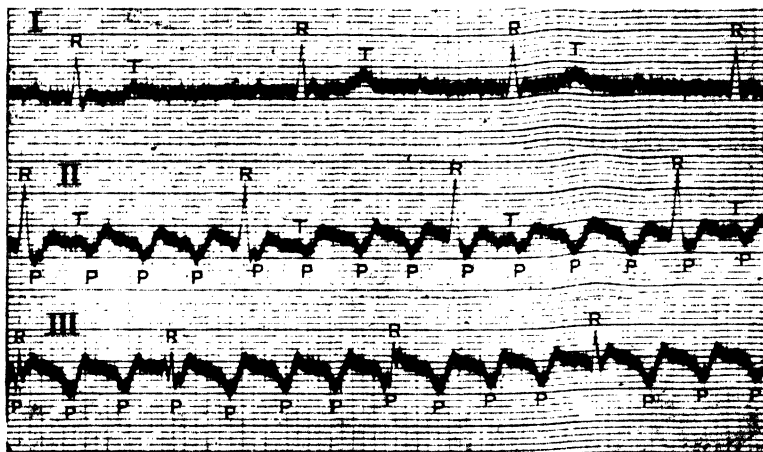

FIG. 109.—Electro-cardiogram from a case of auricular flutter, with 4 : 1 heart-block.

FIG. 110.—Electro-cardiogram from a case of auricular flutter. The auriculo-ventricular ratio is sometimes 2 : 1, at others 3 : 1, and at others again 4 : 1. The response of the ventricle to auricular contraction being at irregular intervals, there is irregularity of the ventricular rhythm.

they are less frequent, rhythmic, and almost invariably of constant form ; whereas in the latter they are more numerous, irregular in rhythm, and inconstant in form.

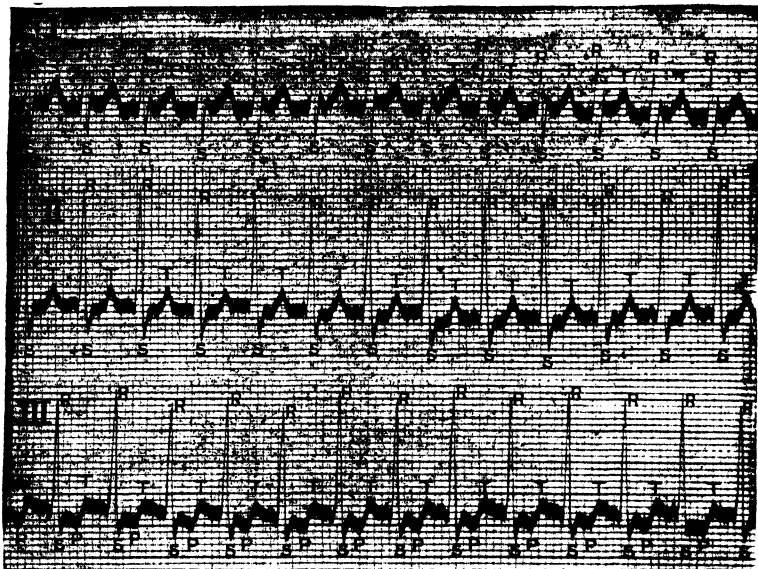

FIG. 111.—Electro-cardiogram from a case of paroxysmal tachycardia. The point of origin of the new rhythm is situated in the auricle. The *P* deflection is inverted, and coincides with the ventricular contraction of the preceding cardiac cycle. It might be regarded as auricular flutter, in which the ventricle responds to each auricular contraction. The rate is between 190 and 200 per minute. There is alternation in the amplitude of the *R* deflections.

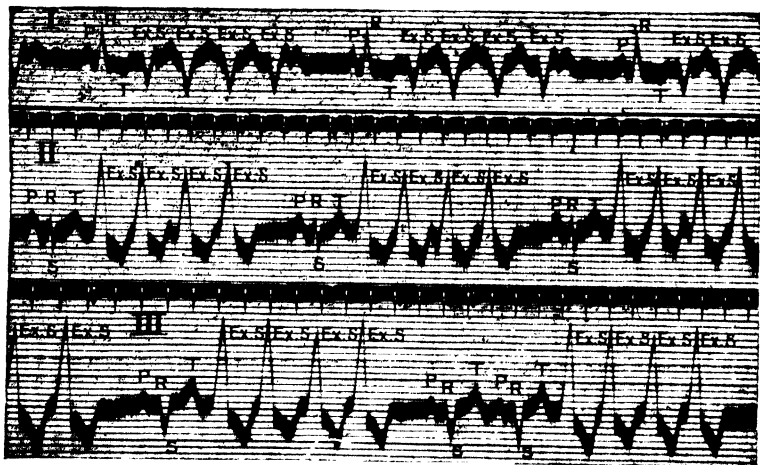

FIG. 112.—Electro-cardiogram showing short paroxysms of extra-systoles, which arise in the right or basal portion of the ventricle. The direction of the deflections is reversed in lead I. There is also inversion of *T* in lead I and left-sided preponderance.

NODAL RHYTHM.—In this condition the ventricular complex is of normal form, as it is supra-ventricular in origin. In cases in which the premature contraction of the chambers is absolutely synchronous, the *P* and *R* superimpose. When, on the other hand, the auricular contraction occurs before that of the ventricle, the *P* deflection is of abnormal form, often being inverted, and the *P-R* interval is diminished.

PAROXYSMAL TACHYCARDIA.—As might be inferred from what has been stated on pages 815 and 816, electro-cardiograms present different features, according to the point of origin and paths of conduction of the stimulus for contraction; for example, they may indicate auricular flutter, paroxysms of auricular systoles, auricular fibrillation, nodal rhythm, or paroxysms of ventricular extra-systoles (Fig. 112).

FREDERICK W. PRICE.

DISEASES OF THE BLOOD VESSELS

Disease of the arteries should be classified from the pathological standpoint. Much confusion has arisen from the use of the term arterio-sclerosis, which means arterial hardening. This term has been applied to at least four distinct pathological arterial conditions:

(a) It has been applied to arteries which have become hardened as the result of inflammation. Chronic inflammation of arteries, or chronic arteritis, is usually the result of syphilis, but may be caused by other infections.

(b) In the degeneration of the intima of the arteries, which is known as atheroma, calcification may take place and the artery become hardened. Marchand has given the name athero-sclerosis to this form of arterial hardening.

(c) Degeneration of the middle coat of the artery is also termed arterio-sclerosis. This form of hardening is especially marked in those arteries which are affected by Mönckeberg's degeneration. This form of degeneration is accompanied by a deposition of lime-salt in the middle coat. The lime-salt is deposited, more or less symmetrically, in rings round the artery.

(d) The term arterio-sclerosis has also been applied to hypertrophied arteries. Here the artery is increased in size, owing to an increase in its muscular elements, which are found mainly in the middle coat, and, to a less degree, in both layers of the intima. Muscular hypertrophy is the essential change in high arterial pressure.

It is therefore clear that the term arterio-sclerosis should not be used in describing arterial disease, and this will be classified as follows:

- (1) Arterial inflammation.
- (2) Arterial degeneration: (a) degeneration of the intima or atheroma; and (b) degeneration of the media.
- (3) Arterial hypertrophy.
- (4) Arterial infiltration, of which the chief example is amyloid infiltration.

ARTERIAL INFLAMMATION

The arteries may be infected from their intima, either by micro-organisms settling on the surface, or by the arrest of an infective embolus within the lumen. They may also be infected by micro-organisms reaching the media

or adventitia through the vasa vasorum, or by direct inward spread of inflammation from the surrounding tissues.

ACUTE ARTERITIS

Acute arteritis was formerly described as a common event in many diseases, the old authorities mistaking staining of the intima for inflammation. Acute inflammation of the arteries is, however, a rare disease, and is usually met with as a complication in the acute infections. The intima of the aorta may be infected in cases of septicæmia and pyæmia. This occurs most commonly in cases of progressive infective endocarditis, and the organisms usually found are streptococci. Vegetations may be seen upon the intima, and the inflammation rapidly involves the subjacent coats. Occasionally the aorta may be infected in a septicæmia or pyæmia, through embolism of the vasa vasorum, or the ascending aorta may be infected by spread through the vessel wall from a pericarditis. The wall of the aorta may rupture, or an aneurysm be formed. Acute multiple arteritis is most frequently seen as a sequel of typhoid fever, but cases have been observed after small-pox, scarlet fever, influenza and pneumonia. In many cases the organisms of the disease have been found in the vessel wall.

Symptoms.—The symptoms depend upon the vessels affected. In the case of the femoral artery, there may be severe pain in the course of the vessel with sometimes redness and swelling in the part affected. The pulse below is obliterated. The limb becomes pale and cold, and then livid. Gangrene may or may not follow; it depends upon the rapidity with which the vessel is blocked. In some cases where the onset is severe, and the symptoms suggest that gangrene will follow, the circulation improves and colour returns to the limb. In other cases, several of the arteries may be infected at the same time, with high fever and symptoms of an acute infection.

Prognosis and Treatment.—In acute arteritis treatment is of little avail, the infection always being a very severe one. Every effort should, however, be made to avoid infectious gangrene, and in some cases a surprising return of circulation may be observed.

CHRONIC ARTERITIS

Ætiology.—Acquired syphilis is by far the most common cause of chronic arteritis, which may, however, follow congenital syphilis. Tuberculous endarteritis is not uncommon in the small pulmonary arteries and in the arteries of the brain in tubercular meningitis. Endarteritis obliterans may also be caused by infection with pyogenic organisms of a subacute or chronic type. Moreover, changes in the adventitia of the small arteries are also found in polio-encephalo-myelitis and in encephalitis lethargica.

Pathology.—Chronic arteritis affects the arterioles. The aorta and other large elastic arteries are, however, affected secondarily, through the vasa vasorum and their terminations in the external and middle coats. The large muscular arteries are but rarely affected by syphilis. Chronic inflammation of the arteries has been divided into—(1) Endarteritis, where the intima is affected; and (2) periarteritis, where the external coat is involved. In the great majority of cases of inflammation of the arterioles all coats are involved. The muscular and elastic fibres tend to be destroyed, and this may result in

direct rupture. The changes in the intima are very conspicuous. Its layers become very much thickened by inflammatory infiltration and proliferation. In the early stages round cells are seen, and later spindle-shaped fibro-blasts appear, definite granulation being thus formed, while in cases of syphilis plasma cells and eosinophil leucocytes are often present. The result of this great thickening is markedly to narrow the vessel, and the condition is often termed *endarteritis obliterans*. The lumen of the vessel may finally become completely blocked, leading in the brain to cerebral softening, and in other tissues to fibrosis. The adventitia is also greatly thickened in chronic syphilitic arteritis and consists of inflamed tissue infiltrated by lymphocytes, plasma cells and occasional eosinophil leucocytes.

Syphilis of the aorta or syphilitic mesoarteritis is due to inflammation of the vasa vasorum, shown microscopically by perivascular infiltration and by intimal proliferation. They become thickened and may show endarteritis obliterans. In the aorta the inflammation is mainly confined to the adventitia and media. Small-celled inflammation in the areas supplied by the diseased vasa vasorum is to be observed microscopically. The thickening of the vasa vasorum results in necrosis in the inflamed areas of the media, in which giant cells may sometimes be seen. The elastic fibres are broken up and destroyed by the infiltration or necrosis in the media, and consequently the artery becomes very much weakened in the area affected. In rare cases the degenerated areas in the media look like tiny miliary gummata, which in fact they are, and the syphilitic nature of this *mesoarteritis* has been proved by the detection of *Sp. pallida* in the lesions. The intima of the aorta is usually thickened over the areas of inflammation, and this thickening has been in the past confused with the degeneration of the intima which we know as atheroma. The inflammatory thickening of the intima due to syphilis can be distinguished by the naked eye from atheromatous thickenings by its greater latitude and prominence, its pearly colour, its rubber-like consistency, crenated outline, pitted surface and freedom from fatty degeneration. The weakening of the vessel wall on account of the replacement of the middle coat frequently results in dilatations, varying in size from minute stellate patches to large aneurysms. The scarring and pitting are due to fibrous tissue replacing the inflamed media and are characteristic of the condition. It should be added that in the later stages atheroma usually occurs in the thickened intima over the areas of inflammation; also that syphilitic mesoarteritis and primary atheroma may co-exist, especially in later life.

The heart is often found affected in these cases. Owing to the *mesoarteritis* of the ascending aorta, the orifices of the coronary arteries become narrowed or blocked. Patches of syphilitic myocarditis are also found in the heart muscle and in the neighbourhood of these, endarteritis obliterans of the terminal branches of the coronary arteries may be found. The result of this is to produce areas of necrosis in the heart muscle, and fibrous patches are found in the myocardium. The heart is, therefore, not uncommonly enlarged. In addition, frequently we find that the aortic valves have become involved by the adjacent syphilitic mesoarteritis, and aortic regurgitation is a common sequel. The brain and spinal cord are frequently affected. Thrombosis results from the endarteritis obliterans and softening of the nerve tissue occurs. The kidneys are but rarely affected, though occasionally gummata are found. The eyes are not infrequently affected, and a condition of syphilitic

choroido-retinitis may be seen on ophthalmoscopic examination. In other organs, such as the liver and testicle, gummatous necrosis, followed by fibrous changes, is found.

Symptoms.—The symptoms that result from syphilitic vascular disease depend upon the organ affected.

In the aorta, the symptoms of aneurysm are a common result from syphilis. Occasionally a dissecting aneurysm may result from a tear of the intima, the blood being forced into the media and splitting the wall into two layers. Aortic regurgitation, with its usual effect on the heart, is also common. The symptoms of fibrosis of the myocardium are severe anginal pains, often resulting in sudden death. Occasionally the heart muscle may give way and the heart dilate, with the usual signs of chronic cardiac failure. If the brain is affected by arterial thrombosis, the symptoms depend upon the area affected: hemiplegia, aphasia and hemianopia may all result. Albuminuria is quite uncommon in syphilitic vascular disease. Iritis may be present, but the usual condition found in the fundi is choroiditis. White patches surrounded by pigmented areas give a striking appearance to the fundus oculi in these cases. The optic disc is often white and atrophied. In gummatous meningitis, œdema of the optic papilla is often present. The radial artery is practically always normal to the touch in cases of syphilitic vascular disease.

Course.—The course of syphilitic arterial disease is extraordinarily variable. The symptoms are generally present in the acute secondary stage, from 2 to 5 years from the date of infection, but the vascular disease may exist with exacerbations all through life.

Prognosis.—The prognosis in syphilitic vascular disease is on the whole good, if the condition be taken early enough and treated properly. It has to be remembered, however, that vascular syphilis is often complicated by parenchymatous syphilis, where the spirochætes are not only found in the walls of the vessels, but also in the cerebro-spinal tissues themselves, and this complication certainly increases the gravity of the condition.

Treatment.—Prophylaxis is of the greatest importance in syphilitic vascular disease. With regard to treatment, in the acute stages of syphilitic vascular disease it cannot be too strongly urged that mercury is the best drug to use. Mercurial inunctions or soluble intramuscular mercurial injections should be given for 2 or 3 weeks before any intravenous injections are prescribed. Moreover, iodides should be given by the mouth, to absorb as far as possible the inflammatory products in the intima of the vessels and to decrease the viscosity of the blood. There is no doubt that the indiscriminate use of salvarsan and neo-salvarsan in the acute stages of syphilitic vascular disease has been followed by most disastrous results. The administration of these strong anti-syphilitic remedies causes further swelling of the intima and further blocking and thrombosis of the small vessels. After mercury and iodides have been given for 2 or 3 weeks, neo-salvarsan may be administered cautiously in small doses and gradually increased.

THROMBO-ANGITIS OBLITERANS

This name was suggested by Buerger in 1908 for a disease characterised by acute inflammation of the deep arteries and veins, and sometimes a

migratory inflammation of the superficial veins in the extremities. Thrombosis develops, and the vessels become occluded.

Ætiology.—The malady is found almost exclusively in middle-aged male Hebrews. The cause is unknown, but the pathological changes suggest that it is due to an infection. Syphilis is usually not present, the Wassermann reaction being negative. Excessive tobacco smoking has been suggested as a predisposing factor.

Pathology.—The deep vessels of the arms and legs, especially the latter, show an acute inflammatory process in all their coats. In about a quarter of the cases this is associated with a migratory phlebitis in the superficial veins of the limbs. The vessels become occluded by organised thrombus, which does not contain elastic tissue, thus differentiating the process from obliterative endarteritis of syphilitic origin.

Symptoms.—The onset is gradual with pains in the feet and toes. The patient is unable to walk for more than a few minutes without severe cramp-like pain in the legs (intermittent claudication, see page 945). The thrombi in the superficial veins, when they occur, are also very tender. Redness of the extremity, especially when in a dependent position, is often noted, while blanching occurs when the limb is raised. Diminution or loss of pulsation in the arteries, such as the radial or dorsalis pedis, is often present. In the later stages, the cramp-like pain becomes intense, and the disability in walking often leads to marked mental depression. Trophic changes in the skin, with gangrene, appear, and fissures and ulcers may occur.

Diagnosis.—(1) Raynaud's disease more often attacks females; the upper extremities are most affected; and X-rays show marked atrophy of the bones of the hands. This is not present in Buerger's disease. (2) In erythromelalgia the limbs become red and flushed, but the arteries pulsate forcibly. Gangrene does not occur. (3) In gangrene due to Mönckeberg's degeneration, the calcified arteries may be well seen by means of the X-rays.

Prognosis.—The course of the disease varies. Some cases progress rapidly, while others last for years. Gangrene may require high amputation of the limb.

Treatment.—As the cause is not known, there is no specific treatment. With regard to drugs, iodides and nitroglycerine are used. Gentle massage and passive exercises are useful. Ultra-violet therapy has been tried. Pain is relieved by rest in the recumbent position, and heat applied to the painful limb by electric pads or electric light baths is also useful. Ulcers of the legs should be treated surgically.

PERIARTERITIS NODOSA

Periarteritis nodosa is a rare complaint characterised by prolonged fever and the occurrence of nodular swellings, and in some cases aneurysms of the medium-sized arteries.

Ætiology.—Young adults are most commonly affected, and males more often than females. The cause is unknown. The Wassermann reaction is negative, but the pathological changes and course of the disease suggest an infectious agent.

Morbid Anatomy.—The medium-sized arteries are usually affected, especially those of the heart, kidneys and intestines. There are inflammatory

changes in all the coats of the arteries, and within the lumen are often found thrombi, which may become organised. White or yellowish-white nodules, from the size of a pin's head to that of a pea, can be seen on the arteries. Owing to the alteration in the lumen of the vessels, necrosis and infarcts occur in the organs supplied.

Symptoms.—The disease may commence with bronchial catarrh, or with epigastric pain. There is tachycardia and irregular fever, with marked prostration. Acute abdominal pain may be caused by disease of the mesenteric arteries—indeed, even perforation of the intestine and peritonitis have followed. If the arteries of the heart are involved, evidence of myocardial disease will be present; and when the kidneys are affected, blood and casts appear in the urine. Occasionally bronchial asthma, cough and hæmoptysis have been noted. Later, in a small proportion of cases, nodular swellings, varying in size up to a pea, may be felt in the subcutaneous tissues of the abdomen, thorax and limbs. Examination of the blood shows anaemia and a moderate leucocytosis. Blood cultures are sterile.

Diagnosis.—This is extremely difficult, owing to the variable symptoms displayed. In most cases, a pyrexial infection, of unknown origin, has its nature revealed only at the post-mortem. Rarely, however, where a node was felt in the subcutaneous tissues and excised during life, the diagnosis has been made before death.

Prognosis.—In the great majority of cases death occurs within a few weeks to a few months after the onset of symptoms.

Treatment.—This is the same as that of any acute infection. Arsenic, mercury and quinine should all be tried, though the results up to now have not been encouraging.

ARTERIAL DEGENERATION

DEGENERATION OF THE INTIMA; ATHEROMA

Definition.—Atheroma is a variety of arterial degeneration which affects and is almost confined to the intima. It is characterised by the accumulation of débris, which is at first fatty and later becomes impregnated with lime-salts. The Greek word was used by Galen to signify a swelling full of gruel-like material.

Ætiology.—There is no doubt that atheroma tends to increase with advancing age. Long life is a question of the blood vessels, and it has been well said that a man is only as old as his arteries. Occasionally the quality of the arterial tissue that the individual has inherited is poor, and a tendency to atheroma is often seen in all the members of certain families, thus showing the influence of heredity in the production of the condition. Much more commonly, however, atheroma results from the amount of wear-and-tear to which the vessels have been subjected. Hypertension is undoubtedly often a factor; probably because atheroma affects hypertrophied areas of intima much more frequently than the normal intima. The affection is much more common in the male sex than in the female, and in subjects who have prolonged and laborious physical work. Moreover, it is much more common in the aorta than in the pulmonary artery, and when it does occur in the

latter it is nearly always associated with high pulmonary tension, *e.g.*, in mitral stenosis and in pulmonary fibrosis. The severity of the disease increases with the length of time during which the high blood-pressure has existed. Over-eating and stress and strain of modern life are probably factors in the ætiology of the condition. The most important cause of atheroma is chronic poisoning. Acute atheromatous degeneration of the media has been found after typhoid fever in young people. Atheroma has been caused experimentally by the injection of bacterial toxins. Chronic lead poisoning and gout are also ætiological factors. On the other hand, syphilis has no connection with atheroma, though the condition of the aorta known as syphilitic mesoarteritis was for a long time confused with the chronic intimal degeneration we now know as atheroma. Disease of the kidneys probably has no direct relation with atheroma, though the high blood-pressure of chronic interstitial renal fibrosis and of secondary contracted kidney is an important factor in producing atheroma in the large elastic arteries.

Pathology.—Atheroma occurs in the large elastic and muscular arteries. The condition is usually most marked in the aorta. The radial and temporal arteries are frequently affected. The condition may attack the retinal arteries. In the slighter degrees, minute yellow flecks or patches on the aorta may be observed by the naked eye. In the later stages, yellow plaques or buttons are conspicuous, and under the microscope masses of large fatty crystals, with a covering layer of fibrous tissue, are to be noted. Atheromatous plaques may ulcerate and the contents be discharged into the aorta, and thrombi are often deposited on the surface of these atheromatous ulcers. As the atheroma may be associated with degeneration of the media, a diffuse dilatation of the aorta is very common. On the other hand, saccular aneurysm does not occur in simple atheroma. The aortic valves are frequently affected by atheromatous degeneration, and aortic stenosis or aortic regurgitation may result. A yellow atheromatous patch is commonly seen on the anterior flap of the mitral valve. Atheroma often causes great narrowing of the lumen of the vessels, and eventually a thrombosis may form and complete occlusion result; this is the most dangerous result of atheroma; it frequently occurs in the large divisions of the coronary arteries, especially in the anterior interventricular branch of the left, and is not uncommon in the vessels of the brain. With regard to the heart, atheroma has a most profound influence, owing to the fact that it is one of the commonest causes of fibrosis of the myocardium; but the chief danger is a sudden blockage of one of the coronary arteries, generally the anterior ventricular branch of the left coronary. In these cases, if death does not follow immediately, a sudden softening of the heart muscle (*myomalacia cordis*) may occur, and an aneurysm of the heart may result, and in certain rare cases actual rupture of the heart wall has followed—a broken heart. In the brain, atheroma results in cerebral thrombosis, and is the commonest cause of this condition in old people who have not had syphilis. Very commonly, however, especially in those cases of atheroma where the blood-pressure is moderately raised, hæmorrhage may occur. In most cases of atheroma the kidneys are not involved, though occasionally atheromatous plaques may be found on the branches of the renal artery. Should, however, one of these plaques be large enough to cause thrombosis of an interlobular artery, a wedge-shaped

red area of fibrosis in the distribution of the artery will occur. The renal changes, however, are relatively unimportant, and they rarely lead to symptoms during life.

Symptoms.—The blood-pressure is either normal or only moderately raised. In the aorta a diffuse dilatation, with pulsation in the supra-manubrial notch, may be present. The radial and temporal arteries are frequently irregularly thickened and tortuous, and can often be seen pulsating beneath the skin. Atheroma of the coronary arteries frequently gives rise to cardiac failure, and angina pectoris may occur; and sudden death is not uncommon, owing to a sudden thrombosis of a large branch. In the brain, hemiplegia usually results from hæmorrhage and more rarely from thrombosis. Ocular symptoms are rare in atheroma of the retinal arteries, which may be seen with the ophthalmoscope to be irregularly swollen and tortuous, but swelling of the optic disc and retinitis are not present.

Prognosis.—The course and prognosis are extremely uncertain. Circulation through the diseased vessels may proceed fairly satisfactorily for a long time, but thrombosis may occur with alarming suddenness, and with the direst results, if a cerebral or cardiac artery is affected.

Treatment.—The treatment of atheroma is unsatisfactory. Prophylaxis exists in the removal of the cause when possible. Great attention should be paid to diet, and repletion should be studiously avoided. Alcohol and tobacco should be taken with greatest moderation, and attention should be paid to regular exercise, and the action of the skin should be assisted by warm baths. It is doubtful if drugs are of value in the treatment of atheroma; possibly small doses of iodide of potassium may be of some use in absorbing the degenerative products and assisting in the circulation of the blood through the obstructed areas.

DEGENERATION OF THE MEDIA

There are two forms of degeneration of the media, namely—(1) That which is known as Mönckeberg's degeneration or ring calcification; and (2) fatty degeneration, the latter being the more common.

MÖNCKEBERG'S DEGENERATION.—This form of degeneration is accompanied by a deposition of lime-salts in the middle coat.

Ætiology and Pathology.—The cause is undoubtedly a senile degeneration of the elastic tissue and the muscle of the large muscular arteries, and a deposition of masses of lime-salts in the dying tissue. It has no relation to syphilis, and also it is very doubtful whether toxins have any share in its cause, though the disease is not uncommonly found in the later stages of diabetes in old people. The lime-salt is deposited, more or less symmetrically, in rings round the artery. The affection is very common in the arteries of the leg below the bifurcation of the femoral; occasionally the radial and ulnar arteries are affected; rarely the aorta.

Symptoms.—The symptoms are coldness and œdema of the legs, as the result of defective circulation through them, and finally, and not uncommonly, gangrene results, this form of degeneration being usually present in senile cases and in cases associated with diabetes. The arteries feel like pipe-stems, and sometimes crackle when rolled beneath the finger. They can be well seen by means of the X-rays.

Prognosis.—This depends partly upon the amount of gangrene present and partly upon the associated conditions.

Treatment.—It is clear that if amputation is undertaken a local amputation is of little value, and the limb should be amputated above the knee, as the arterial degeneration almost always extends to the bifurcation of the femoral artery.

FATTY DEGENERATION OF THE MEDIA.—Fatty degeneration of the media occurs very commonly in all arteries. *It certainly tends to occur in cases of high blood-pressure, and is consequently a common and important secondary complication of medial hypertrophy.* It is probably the result of toxins or lack of nourishment, and is frequently present in cases of severe anæmia. It also occurs in old age, and is associated with cardio-vascular hypertrophy. The muscle fibres become lost, being replaced by fibrous tissue. The vessel wall usually becomes weakened and is liable to rupture.

ARTERIAL HYPERTROPHY

Increase in the muscular layer of the small and medium-sized arteries is invariably associated with persistent elevation of the blood-pressure. It is also so frequently associated with hypertrophy of the heart, especially of the left ventricle, that the condition may be termed cardio-vascular myo-hypertrophy.

Ætiology.—Arterial hypertrophy is common in late middle age, and is by no means a senile change. In rare cases associated with chronic interstitial nephritis, it may occur in young children. It is more common in males than in females. Syphilis has no part in the causation of this condition, though, of course, it may be present in syphilitic cases; supernormal blood-pressure and cardio-vascular hypertrophy are comparatively uncommon in syphilitic vascular disease. Arterial hypertrophy is the result of the circulation of poisons, which act as pressor substances and cause persistent contraction of the arteries and of the heart. The question as to whether it is the arteries or the heart which hypertrophy first has given rise to much controversy. It is probable, however, that they both hypertrophy simultaneously. These circulatory poisons may be enumerated as follows: (1) They may result from repletion due to over-eating and insufficient exercise, in which case they are absorbed from the intestines. It has been shown that certain diamines, the result of protein putrefaction, act as powerful pressor substances when introduced into the circulation. (2) They may arise from focal sepsis, e.g., in the teeth, the tonsils, the nasal sinuses and the genito-urinary tract. In some cases the removal of these foci of sepsis will permanently lower a persistent supernormal blood-pressure. (3) Poisons may be introduced from without the body. Excessive smoking, chronic alcoholic excess and lead poisoning are frequent causes of arterial hypertrophy. (4) Prolonged mental strain and anxiety are also well known to lead to the condition, which has thus become much more common under the stress of modern civilisation. The isolation of adrenalin and its effect in raising the blood-pressure may supply the clue to the circulating substance in these cases. It has been shown that acute mental strain and fear result in an over secretion of adrenalin, and when this is persistent and prolonged

it may result in suprarenal hyperplasia. In many cases of arterial hypertrophy the suprarenal bodies are found to be hypertrophied at post-mortem examination. (5) Pressor substances are also to be found circulating in the blood stream in renal disease. Here the kidneys fail to perform their function of eliminating poisons from the blood stream. Thus in gout, where defective renal function is an important feature, arterial hypertrophy is common. It is also found well marked in chronic interstitial nephritis, in secondary contracted kidney, and in the later stages of congenital polycystic disease of the kidneys. In all these conditions the diseased kidneys fail to eliminate from the blood stream certain metabolic poisons, which act as pressor substances.

RELATIONSHIP OF CARDIO-VASCULAR HYPERTROPHY TO RENAL DISEASE.—This may be summarised as follows: (1) Cardio-vascular hypertrophy may exist with little or no clinical evidence of renal lesion, which condition has been named hyperpiesia by the late Sir Clifford Allbutt. On post-mortem examination, however, slight changes in the kidneys are usually to be noted. (2) In other cases, cardio-vascular hypertrophy is sooner or later followed by morbid changes in the kidneys (see Hyperpietic Kidney, p. 1211). When this condition has become well marked, evidence of renal deficiency appears, and the failure of the kidneys to eliminate metabolic poisons results in a vicious circle by which the arterial hypertrophy is still further increased. (3) Cardio-vascular hypertrophy may also be a sequel to chronic interstitial nephritis, or to secondary contracted kidney. With regard to the latter, it begins to appear when secondary contraction of the kidney follows chronic parenchymatous nephritis (see p. 1203). It is also well seen in the later stages of congenital polycystic kidneys. As in the course of years the kidneys gradually enlarge, owing to the increase in fluid in the cysts, the kidney substance between them gradually becomes destroyed by pressure, and as the kidneys fail to eliminate metabolic poisons, arterial hypertrophy develops.

Pathology.—As Sir George Johnson described in the year 1852, the condition is a true muscular hypertrophy. This increase in muscle fibres occurs in the heart (mainly in the left ventricle), and in the media of the muscular arteries. In the later stages of the malady, there is also an increase in the musculo-elastic layer of the intima. In the course of time, this being earlier in older people, there is a tendency to fatty degeneration in the hypertrophied muscular tissue. This results in a weakening of the walls of the vessels, which in the case of the arterioles frequently rupture, so that hæmorrhage is the most common complication of cardio-vascular hypertrophy. It also results in ischæmic fibrosis of the organs. According to this view, the cardio-vascular hypertrophy is antecedent to the degenerative changes in the vessel wall, the clinical manifestations of the former, such as supernormal blood-pressure, preceding those of the latter. The muscular arteries are those chiefly affected. The radial and temporal arteries, and the arterioles of most of the organs of the body, are involved. In the case of the cerebral arteries, the perforating branches of the middle cerebral are most frequently affected, especially the lenticulo-striate branch. Hæmorrhage may also take place from the kidneys, the stomach, the intestines and the nasal mucous membrane. While the kidneys may be almost normal in cases of simple hyperpiesia, secondary fatty degeneration of the arterioles tends to appear rapidly, and this leads to ischæmic fibrosis (see Hyperpietic Kidney).

In cases where the cardio-vascular hypertrophy is the sequel either of chronic interstitial nephritis or of secondary contracted kidney, the changes in the kidneys are those described under these diseases respectively. In the heart the most striking change is the muscular hypertrophy, the left side being very much more involved than the right; the left ventricle may be even two or three times thicker than normal. In the aorta there may be little or no change, but patches of atheroma are not uncommon. The aortic valves are rarely affected.

Symptoms.—In cardio-vascular hypertrophy the vessel wall is felt to be uniformly thickened—the so-called “whip-cord” artery. The degree of hardening of the arteries is found on palpation to vary at different times. The artery feels hardest when the vessel is most contracted and consequently smallest. As the muscular arteries are those chiefly affected, the radial and temporal arteries are frequently found to be involved. The systolic blood-pressure in cases of simple hyperpiesia varies from 170–200 mm.; in cases associated with chronic interstitial nephritis it may reach even 300 mm. or more; and in secondary contracted kidney and in polycystic disease of the kidneys it varies between 160 and 220 mm. Symptoms of cardiac hypertrophy are common in the early stages. In some cases cardiac hypertrophy is followed by dilatation, with its attendant symptoms. Headache, of a throbbing and bursting character and generally in the occipital region, is an early symptom of arterial hypertrophy, and giddiness and fullness in the head are frequently complained of. Transient paralysis may occasionally be met with, and this has been attributed to spasm of the hypertrophied arteries. Later on, cerebral hæmorrhage, with the production of hemiplegia, may occur. Albuminuria and casts in the urine may be found, while profuse renal hæmorrhage may occur. Uræmic symptoms are uncommon. Gastro-intestinal symptoms are often present. The patient may first complain of dyspepsia. A chronic diarrhœa without obvious cause in an elderly man should lead to a careful examination of the arteries and kidneys. Bronchitis and emphysema may mask a cardio-vascular hypertrophy, and the enlargement of the heart may be overlooked; it is only by careful examination of the blood-pressure and urine that the underlying conditions can be recognised. The changes in the fundi are numerous and characteristic. The retinal arteries are thickened, and on ophthalmoscopic examination often show a glistening light along their course—the so-called “silver wire” arteries, due to the reflection of light from the thickened artery. If one of the thickened arteries is examined in the neighbourhood of the optic disc, it may be seen to cross a retinal vein and in so doing obstruct the flow of blood through it, leading to distension of the peripheral part of the vein. Retinal hæmorrhages, which are often flame-shaped, are occasionally to be noted, due to fatty degeneration in the hypertrophied muscular tissue. If the cardio-vascular hypertrophy is due either to chronic interstitial nephritis or to secondary contracted kidney, hæmorrhages are much more common, and also further changes in the fundi, due to either of these affections respectively—described elsewhere—are to be noted.

Intermittent lameness or claudication is not uncommon in these cases. The patient is unable to walk for more than a few minutes without severe cramp-like pain in the legs, the pain and the loss of power in the muscles being due to the spasm of the thickened arteries. Pulsation may be absent

in the dorsalis pedis, and in the dependent position the feet and legs may become deeply congested and swollen.

Prognosis.—The prognosis depends very largely on the degree of renal involvement. In hyperpiesia the condition may last for many years and only be terminated by hæmorrhage into the brain. When, however, the kidneys are affected, as shown by persistent albuminuria with casts in the urine and a blood-pressure well over 200 mm. Hg, the condition is grave; and when well-marked albuminuric retinitis is present death usually occurs within six months, though very rare cases have been recorded where a certain amount of ocular change has persisted for years.

Treatment.—The first indication is to remove the cause of the condition as far as possible. Thus, gouty tendencies should be corrected by the administration of alkalis and intestinal antiseptics, such as sodium benzoate or dimol. All sources of focal sepsis, whether in tonsils, teeth, nasal sinuses or genito-urinary tract, should be carefully sought for and, if found, removed. Moderation in food and drink, with regular exercise and care in promoting diaphoresis, is essential. Turkish and vapour baths may be given cautiously. The administration of a brisk purgative pill once a week, and the use of a mild saline purgative each morning are indicated. Nitroglycerine and the nitrites are useful in moderate degrees of increased blood-pressure, though where the blood-pressure is very high they rarely produce any permanent benefit. In these latter cases the administration of thyroid extract has been successful in reducing the pressure to a more reasonable level; while in acute crises the abstraction of one pint of blood from the arm has often saved life.

ARTERIAL INFILTRATION

The commonest form of infiltration is amyloid infiltration.

Ætiology.—Amyloid or lardaceous disease occurs in cases of long suppuration due to pyogenic organisms, and is frequently associated with the secondary pyogenic infections which occur in tuberculosis of the bones and joints, in chronic syphilitic ulceration, and in actinomycosis.

Pathology.—The amyloid substance is extracellular and is deposited first of all in the middle coat of the small arterioles. The affected organs are firm to the touch and have a waxy appearance. The amyloid substance can be demonstrated macroscopically by pouring tincture of iodine on the affected organ, the waxy material being stained a deep mahogany colour. Microscopically, an iodine staining may be used, or a methyl-violet stain, which colours the amyloid substance pink and the parenchymatous cells blue. In the kidney, the small arterioles in the glomeruli, those around the convoluted tubules and those in the medulla, are first attacked. In the intestine, the arterioles in the villi stand out clearly. There are two forms of amyloid infiltration of the spleen: the diffuse waxy spleen, where the venous sinuses are outlined and the central artery of the Malpighian capsule is affected; and the sago spleen, where the Malpighian capsule is greatly enlarged by the amyloid infiltration—its central artery is untouched, but its branches into the capsule are greatly swollen by the waxy material. In all these organs the parenchymatous cells are unaffected directly by the amyloid infiltration,

but in the later stages become compressed and atrophied by the pressure of the waxy substance upon them.

Symptoms.—The patient is pale, but often has a waxy complexion with a bright colour in the cheeks. Chronic, profuse and painless diarrhoea is common. The urine contains a large quantity of albumin, and is usually fair in amount and of low specific gravity. The liver and spleen are enlarged, and ascites and oedema of the legs are often present.

Prognosis.—If the chronic suppuration can be cured, the condition may sometimes disappear; but in the majority of cases this is not possible, as the septic condition is engrafted on to a chronic tubercular or other granulomatous condition, which is almost always impossible to eradicate.

Treatment.—This consists in trying to remove the cause.

ANEURYSM

Definition.—The word aneurysm is derived from the Greek to widen or dilate, and may be said to include any dilatation of an artery.

Aneurysms are generally divided into—

1. **TRUE ANEURYSMS**, in which the walls of the dilatation are formed by the coats of the artery. These may again be divided into—

(a) *Dilatation aneurysm*. (i.) A dilatation limited to a certain portion of the vessel, known as a fusiform aneurysm. This variety is frequently seen in the arch of the aorta. (ii.) A tortuous dilatation extending over the whole of an artery and its branches, the so-called cirroid aneurysm.

(b) *Circumscribed saccular aneurysm*, occurring commonly in the aorta.

(c) *Dissecting aneurysm*, caused by the splitting of the coats of the artery, the blood having passed through the lumen into the wall of the artery, separating one coat from another.

(d) *Arterio-venous aneurysm*, in which there is a communication between an artery and a vein. There are two varieties in this group—(1) aneurysmal varix, and (2) varicose aneurysm.

2. **FALSE ANEURYSMS** are those following a wound or rupture of an artery, with the formation of a diffuse or circumscribed hæmatoma, and are bounded by tissues external to the wall of the artery.

A true aneurysm frequently ruptures and gives rise to a false aneurysm and the resulting structure is known as a mixed aneurysm.

Ætiology and Pathology.—The two main factors in the causation of aneurysm are—(1) degenerative changes in the wall of the artery; (2) strain. The latter may be brought about by either high arterial tension or by repeated and prolonged muscular effort. The importance of strain as a causal factor is borne out by the fact that aneurysm is much more frequent in men than women—about five to one—and occurs more frequently in the fourth decade of life than at any other period. It also occurs much more frequently in hard manual workers, such as dock labourers, soldiers and sailors. *By far the most common cause producing weakening of the large elastic arteries is syphilitic inflammation. In cases of persons dying of aneurysm, examination of the aorta in the neighbourhood of the aneurysm will, in a large majority of cases, reveal mesaortitis* (see page 937). Aneurysm may also result from erosion of the walls of the

arteries in cases of malignant endocarditis—the so-called mycotic aneurysm. Frequently these aneurysms are multiple. Extensive growth of streptococci and septic granulations may be seen in the neighbourhood of the dilatations.

Aneurysm may also be the result of congenital deformity of the wall of the vessel, which is very commonly seen about the circle of Willis, at the junction of the anterior communicating artery with the anterior cerebral. The aneurysms are about the size of a pin's head to that of a pea, and not infrequently their rupture gives rise to a diffuse subarachnoid hæmorrhage, the origin of which is often overlooked unless careful search is made for the aneurysm. Congenital aneurysm has also been described in the aorta, at the point of insertion of the ductus Botalli, and in cases of coarctation of the aorta, in which condition there is great narrowing of the aorta just below the origin of the left subclavian artery.

Loss of support by surrounding tissues also appears to lead to the production of aneurysm, e.g. at the base of a gastric ulcer a small aneurysm often projects as a nodule and is liable to rupture. Peptic erosion may also be a cause of weakening the walls of such arteries. In the cavities of the lungs, occurring as the result of pulmonary tuberculosis, it is quite common to find an aneurysm on the walls of the arteries lying in such cavities.

It is very doubtful whether trauma alone is ever the cause of true aneurysm. Atheroma itself does not lead to sacculated aneurysm, but if combined with fatty degeneration of the media, as it so often is, a diffuse dilatation of the aorta not uncommonly results. Continued high blood-pressure, as in other forms of aneurysm, is an important contributory factor in the formation of a diffuse dilatation of the aorta.

One of the most striking appearances in an aneurysm is the coagulation of blood in the sac itself. This does not occur in diffuse dilatation of the aorta, but in those cases of sacculated aneurysm where the wall has become roughened. The sac becomes lined with fibrinous deposits, and occasionally an aneurysm may be cured by the deposition of successive layers of fibrin, so that the sac becomes almost completely filled. On the other hand, in many fatal cases of aneurysm rupture and hæmorrhage have taken place, the deposition of fibrin having failed to prevent the blood reaching the surface. Rupture may take place externally, or into any of the hollow viscera or the serous cavities. Rupture into the pleura is common, as also is rupture into the trachea or into the œsophagus. In these cases, death is usually sudden, though oozing may have taken place some time before the final rupture. When the hæmorrhage forces itself into the connective tissues or muscles, it takes place much more slowly, and in the cases of the limbs may allow time for treatment. An aneurysm often exercises pressure on the other organs and structures in its neighbourhood. The heart is displaced away from the aneurysm, and the blood vessels are often narrowed so that circulation through them is impeded. The trachea, the bronchus, the œsophagus and the nerves passing near the aneurysm also suffer. When the aneurysm meets bony tissues, absorption of the bone takes place and the vertebræ are frequently eroded in this way, the bone being absorbed more rapidly than the intervertebral cartilage. When the aneurysm presses against the anterior surface of the chest, the ribs and sternum are pushed forward and finally are absorbed and perforated.

I. ANEURYSM OF THE THORACIC AORTA AND ITS BRANCHES

These are two types—(1) The diffuse dilatation which occurs in degeneration of the aorta; and (2) the saccular aneurysm, the result of inflammation, usually syphilitic.

DILATED AORTA

Symptoms.—In diffuse dilatation of the aorta the enlargement is gradual and never reaches a very great size. The symptoms of this form of dilated aorta are generally due to atheroma and the medial degeneration which accompanies it. Very often there is interference with the coronary circulation, and this leads to diminution of the circulation of blood through the heart and consequently to cardiac pain. The aorta may sometimes be felt pulsating in the supra-manubrial notch, and the X-ray photograph will show general dilatation of the aortic arch. When the aortic ring is not stretched, the dilatation of the aorta beyond it may lead to the formation of a systolic murmur. If the part adjacent to the aortic valves is affected, the aortic ring may be dilated and aortic regurgitation will take place. There will then be hypertrophy and dilatation of the left ventricle, with an aortic diastolic murmur, and the symptoms will be those of aortic regurgitation. Occasionally these patients die suddenly, on account of thrombosis of a branch of a coronary artery. Provided there is no aortic regurgitation or coexisting coronary disease, patients with dilated aorta may live for many years without serious discomfort.

SACCULAR ANEURYSM

Symptoms and Diagnosis.—ANEURYSM OF THE ASCENDING PART OF THE ARCH OF THE AORTA.—An aneurysm of the ascending part of the arch tends to grow forward and outwards, and to produce a pulsating tumour which is palpable and audible at the level of the second or third interspace, and is hence often called the *aneurysm of physical signs*. It often erodes the ribs and sternum. The tumour is tender and is often the seat of pain, which may be constant but is increased by exertion. A soft systolic murmur may be heard over it.

The pressure effects produced by an aneurysm of the ascending aorta are as follows: The heart is displaced downwards and to the left. The superior vena cava is pressed upon. This may result in cyanosis of the head and neck, and oedema of the arms, and enlarged veins may frequently be seen coursing over the front of the thorax. Occasionally the aneurysm may rupture into the superior vena cava, in which case the symptoms noted may come on quite suddenly and are very marked. There is often a systolic thrill, and on auscultation a continuous murmur, which is increased during systole, is of great diagnostic value. The aneurysm may press upon the right bronchus, causing a chronic cough, due to irritation of the bronchus and stasis of its contents, and deficient or absent breath sounds over the upper lobe of the right lung. The aneurysm may occasionally press upon the pulmonary artery and in rare cases actually open into it, causing great dilatation of the right ventricle and auricle. Such aneurysms may present

themselves to the left of the sternum rather than in the usual place, the right. In rare cases aneurysm of the ascending aorta has perforated the right ventricle, the right or left auricle, and the pericardium. When the aneurysm comes forward it may irritate the pleura; and in some cases a loud pleuritic rub, audible over the aortic area, may be one of the early signs. Not uncommonly this form of aneurysm may rupture into the pleura and occasionally it ruptures externally.

ANEURYSM OF THE TRANSVERSE ARCH OF THE AORTA.—As the arch of the aorta passes from right to left it also passes from before backwards, and consequently aneurysms arising from the transverse and descending parts of the aortic arch are situated more deeply in the chest than those arising from the ascending portion. Aneurysms of the transverse and descending parts of the aortic arch have been called by Broadbent *aneurysms of symptoms*, because their presence has often to be inferred by the pressure symptoms which they produce, while a pulsating tumour is only present in the very late stages and may never appear at all during the whole course of the disease.

1. *Pain.*—Pain is one of the most common and earliest symptoms of aneurysm. It may often be anginal in character; that is to say, it may occur in the cardiac region or across the back and pass down the left arm and be very severe. This form of pain occurs when the aortic valve is affected and when the ascending aorta is distended. When, however, the transverse arch is affected the pain is sometimes felt on the left side of the neck and even in the occipital region. It is probable that this pain in the neck is a reflected pain from the spinal cord, resulting from the abnormal afferent impulses reaching the cervical spinal cord as a result of the distension of the transverse arch. A boring, persistent pain in the chest is probably the result of direct pressure of the aneurysm.

2. *Respiratory symptoms.*—Dyspnoea is common in aneurysm, and is usually caused by pressure upon a bronchus. There is often stridor, which in this case is heard both in inspiration and in expiration. Hæmorrhage also occurs as a result of leaking of an aneurysm through the bronchus. It may at first be slight, but often a huge gush of blood supervenes, causing death. It is said that reflex irritation of the vagi will occasionally cause bilateral adductor spasm of the vocal cords and marked dyspnoea. In this case the stridor is only heard with inspiration and disappears if a little chloroform is inhaled. Patients with aneurysm often have a ringing, rough, brassy cough. If the pressure on the bronchus has been gradual, secondary changes occur in the lung. Dr. Newton Pitt has brought forward evidence to show that compression of the left bronchus in the early stages produces over-distension of the left lung with diminished or absent breath sounds. This may be so great as to lead to a suspicion of pneumo-thorax; later on bronchitis occurs with dilatation of the bronchus with expectoration of purulent phlegm. Pressure on the trachea may occasionally be observed in cases of aneurysm of the aortic arch, the larynx being drawn downwards and backwards with each cardiac pulsation. A very important physical sign was described by Surgeon-Major Oliver and is known as *tracheal tugging*. The patient should be placed in the erect position, and directed to close his mouth and elevate his chin. The cricoid cartilage should be grasped between the finger and thumb and gentle steady upward pressure be made upon it.

If aortic dilatation or aneurysm exist, the pulsation of the aorta will be distinctly felt transmitted through the trachea to the hand. This is a valuable sign, and often occurs in aneurysm before other symptoms are evident. Occasionally a systolic murmur may be heard in the mouth when the patient compresses his chest with his mouth wide open. Dr. Sansom has pointed out this tracheal whiff may be rendered distinctly audible with a binaural stethoscope when the end is placed in the mouth with the lips closed over it. It is either the aortic systolic murmur produced at the mouth of the sac, or the result of driving the air out of the windpipe during systole by the pressure of the aneurysm.

3. *Pressure on nerves.*—(a) The left recurrent laryngeal nerve.—This nerve ~~courses round the~~ arch of the aorta and passes up behind it, and is consequently often involved in aneurysm of the transverse arch. The abductor fibres of the recurrent laryngeal nerves succumb to the effect of pressure before the adductor fibres and consequently the vocal cord is at first in the position of adduction. During respiration, the right vocal cord moves up to and meets the adducted left vocal cord and respiration is unaffected. During phonation, the right vocal cord again comes up to and meets the left vocal cord, and the voice may be quite normal. It is therefore clear that a laryngoscopic examination may reveal the early stage of pressure on the left vocal cord before there has been any alteration in the voice. As the pressure increases, the adductor muscles are affected and the left vocal cord remains motionless in the cadaveric position half-way between full inspiration and full expiration. The voice is now hoarse, and it not uncommonly happens that hoarseness is the first symptom for which the patient presents himself. (b) *Pressure on the sympathetic nerve.*—Pressure upon the sympathetic nerve causes first of all irritation and later on a paralysis of the cervical sympathetic fibres. When the sympathetic is irritated, the pupil on the same side is dilated, and this is accompanied by slight protrusion of the eyeball, slight retraction of the upper eyelid, together with sweating and flushing of the same side of the face and ear. When the cervical sympathetic is paralysed, the pupil is smaller than on the opposite side, the eyeball is sunken into the orbit, and there is a slight degree of ptosis. Unequal pupils in aneurysm are, however, frequently found without any of the other symptoms of sympathetic irritation or paralysis, and in these cases another explanation must be found. Doctors Wall and Walker suggest that the difference in the pupils is due to pressure of the aneurysm upon the arteries passing to the neck. They have shown that in a condition of low blood-pressure the pupils are dilated, whilst in a condition of high blood-pressure they are contracted, and that pressure upon one common carotid will cause dilatation of the pupil on the same side. They point out that under these conditions the dilated pupil is constantly on the same side as the smaller temporal pulse, and they consider that the dilated pupil and the small pulse are due to the same cause, namely, pressure upon the arteries supplying that side of the neck. Unequal pupils also occur as the result of syphilitic disease of the nervous system. We may get bilateral pin-point pupils, or the pupils may be unequal and irregular in outline. In both cases the reaction to light is lost, while the reaction to accommodation remains. I have seen a case where a syphilitic aneurysm occurred coincidently with a syphilitic paralysis of one third nerve, and in

this case the pupil was dilated and the other symptoms of paralysis of the third nerve were present. (c) Pressure upon the intercostal nerves occasionally results from an aneurysm which presses backwards and erodes the vertebræ and posterior portions of the ribs. In these cases the pain is very severe along the affected nerves. In the distribution of the nerve itself the skin may be anæsthetic—the so-called *anæsthesia dolorosa*. (d) In some cases the aneurysm presses upon the brachial plexus, shooting pain occurring in the head and neck and down the right arm.

4. *Pressure upon the branches springing from the aorta is not uncommon.*—This may result in the absence of one radial or temporal pulse, or inequality between the two pulses. If the innominate artery is pressed upon, the right radial and temporal arteries may be small and imperceptible, while in an aneurysm of the transverse arch of the aorta, the left subclavian artery is compressed, in which case the left radial pulse may be affected. A sphygmographic tracing is often of value in demonstrating the difference between the two pulses, and a forced expiration, by increasing the intrathoracic pressure, will often accentuate the difference between the two sides. When the pulses are markedly unequal, the blood-pressure is also diminished on the side of the feebler pulse; a difference of pressure of over 30 mm. between the two sides is strongly in favour of aneurysm.

5. *Pressure on the œsophagus may result in slight difficulty in swallowing, but the dysphagia is very rarely complete.*—Occasionally the aneurysm may ulcerate into the œsophagus, until at last death takes place from a sudden rupture.

ANEURYSM OF THE DESCENDING PORTION OF THE ARCH.—In these cases the sac frequently projects backwards and erodes the vertebræ from the third to sixth thoracic, causing great pain and occasionally compression of the spinal cord, resulting in paraplegia. Dysphagia is common, and sometimes a tumour appears in the region between the scapula and the spine, and may attain a very large size.

ANEURYSM OF THE DESCENDING THORACIC AORTA may occur close to the diaphragm. Aneurysm of this form is frequently overlooked, pain in the back being the most prominent early symptom.

ANEURYSM OF THE INNOMINATE ARTERY.—This is not uncommon. It forms a pulsating tumour, which can sometimes be felt above the right clavicle, and nearly always produces marked diminution in the right radial and temporal arteries. In this form of aneurysm, paralysis of the right recurrent laryngeal nerve occurs not infrequently, the right vocal cord being paralysed instead of the left.

Inspection.—This is most essential. Abnormal pulsation should be looked for in the thorax, and can often be seen when the patient is looked at obliquely in a good light. Posterior pulsation is generally observed to the left of the spine. Enlarged veins over the chest, suffusion of the face, and alteration in the pupil may be noted. The apex-beat is often dislocated from its normal position, especially when the sac is large, this being due to pressure of the aneurysm on the thorax; the heart itself is seldom hypertrophied, unless there is a leakage through the aortic valves.

Palpation.—Palpation may reveal the area and degree of the abnormal pulsation. There may only be a diffuse impulse, but if the sac has perforated the chest-wall, a forcible heaving and expansile impulse may be felt. Occasionally a diastolic shock is to be noted. This has been thought by some to be

due to the forcible closure of the aortic valves producing an effect within the aneurysmal sac; another explanation is that the contraction of the heart draws in the ribs during systole at the point where they are adherent to the aneurysm and the diastolic shock is produced by the elastic recoil of the ribs and costal cartilages. Occasionally a systolic thrill may be felt.

Percussion.—A dull area may in some cases be made out in the second right interspace in cases of aneurysm of the ascending aorta. Much more rarely an aneurysm of the arch may press forwards and to the left, and produce dullness below the left clavicle. Pressure upon a bronchus may at one period result in hyper-resonance from lung distension, and later, owing to absorption of air in the lung, the percussion note may become dull.

Auscultation.—There may be no murmur, even in a large aneurysm, but a systolic murmur is not uncommonly present. When both systolic and diastolic murmurs are heard, aortic regurgitation is present in addition to the aneurysm. Accentuation of the aortic second sound is the most reliable auscultatory sign of aneurysm.

Reference has already been made to alteration in the radial and temporal pulses. Occasionally in a large aneurysm of the descending aorta there may be absence of pulsation in the abdominal aorta and peripheral arteries of the legs, the dilatation of the thoracic aorta being sufficient to convert the intermittent into a continuous stream.

Tracheal tugging is another very valuable physical sign of aortic aneurysm, especially in the differential diagnosis of aneurysm from tumour.

Examination by the Röntgen rays is most important in every case where aneurysm is suspected. The chest should be examined from the anterior, the posterior and the right oblique positions. In the last position, most valuable information as to the state of the aortic arch can be obtained. With the fluoroscope the pulsation of the tumour and its relation to the aorta may actually be seen, but photographs should always be taken, both in the anterior-posterior and oblique positions, as much information is obtained from the density of the shadow cast by the aneurysm. If the latter is very dense, it can be reasonably inferred that deposition of the laminated clot has taken place within the sac.

Complications and Sequelæ.—The main complication, bringing about a fatal termination, is rupture, which may take place either externally, into the pericardium, into the pleura, into the œsophagus, into the bronchus, or into the lung tissue itself. Pressure on the trachea, causing stridor and respiratory obstruction, is a very distressing complication. Bronchitis may occur during the course of the illness, and may be recovered from more than once. Broncho-pneumonia and gangrene of the lung not infrequently occur when there is pressure upon a bronchus, and empyema may also result. Tuberculosis of the lung may coexist with aneurysm, but death from hæmoptysis, the result of perforation of a deep-seated aneurysm into the bronchus, has often been mistaken for the profuse hæmorrhage of tuberculosis. Cardiac failure is responsible for a large number of deaths. This may be the result of exhaustion, or of displacement of the heart, or of interference with the circulation through the coronary arteries; in other cases it is due to the aortic regurgitation. Cerebral embolism sometimes occurs in cases of aortic aneurysm, a portion of the clot within the artery becoming displaced and passed up to the brain.

Course.—Most cases live from 2 to 3 years from the time when the first symptoms have appeared. Occasionally life may be prolonged for several years by treatment. In rare cases spontaneous cure may be obtained by deposition of laminated clots within the cavity of the aneurysm, but this result is comparatively rare.

Diagnosis.—Intrathoracic aneurysm is often difficult to diagnose from intrathoracic new-growth. In both there may be an externally projecting tumour, but in aneurysm the pulsation may be seen to be expansile. The diastolic shock present in aneurysm is absent in a case of new-growth. Systolic murmurs may occur in both conditions, but the ringing aortic second sound is of great importance, and is rarely heard in tumours. Tracheal tugging is in favour of aneurysm, while progressive wasting and enlargement of glands in the neck are in favour of new-growth. Aneurysm, as a rule, occurs in apparently healthy men under 55 years of age, whereas malignant growth in the chest occurs either in early life or advanced years, and is associated with emaciation and pallor. In aneurysm there is a greater likelihood of the pupils and pulses being unequal, while in new-growth oedema of the upper extremities and chest-wall is not uncommon. In all doubtful cases an X-ray examination should be made, and will nearly always clear up the diagnosis between the two conditions. Clinical evidence of infection by syphilis and a positive Wassermann reaction are important in diagnosis.

A violently pulsating thoracic aorta, either in association with aortic regurgitation or with violent throbbing of the heart, may lead to the unfounded suspicion of an aneurysm.

In cases where an empyema is pointing on the left side in the region of the heart, the tumour may pulsate. The throbbing is usually diffuse and widespread, and there is a coexistence of a pleural effusion. Exploration with a fine needle will usually settle the diagnosis. It must, however, be remembered that occasionally an empyema may be the result of extension of septic trouble from a bronchus which has become compressed by an aneurysm.

Prognosis.—In aneurysm this is always difficult. Complete cure is very unlikely, although pain and other unpleasant symptoms and physical signs may give way to treatment. The presence of aortic regurgitation is unfavourable, while an aneurysm progresses much more slowly in people of a placid disposition and those who lead a quiet life. Even in cases where treatment has apparently been most successful and pain and dyspnœa have been apparently relieved, sudden death not uncommonly occurs from rupture of the sac.

Treatment.—The recognition of the fact that the main cause of aneurysm is the weakening of the wall by syphilitic mesaortitis has brought anti-syphilitic treatment into the forefront of modern treatment of aneurysm of the thoracic aorta. Mercurial inunctions and injections have been but little tried, but in many cases a good deal of benefit has been observed. The iodides have been given in aneurysm for many years—long before syphilis had been recognised as a cause of the condition. The most striking effect of iodide is the relief of pain, and this may be obtained by even small doses, such as 5 grains three times a day. In all cases, however, large doses, such as 20 grains three times a day, should be given a trial. Dr. de Haviland Hall, in his lectures on intrathoracic aneurysm, states that it is inadvisable to give salvarsan; but I have given this drug intravenously in

several cases with marked success. In two cases where the patients appeared to be almost moribund from respiratory complications, owing to pressure, the administration of salvarsan was followed by distinct improvement, and both these patients have remained comparatively well, one for 3 and the other for 4 years.

Efforts to produce clotting within the sac should be tried in early cases of aneurysm. Of these the best known is Tufnell's method—that of a complete rest and restricted diet. The patient must lie in a perfectly quiet and secluded room, and the treatment should be pursued for several months. He should not consume more than 10 ounces of solid food and 8 ounces of fluid per diem. Iodide of potassium should not be given during this period, as it increases thirst and makes it impossible to limit the amount of fluid. Few patients put up with such a rigid diet and rest, but an endeavour should be made in an early case to attempt this method. Secondly, the administration of lime-salts, such as the chloride or lactate of calcium, should also be tried, in an endeavour to promote clotting within the sac. Twenty grains of calcium lactate three times a day may be given for the first 3 days of a week, and be omitted for the remaining 4 days. Normal horse serum may be given in conjunction with the calcium lactate, either by the mouth, per rectum or hypodermically. The gelatin treatment, introduced by Lancereaux, consists in the hypodermic administration of 50 c.c. of a 2 per cent. solution. Unfortunately several deaths have occurred, owing to the gelatin solution having become infected by the tetanus bacillus. It is very doubtful whether the treatment has had much success. It has been suggested that the effect on the blood may be due to the amount of calcium the gelatin contains.

Many patients with intrathoracic aneurysm do better if they are allowed to follow their general avocations, provided their work be not too strenuous for body or mind. Patients should be cautioned to take things as easily as possible, to avoid alcohol, eat with great moderation, and avoid any sudden exertion. A certain amount of tobacco may be smoked.

Special symptoms may have to be treated. For severe pain, cyanosis and dyspnoea, venesection will often give marked relief. Amyl nitrite and iodide of potassium are of great service in relieving the anginal pain of aneurysm. Severe paroxysmal dyspnoea is nearly always due to direct pressure on the trachea; both inspiratory and expiratory stridor are present. The inhalation of chloroform does not give relief, and tracheotomy is quite useless. It has been stated that in some cases there is a bilateral abductor spasm of the vocal cords, due to irritation of the vagi—a very rare condition. If present, relief will probably be obtained by chloroform. Intubation of the larynx is generally preferable to tracheotomy; in fact, the latter operation should never be performed to relieve the dyspnoea of aneurysm.

Surgical Treatment.—This may be considered under four heads—(1) ligation of the vessels arising from the arch of the aorta; (2) the passage of wire into the sac with or without galvanism; (3) needling the sac; and (4) ligation of the neck of the sac.

Ligation of vessels has been of little service in the case of aneurysm of the aorta. In aneurysm of the innominate artery, combined simultaneous ligation of the right common carotid and subclavian arteries may be tried, but even this may be insufficient to prevent the flow of blood through the sac. Moore's method of introducing silver or zinc wire into the sac through a

cannula has been used, but the best results have been in cases of abdominal rather than intrathoracic aneurysm. Puncture of the aneurysm and scratching its wall with the point of a needle, as advocated by Sir William McEwen, has been partially successful in several cases. Ligation of the neck of the sac may be undertaken when it appears to be small, but suitable cases are very rare.

SUBCLAVIAN ANEURYSM is nearly as frequent as carotid aneurysm.

ANEURYSM OF THE PERIPHERAL ARTERIES is mainly of surgical interest. It most commonly occurs in the common carotid, and is relatively frequent in women. It has been suggested that the carotid is likely to be strained or overstretched during parturition. Syphilis is found in all cases.

II. ANEURYSM OF THE ABDOMINAL AORTA AND ITS BRANCHES

Aneurysm may occur in any part of the abdominal aorta, but it is a comparatively rare disease. A forcible dynamic pulsation of the vessel is often mistaken for aneurysm, and no case should be diagnosed as aneurysm unless a tumour can be grasped between the fingers. In true aneurysm there is evidence of syphilis and the Wassermann reaction is positive. A systolic thrill can sometimes be felt, and a systolic murmur is, as a rule, audible. The complications in abdominal aneurysm are many. Death may result from complete obliteration of the lumen by clots, by erosion of the vertebrae, and compression of the spinal cord, resulting in paraplegia. Occasionally the superior mesenteric artery may become blocked by a clot and acute intestinal obstruction result. The commonest complication is rupture, which generally takes place into the retro-peritoneal tissues, with the formation of a large rapidly-growing tumour in the flank. More rarely death takes place from rupture into the peritoneum or duodenum.

Treatment.—The treatment of abdominal aneurysm is the same as that of thoracic aneurysm. In cases where medical treatment is unsuccessful after a fair trial, surgical measures should be undertaken.

ANEURYSM OF THE SPLENIC ARTERY is occasionally met with. A tumour can be felt near the spleen and it may perforate into the colon. If the diagnosis can be made, removal of the aneurysm and of the spleen should be undertaken.

ANEURYSM OF THE MESENTERIC ARTERY generally results in plugging of the vessel or its branches, with the result that acute intestinal obstruction takes place and death occurs from this cause.

ANEURYSM OF THE HEPATIC ARTERY is very rare.

ANEURYSM OF THE RENAL ARTERY has occasionally been noted, and in some cases successfully removed.

ANEURYSM OF THE FEMORAL ARTERY also occurs.

ANEURYSM OF THE POPLITEAL ARTERY is one of the most common of the peripheral aneurysms. It has been suggested that this is due to the fact of the exposure to stress and strain to which the popliteal region is subjected during violent lifting efforts.

In all cases of peripheral aneurysm a syphilitic basis must be investigated; but as in these cases the sac-wall rapidly changes from a true to a false or mixed aneurysm, anti-syphilitic treatment is of little avail and the treatment is mainly surgical. Distal or peripheral ligation and excision have all been

tried, but a great advance has recently been made in the treatment of aneurysm by Matas. After rendering the limb exsanguine, he freely opens the arterial sac and by a process of suturing reconstructs a channel between the afferent and efferent artery of the sac. He terms this procedure *Reconstructive Endoaneurysmorrhaphy*.

III. DISSECTING ANEURYSM

This may originate in an atheromatous ulcer. Very often the dissection of the coat is small, especially when the blood-pressure is not high. When, however, there is a very high blood-pressure and much fatty degeneration of the media, an extensive dissecting aneurysm may occur. The fatty degeneration of the media may cause a small split in the intima and the dissection separates the intima from the media, so that in some cases there may be a double tube instead of a single aorta. Extensive dissection frequently causes sudden death, but in other cases the patient may live on, and the association of a rapidly beating heart and a feeble pulse in the lower limbs has been suggested as a clinical sign by which the condition may be recognised. Turnbull has shown that in five cases of extensive dissecting aneurysm of the aorta, vascular hypertrophy was well marked, and consequently the blood-pressure was high during life.

IV. CIRROID ANEURYSM

Cirroid aneurysm is a condition in which an artery and its branches are dilated and tortuous. The affection is usually met with in the scalp—the superficial temporal, the posterior auricular, and the occipital arteries being affected. In very rare cases it has been found in the perineum, in the orbit, and in the limbs. Occasionally it follows an injury, but in other cases it seems to be of the nature of an angioma, and has been given the name of serpentine angioma. It is most common between puberty and 30 years of age.

Pathology.—The arteries are dilated, thinned and very tortuous, and the disease tends to spread towards the capillaries and also along the arteries which feed the aneurysm. The skin over the aneurysm is often atrophied and may become ulcerated, leading to very dangerous hæmorrhage.

Symptoms.—There is an ill-defined pulsating tumour on the scalp, in which the tortuous vessels may be felt. In rare cases the tumour may be slow in its growth, but this is generally rapid and the skin over it ulcerates, leading to hæmorrhage.

Treatment.—This is very difficult. In limited cases the tumour may be excised. Generally, however, ligature of the peripheral arteries of the growth is more satisfactory. Electrolysis and injections of perchloride of iron into the mass have been tried, with some success.

V. ARTERIO-VENOUS ANEURYSM

Arterio-venous aneurysm is the name given to the condition in which an artery and a vein communicate, and consists of two kinds—(1) aneurysmal varix, where the two vessels anastomose directly; and (2) varicose aneurysm, where the sac separates the connecting vessels.

(1) **ANEURYSMAL VARIX.**—The condition is usually traumatic in origin and generally occurs at the elbow, as the result of venesection. The artery is wounded at the same time as the vein and they become connected, the result being that the vein becomes markedly dilated and tortuous.

The varix forms a soft, compressible, ill-defined tumour, which pulsates. Pain in the tumour is not uncommon. A marked thrill can often be felt and a loud bruit may be heard over the tumour. If the limb is raised the tumour shrinks, while it becomes large and congested if the limb is held downwards. The limb below the tumour is often œdematous.

In some cases the condition remains stationary, and all that is required is an elastic support. If, however, the aneurysm tends to increase in size, the artery should be ligatured above and below its communication with the vein.

An intrathoracic aneurysm may become adherent to a vein and perforate into it. The most common case occurs when an aneurysm of the ascending arch of the aorta perforates the superior vena cava. The latter vessel becomes greatly distended and an arterio-venous aneurysm is formed. There is often a sudden onset when the lumen of the two vessels becomes connected; there is distinct congestion of the head and neck and upper limbs, great distension of the veins, and often œdema. On auscultation over the tumour, a continuous humming murmur is heard, with marked accentuation during systole.

(2) **VARICOSE ANEURYSM.**—This occurs when an artery and vein are simultaneously wounded. An aneurysmal sac is formed in the tissues which communicate both with the artery and vein. The symptoms are similar to those of an aneurysmal varix, but in addition there is a pulsating tumour, which can be distinguished from the dilated vein. This form of aneurysm should be excised by open operation.

ARTERIO-VEINous ANEURYSM OF THE ORBIT OR PULSATING EXOPHTHALMOS.—This is a form of aneurysm by anastomosis, due to a communication having formed between the cavernous sinus and internal carotid artery as it passes through it. It is generally the result of a fracture of the base of the skull. The condition is usually unilateral, but may be bilateral, and the communication may take place immediately after the fracture, or evidence of the lesion may only appear days or weeks after the injury.

The main symptom is protrusion of the eyeball, the globe being displaced outwards and downwards. It may be seen to be visibly pulsating, but if not, slight pressure upon the globe of the eye will bring out pulsation. A loud bruit, either continuous or increased during systole, may be heard anywhere over the head; this roaring sound is generally very distressing to the patient. There is great dilatation of the veins around the eyelids, conjunctivæ and fundus. Headache is common.

The condition may last for years, and in a few cases spontaneous recovery has taken place.

The treatment of the condition is either compression or ligature of the carotid artery. The great danger in ligaturing the carotid artery is the occurrence of cerebral softening and hemiplegia. To avoid this, it is better to ligature the artery temporarily and see if any cerebral symptoms tend to develop; if they do, the ligature should be removed after 24 hours; but if they do not, the ligature may be tightened and the artery completely occluded.

PHLEBITIS

Phlebitis or inflammation of the veins may be sharply divided into two great classes—(1) non-suppurative or plastic phlebitis, and (2) the suppurative form. The terms endo- and peri-phlebitis have been used to indicate inflammation of the internal and external coats. Peri-phlebitis results from invasion of the veins by inflammatory processes outside it, or from injury. It may extend inwards towards the lumen of the vein, and result in endo-phlebitis and frequently clotting of the blood within the vein. Endo-phlebitis is usually the result of poisons or microbes circulating within the vein. Inflammatory changes occur in the endothelium, and a plastic inflammation results, and in consequence a clot or thrombus is set up within the vein. The clot may adhere to the vessel wall and completely obliterate it. Organisation of the clot by fibrous tissue may occur, the vein being transformed into a hard fibrous cord. In other cases the clot may become softened and broken down, and the circulation may be resumed through the vein. In certain cases changes in the composition of the blood may lead to clotting in a vein, and the presence of this clot itself may give rise to a plastic phlebitis; this is sometimes called thrombo-phlebitis. In other cases the vein and contained clot may become invaded by pyogenic organisms, and leucocytes will enter the clot and cause it to break down into a purulent fluid.

PLASTIC PHLEBITIS

Ætiology.—(1) Traumatic phlebitis; (2) the formation of a non-infective clot—thrombo-phlebitis; (3) gouty phlebitis may accompany an attack of gouty arthritis or may occur independently; (4) typhoid fever not infrequently causes phlebitis and thrombosis; (5) in pneumonia and influenza phlebitis is not an uncommon complication; (6) post-operative phlebitis is not at all uncommon in cases of operation on the lower abdomen and the bladder; and (7) puerperal phlebitis or phlegmasia alba dolens frequently follows parturition.

Phlebitis may attack any vein, but is most common in the lower limb, particularly in the saphena vein.

Symptoms.—Phlebitis is accompanied by pain and tenderness in the course of the affected vein. The vein can be felt as a hard cord. The skin may become reddened over the superficial veins, and the limb is often œdematous when thrombosis has taken place. There is usually more or less febrile disturbance. In gouty phlebitis, the pain is often severe, the areas of inflammation are often multiple, there is a great tendency for more than one vein to be attacked at once, and, in opposition to most forms of phlebitis, the disease may be symmetrical.

Complications and Sequelæ.—The complications and sequelæ of plastic phlebitis are those of the thrombosis which accompanies it, and will be described under thrombosis.

Prognosis.—This is always grave, unless treatment is very carefully carried out.

Treatment.—Patients with phlebitis should be put to bed, and the limbs elevated and wrapped in cotton wool. All sudden movement, friction or

handling should be avoided. The bowels should be freely opened, as chronic constipation and stasis in the colon may impede the circulation in the iliac veins. In gouty phlebitis, the diet should be restricted to fish and light farinaceous foods, but when patients are marasmic and anæmic, the diet should be as liberal as the patient's digestive powers will permit. In all cases of phlebitis foods containing much lime-salts, such as milk, should be avoided. Potassium or sodium citrate with carbonate of ammonia and liquor ammonii acetatis are of service. Glycerine and belladonna smeared over the inflamed vein appears to ease the pain.

SUPPURATIVE PHLEBITIS

Ætiology.—Suppurative phlebitis is the result of infection of the walls of the veins with pyogenic organisms. The micrococci may be in the circulating blood, as in some cases of puerperal phlebitis, or they may reach the veins from a focus of suppuration around it, as in facial carbuncle, middle-ear disease, or inflammation of the portal veins—suppurative phlephlebitis.

Pathology.—The coats of the vein are infiltrated with leucocytes, the clot which has formed within the vessel breaks down into yellow pus, and abscesses are not infrequently found along the course of the vein. Not uncommonly the septic inflammation spreads along a vein, splitting up the coats.

Symptoms.—There is a throbbing, smarting pain in the region of the affected vein, and the part drained by the vein is œdematous. Not infrequently the septic process spreads along a vessel. There is often fever, a rapid pulse, a dry tongue, and delirium, and in many cases a succession of rigors indicates the development of pyæmia.

Complications and Sequelæ.—These depend upon the situation of the vein and the occurrence of emboli, owing to breaking away of the softened clot. (See Thrombosis.) When the vein is superficial the diagnosis is easy, but when a deeply-seated small vein is affected the only symptoms may be those of the pyæmia to which it gives rise.

Treatment.—The prevention of this disease by aseptic and antiseptic methods is one of the greatest advances in modern surgery. As soon as the disease is recognised, a ligature should be placed upon the vein between the affected area and the heart, the inflamed vein should be thoroughly laid open, the septic clot removed and the cavity thoroughly cleansed. In some cases where numerous abscesses are formed, amputation is the only means of arresting the general infection.

THEODORE THOMPSON.

THROMBOSIS AND EMBOLISM

Thrombosis is the name applied to the coagulation of blood within living vessels, whether in the heart, the veins or the arteries.

Embolism is the process whereby a portion of clot or other substance, such as parasites, fat globules, masses of bacteria or particles of tumour, is carried from one part of the circulation to another, and is impacted when it arrives at a vessel too narrow for its further progress. An infarct is the

degenerated or necrosed condition of the tissues due to interference with the circulation of blood within it, and can be caused by embolism, thrombosis, endarteritis, endophlebitis, or strangulation of veins. An infarct is generally wedge-shaped in outline, with the base towards the periphery of the organ affected. As seen post-mortem, it is either yellowish-white in colour (the white infarct), or blood red in colour (the hæmorrhagic infarct).

In the case of the white infarct the tissue deprived of its blood supply becomes permeated with lymph from the surrounding living tissue, and coagulative changes take place in it. In the case of the kidney or spleen, the coagulable material is sufficient to render the infarct hard. In the case of the brain, less coagulable lymph is poured out, and the area of the brain affected becomes softened. In the early stages there is often a zone of congested vessels around a white infarct; this is a reaction on the part of the surrounding living tissues to the presence of the dead material. Later the infarct becomes invaded by fibrous tissue and a scar results.

In hæmorrhagic infarct, coagulation and necrosis also take place, but to this is added hæmorrhage, by diapedesis of the red blood cells from vessels of the collateral circulation. An hæmorrhagic infarct is commonly seen in the lung; a cone-shaped area of lung tissue becomes hard and dark red in colour. Should the embolus, instead of being aseptic, contain living micro-organisms, a septic process is set up within the infarct and an abscess results. Such purulent abscesses are commonly seen in the lungs, as the result of septic phlebitis, and occasionally in the systemic system, as the result of septic endocarditis.

THROMBOSIS

Ætiology.—The causes of thrombosis are—(1) altered conditions of the blood or increase in its coagulability; (2) slowing of the current of the blood within the vessels; and (3) a lesion of the lining membranes of the vessel or cavity of the heart. Thus, thrombosis may occur in cases of chlorosis, where the blood is more coagulable than normal, in the appendages of the dilated auricles of the heart where the current of blood is feeble, and it may result from inflammation of the lining of the vessel or degenerative changes in its endothelium.

(1) **CARDIAC THROMBOSIS.**—Cardiac thrombosis is one of the commonest forms of thrombosis and is very important. It occurs in the left auricle, when it has become extremely dilated, as the result of mitral stenosis, or more rarely of mitral regurgitation. The ante-mortem clot generally begins to form in the dilated appendix of the left auricle, but it may extend by the deposition of excessive layers of fibrin and invade the auricle itself and a large ball thrombosis be formed within the cavity. Portions of the ante-mortem clot may break away from the thrombus, and may be carried into the left ventricle and into the general circulation, and embolism may occur in the brain, spleen, kidneys, intestines and the main arteries of the limbs.

Ante-mortem clot is occasionally deposited among the meshes and cavities of the dilated left ventricle. In cases of cardiac fibrosis and myelomalacia cordis, the result of disease of the coronary arteries, the lining of the heart may become affected and fibrinous deposits occur within the ventricle. Lastly, in infective endocarditis, large vegetations, consisting of clot and masses of micro-organisms, may occur. Inflammation of the ventricle and

of the auricle may also be present, and ante-mortem clot may be deposited on these roughened surfaces. Portions of this clot may leave the ventricle and pass into the general arterial circulation, where the effect produced will depend upon whether the emboli are aseptic or contain micro-organisms.

Thrombosis in the right auricle occurs in many conditions where there is gradual cardiac failure and dilatation of the right side of the heart. Portions of ante-mortem clot form in the right auricular appendix, and parts may break away and pass into the lungs and an embolism of the pulmonary artery result. If the embolus is sufficiently large to cause blocking of the artery or of one of its main branches, sudden death ensues, but if only one of the smaller branches is affected, a pulmonary infarct results. Much more rarely ulcerative endocarditis occurs on the right side of the heart, and portions of the valves or affected clot reach the lungs in the same way.

Thrombosis of the coronary arteries is a very important condition, since it is a frequent cause of sudden death. The usual artery affected is the anterior interventricular branch of the coronary artery. Atheromatous plaques are constantly found within the thrombosed vessel, and sometimes atheroma has occluded the orifice of the artery. In cases where the circulation has been slowed and greatly diminished before the final clotting, changes in the wall of the left ventricle are very common. Syphilitic mesaortitis sometimes occludes the orifices of the coronary arteries.

(2) VENOUS THROMBOSIS.—*Thrombosis of the lateral sinus* occurs in disease of the middle ear. The mastoid cells become infected with pyogenic organisms and the disease spreads to the petrosal or sigmoid sinus. The clot in the vein becomes softened by pyogenic organisms, and particles break away and are conveyed to the lungs, in which pyogenic abscesses are formed.

The symptoms of septic thrombosis of the lateral sinus—and its continuation of the jugular vein—are infiltration of the tissues of the neck, with a cord-like induration of the vein itself, with some restriction of the movements of the head. There is a history of a chronic and often offensive discharge from the ear of the same side. A high temperature and rigors, due to flooding of the circulation by poison, occur when a portion of the septic clot is dislodged. In these circumstances the jugular vein should at once be ligatured below the clot, in order to prevent further portions of the clot gaining access to the blood stream. A radical mastoid operation should also be performed, the sinus opened and its septic contents removed.

Thrombosis of the longitudinal sinus of the brain occurs as the result of injuries and infected wounds of the skull. It is a common war injury, the vertex of the head having been injured by a bullet as the soldier passed along the trench. Thrombosis of the cranial sinuses also occurs in marasmic patients, but it is usually agonal.

In many of these cases, owing to the vertical position of the leg areas in the brain, a paraplegia is produced, while the arms are not affected. The condition should be treated by trephining and draining the cranial cavity. Occasionally the longitudinal sinus becomes thrombosed in septic conditions in children and also in chlorotic anemia in adults.

Thrombosis of the cavernous sinus is not infrequently the result of the extension of a chronic suppurative process of the sphenoidal cells at the back of the nose. The cavernous sinus is also affected by septic processes on the face; a small boil on the nose or a mosquito sting on the face may produce

a septic thrombosis of the angular vein; this vein communicates with the ophthalmic vein, and the septic clot may extend along the latter into the cavernous sinus. As the venous plexuses of the pterygoid and zygomatic fossæ communicate through the foramina in the middle fossa and by the inferior ophthalmic vein, purulent inflammation of the jaw and of the teeth sockets is sometimes a cause of cavernous thrombosis. The result is that a marked degree of exophthalmos and swelling of the lids and œdema of the optic disc and extensive retinal hæmorrhages occur. Not infrequently the septic condition of one cavernous sinus spreads to that on the other side through the circular sinus, and the exophthalmos may be double. Death from pyæmia or meningitis results. Owing to the position of the sinus, operation is impossible.

Femoral thrombosis is perhaps the commonest form of thrombosis. It frequently occurs after parturition and in anæmic and marasmic states. It is met with after infectious fevers, especially after typhoid fever, more rarely after influenza and pneumonia. It also follows operations, especially if a septic condition has been dealt with, or results from the operation. The thrombosis generally occurs in the femoral vein, and there is often some rise of temperature and a slight rise in pulse-rate. The limb affected becomes œdematous, and a hard cord is found in the course of the vein.

In other cases thrombosis of the veins may also occur in marasmic conditions secondary to carcinoma, tuberculosis and tertiary syphilis.

Complications and Sequelæ.—Collateral circulation is usually satisfactorily accomplished in femoral thrombosis. In cases where the arteries as well as the veins are involved gangrene may occur. Occasionally the thrombosis may spread up into the iliac vein and into the inferior vena cava, in which case both legs may become swollen and œdematous. Even in cases where the inferior vena cava has become thrombosed, recovery may take place, collateral circulation being established by means of veins passing up from the legs into the axillæ. If, however, the clot reaches the entrance to the renal veins, death nearly always results from renal thrombosis. Embolism is not at all uncommon in femoral thrombosis, the clot passing into the right auricle, and then into the right ventricle and pulmonary artery.

Treatment.—Complete rest for 4 or 5 weeks, as a precaution against embolism, should be insisted upon. Avoidance of foods containing quantities of lime salts, such as milk, and the administration of citrates and salts of ammonia will materially help in the treatment of the case. The leg should be elevated and wrapped in cotton wool and kept warm.

Thrombosis of the portal vein is not uncommonly the result of septic conditions within the abdomen. The most common affection is suppuration in the region of the appendix. The condition is not always acute. Gastric and duodenal ulcers also lead to portal thrombosis, and tubercular glands along the course of the portal vein have been found to cause clotting within the lumen of the vessel. Dysenteric ulcers resulting from bacillary dysentery may also give rise to septic portal thrombosis, but typhoid ulceration very rarely does so.

The effect of portal thrombosis is to produce a portal pyæmia, portions of the clot passing into the liver and causing abscesses within the radicles of that organ. Occasionally the portal vein itself becomes converted into a

sac containing pus, and the liver is then riddled with abscesses along the course of the portal branches. This condition is known as *portal pyelephlebitis*.

Symptoms.—The symptoms of septic portal thrombosis are the occurrence of fever and of rigors. The liver becomes enlarged and tender, and jaundice of a slight degree is quite common.

As the condition is such a generalised one, recovery very seldom takes place, even if treatment is adopted.

Treatment.—This consists in removing the cause and incising any liver abscesses.

(3) **ARTERIAL THROMBOSIS.**—Arterial thrombosis is much rarer than venous thrombosis. It is generally due to arterial embolism, but is occasionally the result of trauma or disease of the arterial walls, such as atheroma or endarteritis.

Thrombosis of the coronary arteries of the heart has already been described (pp. 860 and 962). Thrombosis is very common in the small cerebral arteries, especially when they have become narrowed as the result of disease. In middle-aged people this narrowing is usually the result of syphilitic endarteritis, while in the elderly the arterial lumen is diminished by atheromatous changes in the wall of the vessel.

Thrombosis of the main artery of a limb usually results in gangrene: the limb becomes first white and pallid, later mottled in appearance, and finally black. If the patient survives the immediate shock and the disease to which the thrombus owes its origin, a line of demarcation will form between the vital and devitalised tissues, and the limb should be amputated well above this level.

EMBOLISM

Embolism may occur in three main situations, namely—(1) In the systemic circulation; (2) in the pulmonary circulation; and (3) in the portal circulation.

Emboli in the systemic circulation are derived from *ante-mortem* clots in the left auricle and left ventricle. These clots are formed in cases of mitral stenosis and more rarely in mitral regurgitation, and also when the left ventricle is greatly dilated and hypertrophied. In these cases the emboli are asepti*c*. Systemic emboli also occur in infective endocarditis, when portions of the valve break away or masses of fibrin and micro-organisms pass into the general circulation. These emboli are septic, and when they reach their destination usually form abscesses.

Emboli in the pulmonary circulation usually have their origin in clots which form within the right auricle and right ventricle. More rarely they are the result of infective endocarditis of the tricuspid and pulmonary valves. They may also come from any part of the systemic venous system. A very important form of pulmonary embolism is met with after abdominal operations and after childbirth. About the tenth day after an apparently successful abdominal operation or an uneventful parturition, a pulmonary embolism may occur with appalling suddenness. Death may take place at once, or hæmoptysis and pleurisy supervene. The clot forms in the common iliac vein, at the junction of the internal and external iliacs. Not only may a clot pass along the veins, but we also get droplets of fat in fat embolism, air bubbles in air embolism, and masses of parasites in parasitic embolism.

In embolism in the portal circulation portions of clot in the radicles of the portal vein are finally arrested in the liver.

Symptoms.—1. *Embolism of the cerebral arteries.*—The onset is sudden, and the left side of the brain is rather more often affected than the right. Hemiplegia or aphasia is produced; consciousness is only lost for a few minutes during the attacks.

2. *Embolism of the splenic artery.*—The onset is sudden, with pain in the left side and sudden enlargement of the spleen, which is very tender. During the next few days, the spleen diminishes in size, but it often remains permanently enlarged.

3. *Embolism of the renal arteries.*—Sudden pain in the back is produced, and blood and a little albumin are present in the urine. The hæmaturia may last for a week or 10 days and then disappear.

4. *Embolism of the superior mesenteric artery.*—The patient is seized with sudden, violent abdominal pain and distension. The collateral circulation, in spite of the numerous vascular arteries that supply the intestine, fails, and gangrene of the small intestine results. There is a complete intestinal obstruction, and blood finds its way into the stools and into the peritoneal cavity. Operation should be at once undertaken, but owing to the large amount of bowel affected recovery is very rare.

5. *Embolism of the central artery of the retina.*—This is not an uncommon event in cases of mitral stenosis and in infective endocarditis of the aortic and mitral valves. The patient is seized with pain in the eye and becomes suddenly blind on one side. The optic disk becomes pale and the retinal vessels small. Occasionally only a single branch of the vessel is affected.

6. *Embolism of a large artery in a limb.*—This sometimes occurs. There is acute pain in the limb, followed by numbness and loss of power. The pulse is imperceptible below the seat of the embolism, and gangrene results.

7. *Air embolism.*—Air may enter the veins during operation on a large vein, or during intravenous injection of saline or other solutions, or after distension of the bladder and the urethra with air. It is said that occasionally air may enter the open uterine sinuses after parturition or miscarriages, but some of the cases are probably due to the invasion of the *Bacillus aerogenes capsulatus*. Air embolism is undoubtedly capable of causing death, but a small quantity may enter a vein without any effect whatever, or if some disturbance should arise without fatal termination. The exact way in which air embolism causes death is doubtful; it may be due to arrest of the pulmonary circulation or to cerebral anæmia.

The diagnosis is not difficult, the respiratory embarrassment, convulsions, the feeble pulse and the characteristic sound upon air entry into the veins are usually sufficient.

Treatment consists in immediately occluding the vein into which the air has entered. Stimulants should be administered hypodermically and nitrite of amyl inhaled. Venesection may be used to relieve the embarrassment of the heart.

8. *Fat embolism.*—Fat may reach the blood vessels in cases of fracture of bones and in cases of hæmorrhage into or rupture of the liver. The fracture is usually situated in the long bones, generally in the tibia or femur, and occasionally in the ribs. Fat embolism may occur within a few hours of fracture of the bones.

The fat droplets first lodge in the capillaries of the lungs. Occasionally they are forced on through the lungs into the general circulation, and the glomeruli of the kidney may be plugged with fat cells, and they may also lodge in the brain or spinal cord.

The patient becomes cyanosed, and crepitations from œdema of the lungs may be heard at the bases. The temperature remains normal. Cerebral complications, such as delirium, coma and rarely localised paralysis, may be found. The urine should always be examined, as oil drops have been detected by staining with osmic acid, and also the retinae, as in one case the fat drops were recognised in the retinal vessels before death.

When fat embolism occurs within a few hours of fracture of the bones it has to be diagnosed from the general shock of the accident. It is doubtful whether fat embolism in the lungs can alone cause death. It is probable that a fatal termination is due to the disturbance of the kidneys or lesions of the brain.

The indication for treatment is to sustain and stimulate the heart. Nitrite of amyl is often useful, and inhalations of oxygen should be given to lessen cyanosis.

9. *Paradoxical Embolism.*—In certain cases of venous thrombosis, emboli occur not only in the lungs but also in the systemic arteries. It has been shown that in these cases the embolus has passed from the right auricle to the left auricle through a patent foramen ovale. These crossed or paradoxical emboli in many cases are preceded by pulmonary embolism. The latter causes a rise in pressure in the right auricle and a fall in pressure in the left auricle, and thus the embolus in the right auricle can pass to the left side of the heart.

ARTERIAL BLOOD-PRESSURE

By the blood-pressure is meant the pressure that the blood exerts against the wall of the vessel in which it is contained. The term, therefore, includes endocardial pressure, arterial pressure, capillary pressure and venous blood-pressure. We are here concerned only with arterial blood-pressure. This depends upon (1) the force of the contraction of the left ventricle; (2) the volume of blood which the left ventricle propels into the already full arteries; (3) the elasticity of the middle coats of the large arteries; and (4) the peripheral resistance.

The arterial pressure synchronous with the systole of the ventricle is called the *systolic blood-pressure*, that synchronous with the diastole is called the *diastolic blood-pressure*, while the difference between the two is called the *pulse-pressure*. The *mean arterial pressure* is the mathematical mean between the systolic and diastolic pressures.

The introduction of the sphygmomanometer has proved of great value in clinical medicine. The results obtained are more reliable, and, indeed, not infrequently the practitioner will detect cases of supernormal blood-pressure which might otherwise have been overlooked; further, the results can be expressed in terms of mathematical formulæ, which

can be kept for reference, and in this way the practitioner is enabled to compare the records while patients are undergoing treatment with the aim of reducing tension. A word of warning, however, is necessary: it should be remembered that the sphygmomanometer may exhibit fallacies and possesses limitations, and there is undoubtedly a danger of overestimating its value in clinical work, when we rely upon its readings alone as an indication of the patient's condition. Blood-pressure measurements should be considered in conjunction with other clinical data. The normal blood-pressure in all probability has a wider range of variation in different individuals than is generally supposed, and, if this be so, great caution should be exercised in arriving at the conclusion that a blood-pressure outside what is generally supposed to be the normal limit is necessarily indicative of a diseased state. At the same time it should be remembered that the detection of supernormal blood-pressure in its earliest stages is of great practical importance, because it is in these stages that therapeutic measures may be successful. In considering the question whether a rather high pressure reading is normal to the individual, or is indicative of a pathological departure, it is important that inquiries should be made with regard to four points—viz. (1) what was the patient's usual blood-pressure previously? (2) are there any symptoms other than a supposed abnormal blood-pressure, such as a sensation of fullness or throbbing in the head? (3) what is the condition of the heart, the arteries, and the kidneys? and (4) what is the result of treatment? If there be a fall in the pressure readings, together with a coincident improvement in the general health of the individual during treatment, it may be inferred that the higher pressure reading is pathological.

The following may be regarded as the normal standard of systolic blood-pressure, as measured in the brachial artery, while at rest. In children under 10, 100 mm.; in early manhood, from 100 to 120 mm.; in middle life, from 125 to 135 mm.; above 60 years of age, 145 to 150 mm. The suggestion that if the figure 1 is prefixed to the age of individuals of 15 years or upwards the result will give the normal systolic blood-pressure is inaccurate, especially in the case of older people. In the female, the systolic pressure is generally from 10 to 20 mm. lower than in the male. The range of diastolic blood-pressure, as estimated by the auscultatory method in healthy young adults is usually accepted as 70 to 90 mm.; but MacWilliam and Melvin found it when examined in the sitting position to be considerably lower, the figures being 50 to 80 mm. It is held by some that the diastolic pressure is about two-thirds that of the systolic, while others are of opinion that up to middle life this proportion is as high as three-fourths, and that afterwards it is less and may not exceed a half of the systolic pressure.

VARIATIONS IN BLOOD-PRESSURE UNDER PHYSIOLOGICAL CONDITIONS

There are variations in the blood-pressure under physiological conditions, among these being mental states, sensory stimulation, sleep, change of posture, meals and physical exertion.

Those of nervous, anxious temperament, as well as those whose mode of life necessitates considerable nervous strain, have a tendency to exhibit higher readings, especially in the later period of life; while in those of an equable and placid temperament, and those whose lives are less harassed, the

opposite is found. Sensory stimulation causes a rise in the arterial pressure, especially in the diastolic. The effect of pain varies in different individuals; in some it results in a rise of pressure, in others it results in a fall, while in others again there is no effect produced. In sleep there is a fall in the minimum blood-pressure, and probably a slight fall in the maximum pressure also. Opinions as to the effects of the digestion upon the systemic blood-pressure vary, some holding that there is a constant rise, others that there is a constant fall, while others again are of opinion that there is no alteration. In all probability the maximum and the pulse pressures are increased, and the minimum pressure may be also to a less extent. It is probable that the change in pressure commences within a quarter of an hour after a meal, the highest reading being reached in about an hour, after which it gradually returns to the normal, which is reached in about two hours. During exercise the maximum and minimum pressures of the systemic circulation are raised, and the pulse-rate is also increased. Immediately after exercise, the arterial pressure may be supernormal, normal, or even subnormal; in the first case, a lowering quickly supervenes, that of the diastolic pressure usually occurring before the systolic. The arterial pressure generally returns to the normal in about half an hour; it is, however, usually better to postpone taking a measurement for at least one hour after exercise. The blood-pressure readings of those who engage in arduous physical exertion while in training, when taken at rest appear to be somewhat below the normal.

SUBNORMAL ARTERIAL PRESSURE (HYPOTENSION)

Ætiology and Pathology.—Subnormal blood-pressure may be met with in acute cardiac disease which is not accompanied by a pronounced degree of cyanosis, in most cases of chronic valvular disease—especially mitral disease, in most cases of fatty degeneration of the myocardium, in some cases of chronic interstitial myocarditis, in congenital deficiency of the vasomotor system, in Addison's disease, in the early stages of Graves' disease, acute infective diseases—particularly enteric fever, influenza, diphtheria, and pneumonia, in auto-intoxication—especially from the teeth, the tonsils, the accessory nasal sinuses, the colon, and the genito-urinary tract, in pulmonary tuberculosis, shock, and collapse, after severe bleeding, after severe vomiting, in gastric disorders, diarrhoea, dysentery, cholera, cancer, and other wasting diseases, cerebral thrombosis, neurasthenia, the excessive use of tobacco, in some cases in which there is an unduly slow pulse, and after prolonged rest in the recumbent posture.

The chief factors in the causation of subnormal arterial pressure are (1) a diminution of the ventricular output, and (2) lowering of the vasomotor tone, splanchnic stasis being usually associated with the latter. It should be noted that a subnormal blood-pressure is more often an indication of derangement of the vasomotor centre than of cardiac impairment. Some are of opinion that in subnormal arterial pressure due to lowering of the vasomotor tone, there is in the large majority of cases adrenal insufficiency, frequently thyroid insufficiency, and not rarely pituitary insufficiency, and that these are the cause of the condition; and, therefore, that in all cases of this group an endeavour should be made to ascertain whether there is endocrine insufficiency, and if so to what extent, with a view of remedying this, in the

belief that when once this is done the arterial pressure will be raised to normal and remain so, as long as these glands continue to functionate effectively. Adrenal insufficiency may be due to, among other things, inadequate development, lesions of the adrenals, and auto-intoxication.

Symptoms.—Among these are asthenia—especially myasthenia, premature exhaustion on maintaining the upright posture, giddiness and faintness—especially on change of posture, neurasthenia, mental depression, insomnia, irritability of temper, nervous instability, sensitiveness to cold, numbness, and pallor or lividity of the extremities, subnormal temperature, increase in the cardiac rate of more than 10 per minute when the individual assumes the upright posture after lying down, and splanchnic stasis. When giddiness and faintness are especially associated with change of posture, it is suggestive of vasomotor derangement, as is also an abnormal increase in the pulse-rate on assuming the upright posture after lying down. In splanchnic stasis, pressure on the abdomen by the hand while the patient is lying down is sometimes accompanied by distension of the jugular veins.

Treatment.—Our first duty is to review the ætiology of the condition, and in this connection a searching inquiry should be made for any possible source of auto-intoxication—from the teeth (including X-ray examination), the tonsils, the accessory nasal sinuses, the colon, and the genito-urinary tract, and if this is found to be present it should be adequately treated. In acute cases rest in bed may be advisable; and after the acute stage has passed, great care should be taken to avoid over-exertion, and an adequate amount of rest after exertion, and before and after meals, is indicated. In shock and collapse the patient should lie on his back, and the foot of the bed may with advantage be raised by 1 or 2 feet. Massage is helpful in certain cases. A tepid or cold sponge bath in the morning, followed by suitable exercises, and residence in a bracing climate are to be commended. The proportion of those articles of food which especially stimulate the cardio-vascular system, such as meat and meat-extractives, should be increased, roasted meat being of greater value than meat which has been boiled, while meat soups and gravies should also be given. Cod-liver oil, malt, glycerophosphates, phosphorus, iron, and arsenic may be tried. Digitalis, and to a less extent strophanthus, have gained a reputation in the treatment of subnormal blood-pressure; but my investigations have shown that, *judged by the methods in use for observing the blood-pressure clinically*, the internal administration of digitalis does not raise the blood-pressure in man. Strychnine also has a considerable reputation in the treatment of this condition, especially when present in diphtheria or other acute infective diseases. Among other remedies advocated are adrenalin, pituitary extract, and ergot. The wearing of an abdominal belt is very useful in some cases of subnormal blood-pressure.

SUPERNORMAL ARTERIAL PRESSURE (HYPERTENSION)

In pathological hypertension the blood-pressure is *persistently* above the normal of the individual; *temporary* supernormal blood-pressure is found, for example, in the nervous excitement incidental to medical examination. The late Sir Clifford Allbutt introduced the term *hyperpiesia* to denote a clinical

condition in which there is a persistently-raised blood-pressure independent of renal disease.

Ætiology and Pathology.—Hyperpiesia is common in late middle age and is by no means a senile change. In the case of women it often occurs at the time of the menopause. It is more common in males than in females. The condition may be met with in prolonged mental strain or anxiety, in individuals who habitually over-indulge in food or tobacco or alcohol, in auto-intoxication—especially from the teeth, the tonsils, the accessory nasal sinuses, the colon, and the genito-urinary tract, in gout and in lead poisoning. Other causes of supernormal blood-pressure are nephritis—more especially the chronic interstitial form, in the later stages of hyperthyroidism, often in the cyanosis of cardiac failure, and usually in polycythæmia. In rare cases associated with chronic interstitial nephritis, it may occur in young children. It will thus be seen that the ætiology of supernormal blood-pressure is similar to that of arterial hypertrophy (see pages 943–944).

In the course of time arterial hypertrophy and cardiac hypertrophy, more especially of the left ventricle, tend to develop: and still later fatty degeneration in the hypertrophied muscular tissue of the arteries, resulting in a weakening of the walls of the vessels, and it may be ischæmic fibrosis of the organs may occur. These morbid changes are fully described on pages 944–945. Supernormal blood-pressure is also often a factor in the causation of atheroma.

Symptoms. The patient is often plethoric and well nourished. There may be a complete absence of subjective symptoms for some years. The patient is, however, apt to suffer from a sensation of fullness and throbbing in the head, headache, usually in the occipital region, flushings, tinnitus aurium, flashes of light before the eyes, giddiness, insomnia and palpitation. The systolic blood-pressure in cases of simple hyperpiesia varies from 170 to 200 mm.; in cases associated with chronic interstitial nephritis it may reach even 300 mm. or more; and in secondary contracted kidney and in polycystic disease of the kidneys it varies between 160 and 220 mm. There is evidence of high-tension pulse. The vessel wall may be felt to be uniformly thickened—the so-called “whip-cord” artery. As the muscular arteries are those chiefly affected, the radial and temporal arteries are frequently found to be involved. There may be the physical signs of hypertrophy of the left ventricle, reduplication of the second sound over the septum ventriculorum and accentuation of the aortic second sound. Later on the history may show great diversity. This is fully dealt with in Arterial Hypertrophy (see pages 945–946). If atheroma supervenes, the radial and temporal arteries frequently become irregularly thickened and tortuous.

Diagnosis.—In cases of persistent hypertension and cardio-vascular hypertrophy it is necessary to distinguish between hyperpiesia and chronic interstitial nephritis, in which connection the following are among the points which should be noted. In hyperpiesia the patient is often plethoric, with a high colour and well-nourished body, there is absence of symptoms of toxæmia, and the urine is of good colour and of normal specific gravity—indeed, it differs from healthy urine only in the presence of a trace of albumin and occasional casts of granular or hyaline kind; while in chronic interstitial nephritis there is often a sallow tinge in the complexion and loss of weight, gastric disturbance is more often that of hypochlorhydria than is the dys-

pepsia of hyperpiesia, and the urine is of low specific gravity. Further points in the differential diagnosis of hyperpiesia will be found on pages 945-946.

Prognosis.—This is dealt with on page 946.

Treatment.—Treatment is mainly prophylactic, hygienic and dietetic, the actual specific treatment being of far less value.

It is important first of all to review the ætiology of the condition. I would especially urge the importance of a searching inquiry for auto-intoxication—especially from the teeth (including X-ray examination), the tonsils, the accessory nasal sinuses, the colon, and the genito-urinary tract.

The value of rest, both physical and mental, in the management of high blood-pressure is great, and is not sufficiently appreciated. It is sometimes necessary to keep the patient in bed, the period varying according to the nature of the case. Rest, especially when combined with hepatic stimulation and suitable purgatives, may be sufficient. Exercise, provided it be moderate and regulated, also ranks high as a therapeutic measure, and this applies with suitable discrimination to any period of life. A cardinal rule in all cases should be that exercise should not be carried to the point of inducing increased frequency of the pulse or respiration, or indications of cardiac distress. It is much better to abstain from exercise soon after a meal, when rest should be enjoined for a period of half an hour to an hour. Walking is an excellent form of exercise; quiet cycling, golf and horse-riding are useful in some cases; while special forms of exercises, such as the Swedish form, and slow breathing exercises, are not infrequently of value. Sudden exertion, hurry, straining at stool, and mental strain of every kind should be carefully avoided.

The quantity of fluid taken with meals should be diminished; but, on the other hand, it is advisable to take a quantity of fluid from 1 to 2 hours before meals. My usual custom is to order the patient to take 1 or 2 tumblers of hot water, preferably soft or distilled, before breakfast and also before the midday meal, and perhaps in addition a tumblerful before going to bed. A preference is given by some to the mildly alkaline waters.

Some writers lay great emphasis upon the necessity for drastic regulation of the diet, and many patients are in consequence rendered miserable by the deprivations to which they are subjected in this respect. Whilst I am of opinion that regulation of the diet may be too drastic, I believe that the value of a regulated diet of moderate latitude may be great, and it is very important for the patient to avoid dietary excesses of all kinds, both in regard to the quantity and character of the food. In choosing a diet, therefore, for a patient suffering from supernormal blood-pressure, we should see that the number and bulk of the meals are limited, and that those articles of food which especially stimulate the cardio-vascular system are proportionally reduced: thus, the quantity of beef and mutton should be diminished below the proportion ordinarily taken, while the allowance of white meat, such as chicken and fish, may be correspondingly increased. In cases of moderately increased arterial pressure, my usual custom is to recommend a fair helping of meat once daily on 4 or 5 days in the week, fish and chicken being substituted on the remaining days. When the increase in blood-pressure is severe, the amount of beef and mutton should be decreased still further. Some authorities go further than this and recommend a reduction also in the quantity of veal, poultry and fish. Meat which has been boiled, and is taken without the

broth, is preferable to roasted meat taken with the gravy. Meat extractives, such as meat soups and gravies, should certainly be largely diminished or totally excluded from the dietary. An adequate supply of carbohydrate foods may be allowed, while the proportion of green vegetables and the simpler fruits should be increased. Some physicians, and especially Continental physicians, attach great importance to the diminution or exclusion of chlorides from the diet. If this view be correct, we should remember that the deprivation of the salt usually added at table is not enough; food-stuffs which, before being cooked, have the smallest proportion of salt should, therefore, be chosen. The late Sir William Roberts recommended chloride of potassium in place of chloride of sodium as a table-salt, but some have found it disagreeable to the taste. An exclusively milk diet for a few days, combined with rest, is useful in some cases. Tea and coffee in strict moderation may be allowed in most cases. Strict moderation in the use of tobacco should be enjoined. With regard to alcohol, my view is that it is better left alone altogether. If, however, the increase in arterial pressure be not considerable, a moderate amount may be allowed; and even in cases in which the increase of pressure is of severe grade, if the patient be made unhappy by being deprived of all alcoholic beverages, it becomes a question whether a certain allowance of alcohol should not be made, preferably avoiding wines and liqueurs.

Purgatives are certainly useful in the treatment of supernormal arterial pressure, and it should be noted that a slight laxative action of the bowels each day is of greater value than an occasional purge. In choosing an aperient, saline purgatives, as they induce fluid motions, are the most suitable, and should be administered in hot water some time before breakfast. It is advisable also to administer some mercurial preparation once a week at bedtime. Some writers are of opinion that the administration of mercury results additionally in vascular relaxation, and, if this be the case, minute doses of calomel may advantageously be given two or three times a day for a few weeks occasionally. Sulphur is also supposed by some to reduce the blood-pressure, as well as to act on the bowels. The functions of the skin should be attended to, and in this connection a warm equable climate and woollen underclothing, especially in winter, are to be commended. Cold baths are to be avoided; but a warm bath, the temperature of which is gradually lowered, may be taken daily. A Turkish bath once or twice a week, perhaps followed by massage, or hot packs about thrice weekly, may be of service. A regular course of balneological treatment is sometimes beneficial, and different kinds of baths, among these being the Aix-les-Bains douche, are in fashion in this country, and especially on the Continent. Recently diathermy has been advocated by some physicians. Venesection undoubtedly reduces high blood-pressure, but in my investigations at the Mount Vernon Hospital I found that, while it certainly acts rapidly, its effects are only transient; at the same time, it is undoubtedly of great value as a temporary measure.

It is not right, even if it were possible, to lower supernormal blood-pressure by drugs which act by diminishing the force of the cardiac action. We must, therefore, resort to drugs which are supposed to cause dilatation of the blood vessels, especially of the peripheral vessels; among these are sodium nitrite, erythrol tetranitrate, mannitol nitrate, and nitroglycerine. I must say, however, that in my investigations at the Mount

Vernon Hospital I had very disappointing results from the administration of drugs in severe degrees of supernormal blood-pressure, even with regard to their temporary results. If these drugs be used, we should see that those whose action is slowest and most prolonged are chosen, and administer them in increasing doses until the physiological effects are obtained, while they may be continued in rather smaller doses for considerable periods in suitable cases. Some authorities believe that the hippurates and benzoates are useful. The iodides have a great reputation in the treatment of arterial disease, but, in the investigations already mentioned, in no case was their administration followed by a reduction of blood-pressure. In some cases a single dose of 20 to 30 grains of one of the iodides at night-time is better than smaller doses three times a day. When the usual preparations cannot be borne, one of the iodine compounds may be tried. Some physicians advocate thyroid extract.

FREDERICK W. PRICE.

SECTION XIII

VASOMOTOR NEUROSES (ANGIO-NEUROSES)

UNDER this heading are described a group of conditions characterised by a predominance of symptoms of vasomotor disturbance and by the peculiarity of their distribution. Though the vasomotor changes are the prominent feature, sensory, secretory and trophic disturbances are associated. The symptoms of vasomotor neuroses are commonly regarded as due to disordered activity of the involuntary or vegetative nervous system. This hypothesis, however, is by no means equivalent to the theory that the involuntary nervous system is the starting-point of the condition. From this point of view, Raynaud's disease is regarded as an expression of vaso-constrictor spasm, erythromelalgia as the result of vaso-constrictor paralysis, and angio-neurotic oedema as an expression of vasomotor irritability. Variations in capillary permeability and tone are necessarily included in any conception of vasomotor neurosis. Vaso-dilator impulses must play their part in the production of these complexes, but they are not usefully included in any working hypothesis, so long as the anatomical distribution of the nerve fibres that carry these impulses remains in doubt.

The conditions to be described are called "neuroses," because a pathological lesion is not an essential part of their appearance and because they tend to occur in persons of an unstable nervous temperament. A hard-and-fast distinction is not to be drawn between these diseases occurring as neuroses and their occurrence in recognised pathological states, such as lesions of the spinal cord or brain (tabes dorsalis or hemiplegia), lesions of peripheral nerves (peripheral neuritis), and lesions of vascular channels, or local pressure effects, such as may result from a cervical rib: nor are they separated by any rigid line from slighter manifestations of vasomotor instability, such as are frequent in women at the climacteric, and in clinical disorders resembling exophthalmic goitre. They are undoubtedly akin to such common symptoms as flushings, cerebral hyperæmia, facial congestion, angio-spasm in all its varieties, tachycardia (in some of its forms), anginal attacks, migraine, vertigo, tinnitus aurium, universal or circumscribed hyperidrosis, and gastric disorders of certain functional types.

RAYNAUD'S DISEASE

Synonym.—Symmetrical Gangrene.

Definition.—A paroxysmal affection of the blood vessels of the extremities, frequently symmetrical, characterised by persistent ischæmia or a

passive hyperæmia, which leads to disturbance of function, or to a loss of vitality with necrosis.

Ætiology.—If the disease is regarded as an independent affection in which pathological changes in tissue structure are not responsible for the symptoms there is no actual cause. The affection is more common in women than in men, and occurs at any age, though most frequent in the second and third decades. It is chiefly due to a neuropathic diathesis; there may, therefore, be a congenital predisposition, or the affection may occur in more than one member of a family, and it is associated with hysteria, epilepsy and traumatic neuroses. Intestinal toxæmia is often a causative factor. Anæmia, exhaustion and congenital narrowness of the aorta (Oppenheim) predispose to it. It sometimes complicates diseases of the spinal cord, for example, tabes dorsalis, syringomyelia, disseminate sclerosis and tumours. A proportion of cases are due to syphilis, as was first suggested by Hutchinson; this may be congenital or acquired, and is said to be associated with syphilitic endarteritis in some cases. Cases due to malaria have been reported. Lead and tobacco are possible factors; with regard to the latter, its importance in thrombo-angitis obliterans, intermittent claudication and certain forms of angina is of interest. The condition has occasionally been observed after acute infections. Exposure to cold, mental emotion and trauma are exciting causes.

Pathology.—As an independent affection, a pure neurosis, it has no pathology. It is probably a vascular spasm, affecting arteries, capillaries and veins. Peripheral nerve changes have been observed and are probably secondary. Dehio observed endarteritis and endophlebitis. Vascular changes are not always present; also they may be secondary. When due to syphilis or disease of the nervous system, the pathology is that of the primary disease.

Symptoms.—The affection is characteristically paroxysmal. It may be preceded by great pain in the whole extremity, especially in its distal part, increasing with the onset, and becoming intense. The discomfort is not always limited to the extremity. The attack itself begins in the fingers or toes, with numbness and tingling, or pain. Later these parts are noticed to be white and cold, or waxen-white like dead fingers (local syncope); the vessels in this stage are contracted, so that no blood enters the part. After an interval of perhaps an hour or two, the fingers or toes become red and hot (active hyperæmia); the vessels dilate widely in this stage. More commonly there is an intervening period of local asphyxia, during which the affected part is deeply cyanosed—blue or blue-black—a condition which may persist, with variations, for days, weeks or months. It may be accompanied by swelling of the part. The process gradually subsides, or is followed by the stage of hyperæmia, and recovery occurs. Alternatively, gangrene develops, with the appearance of small black spots or vesicles filled with bloody fluid. These burst and a black scab forms, which gradually separates, leaving a scar, or an ulcer that heals slowly. In this way the pad of a finger may necrose, or the necrosis may involve the tip of the finger, the terminal phalanx, or the whole finger. More than one finger or toe may be lost in very severe cases. A line of demarcation gradually forms and the necrotic part separates. Movements of the affected part are stiff and slow, and their sensibility for all kinds of sensation is greatly diminished. In some cases the edges of

the ears, the tip of the nose, the chin, the lips and the eyelids are affected.

Mental depression accompanies a moderate or severe form of Raynaud's disease, and gastric disturbance; for example, anorexia and vomiting may precede or accompany an attack. Osler reported a case complicated with three attacks of aphasia with hemiplegia, ending in recovery. There may be affections of the special senses (hemipia, deafness, tinnitus and affections of the sense of taste), and albuminuria, glycosuria and hæmoglobinuria have been observed. An associated multiple arthritis is sometimes seen. The chronic form may progress to scleroderma; occasionally true generalised scleroderma begins with features of Raynaud's disease.

A severe attack lasts from 2 to 4 months or even longer. There may be no further attack, or there may be a recurrence after an interval of a year or more.

Mild degrees of Raynaud's disease scarcely merit the title, and are relatively common. Only a part of a finger, or one finger, or the fingers alone, or the hand as far as the wrist (often also the toes), go numb and white in winter or when bathing, and with a warmer temperature there returns the stage of active hyperæmia—the so-called "beef-steak" hand. The circulation may return to normal without a marked stage of hyperæmia. Chilblains belong to this group of vasomotor manifestations, and severe chilblains may lead to superficial necrosis. Transition forms between erythromelalgia and Raynaud's disease have been described.

Diagnosis.—Raynaud's disease differs from frost-bite in that the sequence of events in the former is usually syncope, cyanosis, hyperæmia, while in the latter it is hyperæmia, cyanosis, syncope. In mild and more chronic forms of the disease, the differential diagnosis from acroparæsthesia may be required. The age of onset is different. In general, acroparæsthesia is a subjective complaint. The feeling of numbness and tingling is continuous, and sometimes painful, and in rare cases there is evident pallor of the fingertips, but asphyxia and necrosis do not occur. The toes are rarely affected. Local gangrene of the toes occurs in senile and diabetic arterial disease. In both conditions arterial disease is a marked feature, and the pulse in the dorsalis pedis artery is generally imperceptible; the latter condition is obvious in the accompanying glycosuria. The differential diagnosis from thrombo-angitis obliterans is more difficult, since it occurs in the age period in which Raynaud's disease is most common, and in its early stages may closely resemble Raynaud's disease. The points of importance are its occurrence in male Jews of Polish extraction, excessive cigarette smoking, the asymmetrical distribution, and accompanying obliterative endarteritis and thrombosis of the vessels of the affected limb. As Osler remarks, necrosis in Raynaud's disease is a simple matter, as simple as if a string were tied tightly round a finger-tip. To this extent the possibility of self-mutilation requires mention. Leprosy is recognised by its specific characteristics. Erythromelalgia is not paroxysmal, is accompanied by swelling, does not involve local syncope, does not proceed to gangrene, and is aggravated by dependence of the part affected and by warmth.

Prognosis.—The prognosis to life is good, though in rare cases septic infection may cause death. Severe attacks are resistant to treatment. Relapses are common, but the attacks may subside as the patient gets older.

Treatment.--Syphilis, malaria, lead and tobacco, as potential factors, furnish, when present, direct indications for treatment. Measures to improve the general health, to strengthen the nervous system, and to protect the patient from worry and excitement should be employed. Careful investigation of the alimentary canal should be made for any cause of toxæmia, and any tendency to intestinal stasis should be corrected. In our opinion this factor is one of great importance in the causation of the disease. General hygienic measures, attention to clothing and choice of a suitable climate are matters for consideration. During an attack, physical and mental rest and warmth are urgently required. The affected limb should be elevated and wrapped in cotton wool. Great care should be taken to avoid slight injuries, such as might result from tight boots and the cutting of corns or nails. Gentle massage and dry warmth to the extremities may be of benefit. Electrical treatment is of definite benefit in the majority of cases. According to Cumberbatch, the galvanic current is the most effective method; he employs diathermy, however, as a preliminary measure in those cases in which there is gangrene, this to be followed by the use of the galvanic current after the necrosed portions have separated and the parts are completely healed. Treatment by the galvanic current lessens the frequency and severity of the attacks, and the patients note a feeling of well-being after each treatment. He applies the kathode to the spine over the cervical (or lumbar) enlargement of the cord. The hands (or feet) should be immersed in warm water and connected to the anode. A current of 20 to 25 milliamperes should be passed for 20 minutes. Treatment should be given thrice weekly. Thyroid extract is well worth a trial, but other drugs are of little value, though calcium lactate in 15-grain doses, given three or four times daily, has proved useful in some cases. The drug sometimes relieves chilblains. Chloral or morphine may be given for the relief of severe pain.

ACROPARÆSTHESIA

Definition.--A vasomotor neurosis, characterised by paræsthesiæ of the hands, especially affecting the finger-tips.

Ætiology.--The condition is usually observed in women, especially at the climacteric. It rarely occurs before the age of 30. It is frequently associated with a neuropathic diathesis and a lowered vitality due to any cause. General causes include such conditions as inanition, cachexia, anemia and pregnancy. Local causes are exposure to cold, particularly cold water, or to alternate hot and cold water as experienced by washerwomen.

Symptoms.--The onset is insidious and the symptoms are almost entirely subjective. The affection is often limited to one hand or certain fingers, the toes rarely being affected. The patient complains of numbness, tingling, formication of the fingers or tenderness of the finger-tips. There may be slight loss of sensibility in the finger-tips and occasionally evident pallor.

Diagnosis.--The condition is readily distinguished from Raynaud's disease by the absence of local asphyxia. It is important to exclude any affections of the spinal cord, such as *tubercles dorsalis*.

Prognosis.--The complaint tends to be continuous and persistent. The

outlook regarding recovery is not good, unless the condition is due to a recognisable and removable cause. There are, however, no complications.

Treatment.—This is directed to the removal of the cause, and improvement of the general health and of the local circulation. Salicylate of soda and bromides are often helpful, and radiant heat and massage are of value.

ANGIO-NEUROTIC OEDEMA

Synonym.—Quinke's Disease.

Definition.—A paroxysmal affection, characterised by the appearance of circumscribed œdematous swellings of the skin and subcutaneous tissues of transient duration. The mucous membranes are sometimes affected.

Ætiology.—Heredity is an important factor. Osler reported the case of a family in which five generations had been affected, involving 22 members. The condition is more common in men than in women, and generally affects the young. Those attacked are usually of a nervous disposition. Neurasthenia, hysteria and rarely exophthalmic goitre are associated conditions. Garrod has reported a case in which each recurrence of periodic hydrarthrosis was attended by circumscribed œdema, either of the lips or eyelids. The attacks may coincide with menstruation. The exciting cause is generally difficult to determine. It may be mental emotion, exposure to cold, or trauma. Local trauma sometimes determines not only the onset but the site of an attack, as in a case recently reported in which riding provoked an attack on the inner aspect of the thighs and knees.

Pathology.—In the absence of a known pathology various theories have been advanced to explain the condition. Local venous spasm, a direct nervous influence on capillary walls, as a result of which the permeability of the vessels is increased, and, more recently, the local action of a circulating toxin on the capillary walls, are theories which have obtained support. With regard to the last named, Garrod has drawn attention to the joint swellings that frequently accompany erythematous and urticarial rashes resulting from known toxic causes. Such conditions form a part of the clinical picture of serum sickness, or may occur after taking certain articles of diet, or as the result of stings of insects or nettles. This thesis illustrates the present view of angio-neurotic œdema as being a local expression of the presence of a circulating toxin, prone to occur in persons of **nervous** temperament, rather than a disease *sui generis*. The patients often show other signs of vagotonia, especially in their sensitiveness to foreign proteins.

Symptoms.—The complaint takes the form of acute circumscribed swellings of the skin and subcutaneous tissues, 1 to 4 inches in diameter. The swellings are rounded, painless, rarely itch, and are generally pale or sometimes redder than the surrounding skin, from which they stand out prominently. They may develop simultaneously in different parts of the body, and disappear in a short time. They may recur repeatedly, or only after a period of years; the recurrence is occasionally periodic. They occur most commonly in the eyelids, lips, cheeks and backs of the hands, and are asymmetrical. The whole side of the face, one side of the scrotum, the penis, a whole limb, or in fact any part of the skin, may be involved. The pharynx, tongue and conjunctivæ may be implicated. (Edema of the glottis is very

rare, and has proved fatal. Swelling of mucous membranes may lead to symptoms of gastro-intestinal disturbance, such as nausea, vomiting and abdominal pain (colic). Cases in which hæmorrhage from mucous membranes, stomach, bronchi, bladder, etc., occurred have been reported. Hæmoglobinuria has been observed; in such a case a Wassermann test is indicated. The attacks are generally afebrile, and there is no constitutional disturbance, unless the stomach or intestine is involved.

Course.—This is variable. Recurrence is frequent, often at intervals of 3 to 4 weeks, but sometimes after long intervals. It is rarely periodic.

Diagnosis.—The complaint is so characteristic, in the sudden onset and rapid subsidence of asymmetrical rounded swellings, that it is hardly likely to be confused with other affections. The condition is nearly allied to urticaria, from which it is distinguished by the circumscribed and deep-seated nature of the swellings and the absence of itching. No distinction is made between angio-neurotic œdema and giant urticaria.

Treatment.—The general health must receive first attention, and a saline purge is indicated. Both arsenic and quinine have been warmly advocated. It is advisable to avoid any particular protein in the food which is found to excite attacks. When the attacks occur after a particular meal of the day, a capsule containing 1 to 2 grains of peptone half an hour before that meal appears to have an effect in temporarily desensitising the body against foreign protein. This, combined with 5 to 7½ minims of the tincture of belladonna and 10 to 15 grains of calcium lactate after meals, has prevented recurrences in several cases. The former drug diminishes the vagal hypersensitiveness, and the latter increases the viscosity of the blood. One of the most useful forms of treatment for the relief of the paroxysm is a subcutaneous injection of 3 to 7 minims of liquor adrenalin hydrochlorid. This excites the antagonistic action of the sympathetic. When the tongue is involved the patient should be given one or two of Armour's suprarenal tablets to suck. Pituitrin injections have also been recommended. Bromide is often helpful as an additional measure when the symptoms are marked. In severe cases the intravenous injection of small doses of peptone might be considered. Autohæmotherapy has proved useful in some cases.

Intermittent Hydrarthrosis, which is described fully under "Diseases of the Joints" (p. 1256), presents some interesting affinities with the vasomotor neuroses, particularly in its association with angio-neurotic œdema.

ERYTHROMELALGIA

Definition.—A rare condition characterised by pain and redness of the skin at the distal parts of the feet, and less often of the hands.

Ætiology.—Little is known of the ætiology of the disease. Men are more frequently affected than women. The condition may occur in the course of a disease of the central nervous system, such as hemiplegia, disease of the cauda equina, and disseminate sclerosis. Exposure to cold is the important exciting cause.

Pathology.—Disease of the peripheral arteries—a chronic endarteritis—has been described in three cases by Batty Shaw. Changes in the peripheral

nerves have been held responsible, and Weir Mitchell found marked degeneration of the fine nerve branches in one case. Others regard the malady as an angio-neurosis, the antithesis of acroparæsthesia and Raynaud's disease, and possibly a primary involvement of the vaso-dilators. The suggestion has also been put forward that it is due to a spinal disease, involving the lateral grey matter of the cord.

Symptoms.—The first case was described by Weir Mitchell, and was that of a sailor, aged 40, whose first complaint, following an African fever, was of "dull, heavy pains at first in the left, and soon after in the right foot. There was no swelling at first. When at rest he was comfortable, and the feet were not painful; after walking the feet were swollen. They scarcely pitted on pressure, but were purple with congestion; the veins were everywhere singularly enlarged, and the arteries were throbbing visibly. The whole foot was said to be aching and burning, but above the ankle there was neither swelling, pain . . . nor flushing."

Pain is generally the first symptom, rapidly followed by redness and swelling, most marked in the terminal phalanges of the toes or fingers. The pain is generally severe; at first it occurs only in the evening, but later it becomes chronic or remittent and may be agonising. The redness may increase to cyanosis. The swelling is more marked in the latter part of the day, and is aggravated by standing, walking, dependence of the limb and by heat. These symptoms are relieved by cold and recumbency. Hyperidrosis of the affected part is not uncommon. The condition may be complicated by general weakness, vertigo, headache, palpitations and tachycardia. Its complication with erythræmia has been described.

Prognosis.—The complaint is intractable, and tends to persist, with exacerbations and remissions, for many years.

Treatment.—Faradism and cold have been recommended. Analgesics are required for the relief of pain, which may even necessitate amputation (Shaw). Excision of the nerve supplying the affected parts has been followed by relief (Dehio, Weir Mitchell); gangrene has, however, resulted from this operation.

MILROY'S DISEASE

Synonym.—Hereditary Œdema.

Definition.—In 1892 Milroy described a persistent œdema of the legs, occurring in the absence of any of the known causes of œdema, affecting members of the same family in successive generations.

Ætiology.—The disease has occurred in six generations of the same family, but the percentage of incidence in the families has varied greatly. It is apt to appear in neurotic families. Both sexes are affected about equally, and the œdema may either appear soon after birth, or its onset may be delayed even to adult life.

Pathology.—Nothing is known of the pathology of the condition. There is no evidence of venous or lymphatic obstruction.

Symptoms.—Only the legs are affected, and these to a variable extent. Thus the swelling may be limited to the ankles; it usually does not extend beyond the knees, but may reach the thighs in long-standing cases. Gradually

the affected part becomes hard and brawny. The swelling increases in the standing posture, and, once established, it is permanent. There is no pain or redness, the veins are not enlarged, and the general health is not affected.

In some cases there are acute attacks accompanied by fever and pain.

Diagnosis.—This is made on the familial incidence, and the absence of all other recognised causes of œdema.

Prognosis.—The affection does not tend to shorten life.

Treatment.—The affected parts should always be kept bandaged with crêpe, as by this means the swelling can be kept under control, and the patient remains capable of strenuous exertion; but if such measures be not employed the œdema gradually extends. Acute attacks may require opium internally, and evaporating lotions locally.

W. LANGDON BROWN.
GEOFFREY EVANS.

SECTION XIV

DISEASES OF THE RESPIRATORY SYSTEM

THE PHYSICAL SIGNS IN THE CHEST IN HEALTH AND DISEASE

ACCURATE diagnosis in diseases of the air-passages and lungs depends very largely upon careful observation and record of physical signs, especially in their relation to subjective symptoms. Unfortunately, there is no strict uniformity in regard to the nomenclature of physical signs. It is, therefore, desirable to define explicitly the sense in which the various technical terms used in this section are employed. At the outset, it is well to emphasise the importance of a careful and methodical examination in every case. The *magistral* sequence of inspection, palpation, percussion, auscultation and *mensuration* has more than the sanction of tradition to commend it. Unless confined to bed, the patient should be examined both in the erect and recumbent positions in all cases of difficulty.

Inspection.—The patient being placed in a good light, the configuration of the chest, the range and character of the respiratory movements, and the position of the cardiac pulsations should be carefully noted. Most of the terms used in this connection, such as flattening, retraction, recession of intercostal spaces and diminished movement are self-explanatory.

The respiration may be unduly slow or rapid. Quickening of the rate is referred to as *hyperpnœa*, and if associated with distress—as *dyspnœa*.

Dyspnœa may be inspiratory, expiratory, or spasmodic. A peculiar periodic disturbance of the respiratory rhythm is that referred to as *Cheyne-Stokes breathing*. In this condition, the respiratory movements wax and wane in short periods of *dyspnœa*, each followed by an interval of *apnœa* or cessation of respiration lasting up to 30 or 40 seconds. It is due to deficient aeration of the blood and is met with in respiratory, cardiac and renal disease, and also in cerebral lesions and after some poisons.

A variety of grouped breathing is *Biot's breathing*, sometimes seen in tuberculous meningitis. The *hyperpnœic period* consists of a few breaths, deep or of increasing depth, followed by *apnœa* without the waning.

Certain abnormal forms of chest configuration are described: The *alar-phthinoïd* or *pterygoid* type of chest is long, narrow and flat, with winging of the scapulæ, the subcostal angle is narrow and the upper interspaces are wide. The *emphysematous* or barrel-shaped chest is broad and rounded, the angle of *Ludovici* is prominent, the subcostal angle is wide, and the movements are restricted. The *pigeon breast* is characterised by prominence of the sternum, with sloping anterior thoracic walls. The *funnel breast* is

the converse of this, with depression of the lower end of the sternum and of the cartilages attached to it.

Palpation.—Vocal fremitus or tactile fremitus is the vibration felt over the lung when the hand is placed flat upon the chest-wall without pressure and the patient says “ninety-nine” or some other resonant syllables. Vocal fremitus may be increased, decreased or absent in disease.

Tussive fremitus.—The similar vibration felt during cough.

Rhonchal fremitus.—The vibrations communicated to the chest-wall by sonorous rhonchi and felt by the hand in bronchitis.

Friction fremitus or pleural fremitus.—A rubbing sensation communicated to the palpating hand in certain cases of dry pleurisy. A similar fremitus is occasionally felt in pericarditis.

Percussion.—This consists in tapping the chest-wall over the lung and observing the note produced and the sense of resistance felt. Percussion may be *direct* on to the chest-wall or *mediate*, when the tap is made on to a finger or an instrument placed on the chest. The applied finger or instrument is called the pleximeter, the tapping finger or instrument, the plessor. Percussion should always be light, except over very muscular parts of the chest.

Normal resonance is the note obtained over healthy lung tissue.

Hyper-resonance is an increased resonance, with diminished sense of resistance obtained over emphysematous lung tissue.

Dullness is diminution or loss of resonance, with increase in the sense of resistance. Various degrees of dullness are described, such as impaired percussion, slight dullness, flat, wooden or stony note.

Tympanitic resonance—a hollow drum-like note.

Skodaic resonance—a clear, high-pitched note intermediate in character between the hyper-resonant and tympanitic notes.

Cracked-pot sound—or *bruit de pot fêlé*—a hollow note with a slight jingle added to it, obtained by smart percussion over a fair-sized cavity. It is also heard on percussion of a crying baby.

Auscultation.—The breath sounds should be listened to first, then the adventitious or added sounds, and lastly the vocal resonance.

BREATH SOUNDS.—The following varieties of breath sounds may be differentiated:

Vesicular breathing.—The normal respiratory murmur or faint rustling sound audible during inspiration and expiration, the former phase being two or three times as long as the latter. The pause between inspiration and expiration is short.

Cog-wheel, jerky or interrupted breathing is a form of vesicular breathing in which inspiration waxes and wanes, or is divided into two or more parts.

Harsh, exaggerated or puerile breathing.—An intense form of vesicular breathing heard in children and in some forms of emphysema.

Vesicular breathing with prolonged expiration.—There is no alteration in the intensity or pitch of inspiration, but expiration is more prolonged and often harsher.

Absent, diminished, weak and suppressed breathing are self-explanatory.

Bronchial breathing.—The pitch of both inspiration and expiration is raised. Expiration is as long as inspiration and is separated from it by a distinct pause.

Broncho-vesicular and vesiculo-bronchial breathing are incomplete forms of bronchial breathing in which inspiration or expiration respectively assume the bronchial type.

Tubular breathing is a peculiar form of high-pitched bronchial breathing of whiffing character, sounding as if produced close under the stethoscope. This term is often used as if synonymous with bronchial breathing, but should be restricted to breathing of the type just described, which is only heard in consolidation from lobar pneumonia and broncho-pneumonia and in collapse of the lung, including that form associated with pleural effusion.

Cavernous breathing is bronchial in type, but both inspiration and expiration have a peculiar hollow character. Expiration is hollower and more prolonged than inspiration.

Broncho-cavernous breathing is incomplete cavernous breathing, inspiration being bronchial, while expiration is cavernous.

Amphoric breathing.—An intense form of cavernous breathing, often having a very hollow metallic sound.

ADVENTITIOUS SOUNDS.—These were formerly divided into dry and moist. The former are now called rhonchi, the latter râles.

Rhonchi are musical sounds produced by the passage of air over mucus or muco-pus in the bronchi. Those arising in the larger tubes are called sonorous rhonchi, those in the smaller tubes sibilant or whistling rhonchi.

Râles are bubbling or crackling sounds produced in the bronchi or alveoli by the passage of air through fluid exudate or secretion. They are usually divided into bubbling and crackling râles. Bubbling râles are heard when the lung tissue is still spongy. Crackling or crepitant râles are produced in consolidated or softening areas of lung. Both varieties are arbitrarily subdivided into fine, medium and coarse râles. Crepitant râles are sometimes referred to as "creps"; this practice may lead to confusion with crepitation and is better avoided. Crepitant râles were formerly called consonating, bubbling râles non-consonating. Gurgling râles are coarse, low-pitched râles, usually heard over a cavity, especially after cough.

Crepitations are fine "hair-like" crackling sounds. They may be produced either in the pleura or in the lung. In the latter they occur only in pneumonia, broncho-pneumonia, collapse and œdema. They are heard chiefly with inspiration and may be increased in number and intensity by coughing. A coarse variety heard in resolving pneumonic lung is called *redux* crepitation.

Pleural crepitations are fine sounds of similar character occurring in the early or dry stage of pleurisy. They are heard rather towards the end of inspiration and are usually unaffected by cough.

Friction is a coarse rubbing, creaking or grating sound heard in pleurisy when there is rough exudate on the pleural surfaces. It may occur with either inspiration or expiration or with both.

Stridor is a loud, coarse sound, heard chiefly during inspiration in cases of obstruction of the larynx, trachea or main bronchi. It is louder and lower pitched than a rhonchus.

Post-tussive suction is a hissing sound, audible directly after cough. It is heard only over a cavity, and is caused by the influx of air to replace that expelled by cough.

Veiled puff of Skoda or Laennec is a puffing sound heard towards the end of inspiration. It is said to indicate small and sacculated bronchiectatic dilatations.

Metallic tinkling and amphoric echo are terms used to describe the quality of certain sounds produced near a very large cavity or a pneumothorax, in breathing or coughing, or by the heart's action. The latter is practically a low-pitched variety of the former.

Succussion splash is a splashing sound produced in a hydro- or pyopneumothorax by shaking the patient, or getting him to shake his thorax. If a gastric splash can be excluded, it is pathognomonic of a pleural or subphrenic hydro- or pyopneumothorax.

Bell sound or *bruit d'airain*.—A ringing sound heard on auscultation over a pneumothorax or any large cavity when a coin placed flat on the chest-wall over the air-containing space is tapped by a second coin. A similar sound is often audible on flicking with the finger and thumb over the chest-wall under similar conditions.

VOICE SOUNDS or Voice Conduction.

Vocal resonance is the muffled sound on listening over normal lung when the patient articulates " ninety-nine " or some other resonant syllables.

Bronchophony is an increase in the intensity of the normal vocal resonance.

Pectoriloquy is conduction of the articulate voice sounds which are clearly heard as if spoken into the stethoscope. It is best appreciated by auscultating the whispered voice, and is then called whispering pectoriloquy.

Egophony denotes a peculiar bleating or nasal modification of the voice sounds, sometimes present on listening to them through fluid in the pleural cavity.

Physical examination of the chest includes mensuration, estimation of vital capacity and examination by the X-rays when these are necessary.

Vital capacity is determined by a spirometer, which measures the amount of air which can be expired by a full expiration after the deepest possible inspiration. The average for an adult man is about 3600 c.c. The vital capacity is diminished in many diseases of the respiratory system, notably in acute pneumonia, pulmonary tuberculosis and in attacks of asthma.

DISEASES OF THE NOSE

ACUTE CATARRHAL RHINITIS

Ætiology.—This affection is part of a coryza or " cold " and is produced not by one specific bacillus, but by various organisms, some of which are present in the throat in health. Among those which are known to be causative are Friedländer's bacillus, *Micrococcus catarrhalis*, *Bacillus septus*, *B. influenza*, pneumococcus, and probably the pyogenic staphylococci and streptococci. Its ætiology is, therefore, largely a matter of the relative susceptibility of the subject and virulence of the invading organism; this virulence is increased by passage through a susceptible person who often

imports colds into a household, and then infects the less susceptible members. Chilling of the body lowers the resistance, and, of all things, a draught in a hot ill-ventilated room most predisposes to infection; but an open-air life is the best safeguard against catching cold. Acute rhinitis is also a symptom of the infectious fevers, especially of measles and influenza.

Symptoms.—At first there is a feeling of dryness and discomfort in the nose or naso-pharynx, with malaise and with or without fever, followed by nasal obstruction, watery discharge and often lachrymation and sneezing. Later, the discharge becomes muco-purulent. The entire attack usually extends over a period of 2 weeks, but a chronic rhinitis may be set up and persist indefinitely. Vasomotor rhinorrhœa closely resembles the acute stage of a coryza, but is much more variable and transient.

Complications.—In simple cases, but more often in those due to the infectious fevers, acute inflammation of the accessory nasal sinuses, or of the ears, may occur. In some cases the inflammation regularly extends down the throat and causes laryngitis, tracheitis or bronchitis.

Treatment.—This is often disappointing and few persons will take the trouble to treat a cold efficiently, but singers and other professional voice-users, as well as patients subject to bronchitis, should submit to treatment. In the earliest stage, it is possible to abort a cold by obtaining free diaphoresis; the patient should be warmly wrapped up in bed and take hot drinks, with or without alcohol; quinine, 5 grains every 2 hours for 3 or 4 doses, or 10 grains of Dover's powder; the essential oils of the odoriferous plants are excreted by the respiratory tract, and are much used in this connection; onions are a household remedy, cinnamon is efficacious in large doses, 1 drachm of the essence in hot milk several times a day, and menthol and eucalyptol may be used in an atomiser. Especially after the early stage is passed, spraying or syringing the nares with warm normal saline, or with Dobell's solution, relieves discomfort and tends to prevent the discharge from becoming purulent.

The frequency and severity of attacks may often be diminished in highly susceptible persons by inoculations with an autogenous vaccine prepared from organisms derived from the patient's nasal secretion or by a "stock" vaccine containing the usual causative germs.

CHRONIC CATARRHAL RHINITIS

Ætiology.—Simple chronic rhinitis appears to result from frequently occurring attacks of coryza, or even from the persistence of a single acute attack. Predisposing causes of this persistence are deficient resistance, local irritation, auto-intoxication from the gastro-intestinal tract, and reflex vasomotor disturbance. Thus we find chronic catarrh associated with anæmia, stuffy and over-heated rooms, occupations involving inhalation of irritating dust or vapour, excessive smoking, snuff-taking (a commoner habit than is generally realised among shop-assistants and clerks who are prevented from smoking during working hours), dyspepsia and constipation, alcoholism, sexual excess and masturbation. Nasal obstruction is an important factor in keeping up chronic catarrh by preventing ventilation of the passages, allowing mucus to collect and encouraging the growth of micro-

organisms; in children the presence of adenoids is the commonest cause of catarrh.

Symptoms.—The symptoms are excessive secretion, which may be watery or muco-purulent, and may come forwards to the nostrils or pass backwards into the throat ("post-nasal catarrh"), and nasal obstruction. Secondary results, from the extension of the inflammation, include catarrhal and suppurative otitis media, pharyngitis, laryngitis and bronchitis.

The nasal mucosa may be reddened, but often has a pale, sodden appearance. The turbinals are swollen and are at first quite soft, but later, when definite thickening has occurred, they feel firmer, and no longer shrink after the application of cocaine or adrenalin. At this stage the condition may be called "hypertrophic rhinitis," and the mucosal thickening, most marked over the two ends of the inferior turbinals and over the lower margin of the middle turbinal, may form large lobulated masses.

Diagnosis.—The diagnosis, in cases of hypersecretion, can only be made after excluding by rhinoscopic examination all other causes, such as a foreign body, mucous polypus, syphilitic, tuberculous and lupoid ulceration, and, more especially, suppuration in any of the accessory sinuses; in the latter, the discharge is not scattered over the nasal passages, but emerges in a localised stream from one or other of the ostia and reappears in the same situation after being removed. The discharge of chronic rhinitis is bilateral, and, though often muco-purulent, is never true pus. The diagnosis from vasomotor rhinorrhœa is often difficult; the symptoms of the latter come and go with great suddenness, often as a result of definite causes such as going into a hot room, and there is complete absence of symptoms between the attacks; a bacteriological examination is often helpful.

Treatment.—General treatment, directed to the predisposing causes mentioned above, is necessary if a good result is to be obtained. Next, nasal obstruction must be removed, and operative treatment is called for if the cause be adenoids, deviation of the septum, or great hypertrophy of the extremities of the inferior turbinal bodies. For details, the reader is referred to surgical works; but it must be emphasised that the valuable secreting surface of the nasal mucosa must not be recklessly sacrificed, and that large portions of inferior turbinal must on no account be removed, nor should every slight deviation of the septum be submitted to operation, for it is rarely quite straight. When the turbinal enlargement is soft and shrinks after the applications of cocaine, the galvano-cautery should be used under local anaesthesia to draw one or two lines along the length of the inferior turbinal, the result of which is to produce a scar binding the mucosa to the bone. When the case has not gone on to definite hypertrophy, the most valuable form of local treatment is cleansing of the nasal passages. The lotion must be warm, about 90° F., and quite unirritating; for this reason it should have approximately the same specific gravity as serum, and normal saline solution does very well. A mildly antiseptic and alkaline lotion is usually to be preferred, of which Dobell's solution is the type, such as sodium bicarbonate, grs. iij; sodium chloride, grs. iij; carbolic acid, gr. i; glycerine, ℥ xlvi; water, ℥i. A convenient instrument for the purpose is a small rubber ball of a capacity of 2 oz. with a blunt nozzle moulded in one piece, which is slowly emptied into the nostril, while the patient breathes deeply through the mouth and inclines the head forward over a basin; in this way

the palate is raised and the lotion passes through the naso-pharynx and out by the other nostril. The nose must not be violently blown afterwards, nor must any force be used during syringing, or fluid may be injected into the Eustachian tubes. Occasionally syringing causes headache, in which case the lotion may be used in a coarse spray-producer. Chronic nasal catarrh is, however, in certain cases notoriously resistant to treatment, especially under the conditions of civilised town life; indeed, many sufferers found themselves better in the wet and exposure of life in the trenches. Vaccine therapy is uncertain in its effect, but gives good results in a proportion of cases; an autogenous vaccine should be prepared from the patient's nasal secretion.

RHINITIS SICCA

This is a condition which results from failure of the nasal mucosa to secrete enough fluid to saturate the inspired air without itself becoming dry, and is frequently accompanied by dryness of the pharynx and larynx.

Ætiology.—The cause is found in any constitutional disturbance which interferes with free nasal circulation and secretion, such as anæmia, dyspepsia or alcoholism, and in breathing unusually hot dry air, as by cooks or stokers. As a temporary disturbance it is a usual accompaniment of any febrile condition.

Symptoms.—Small dark scabs of dry mucus are found especially where the current of air most impinges, on the front end of the middle turbinal and more particularly on the anterior inferior portion of the septum. In the latter situation the scabs are removed by blowing or picking and leave a small erosion, which is the commonest source of epistaxis. Sometimes the septal cartilage is completely perforated; this, the so-called "idiopathic perforation," is smooth and round and always limited to the cartilage, which serves to distinguish it from syphilitic perforation which usually involves the bony septum; the perforation due to lupus is, like the idiopathic variety, limited to the cartilage, but can be distinguished, in the active stage, by the characteristic nodules and by coexisting lesions elsewhere.

Treatment.—This consists in dealing with the anæmia, constipation, etc., avoidance of dust and excessive alcohol or tobacco, and the use of an emollient spray, such as menthol, grs. x, paraffinum liquidum, ʒi; or for erosions on the front of the septum an ointment, e.g., ung. hydrarg. nitrat., ʒi, vaseline, ad ʒi.

ATROPHIC RHINITIS

Ætiology.—Cases usually first come under treatment between the ages of 15 and 18, but its insidious beginnings date from an earlier age, and a history of nasal discharge through childhood is often obtainable. It affects females at least three times as often as males. A peculiar physiognomy is to be noticed in nearly half the cases; the skull is brachycephalic, the nose wide and flat, and the nostrils broad, and so directed forwards as to be more than usually conspicuous. The affection is sometimes unilateral, in which case the septum is deflected, and the disease occurs on the wider side. Occasion-

ally it is found among several members of a family, which might be the result of contagion, but it is also inherited in circumstances where contagion cannot apply, and this may be due to inheritance of the disease or merely of the predisposing physiognomy. Of the many bacteria found in association with the affection, the most important are the Klebs-Loeffler bacillus, the *Coccobacillus fatidus* of Perez, and the *Cocco-bacillus mucosus* of Beeritz, but the consensus of opinion is that they are secondary and, though helping to produce the fœtor, are not the primary cause of the disease. The condition occurs at too early an age to be the final stage of hypertrophic rhinitis, nor is it usually due to accessory-sinus disease, which can be excluded in the majority of cases. It is probably the sequel of prolonged purulent rhinitis in childhood, which results in the replacement of the ciliated by squamous epithelium, and thus destroys the principal agent for the removal of secretion; the undue width of the nasal passages promotes this retention by diminishing the force of the expulsive current of air, by drying the secretions and by unduly admitting dust and micro-organisms. In this way crusts of dried mucus are formed and decompose, and the resulting inflammation prevents the development of the turbinals and further increases the width of the nasal fossæ.

Pathology.—There is a chronic inflammation resulting in sclerosis and atrophy of the mucosa; the ciliated epithelium is replaced by squamous, the mucous glands are degenerated and the venous sinuses have disappeared. These changes are most marked over the inferior turbinals, and the middle turbinals are frequently large and œdematous. The discharge is not pus, but mucus precipitated by evaporation, mixed with shed epithelial cells and teeming with micro-organisms. This collects and dries into large greenish-black crusts which give rise to the peculiar sweetish and horribly offensive odour. There is never true ulceration or necrosis of bone.

Symptoms.—The symptoms are chiefly those of the nasal discharge and the offensive stench; the latter is rarely perceptible to the patient, who usually, in established cases, has complete anosmia. There are also obstruction from the crusts, dryness of the throat and cough, and often some degree of ill-health from toxic absorption.

The inside of the nose is full of crusts; the inferior turbinals are reduced to mere ridges, the mucosa is pale and thin, and through the widened nasal passages the body of the sphenoid and the wall of the pharynx are plainly visible.

Complications.—Infection of an accessory sinus may result by extension from the septic nasal cavities, but is not very common; conversely suppuration of the sphenoidal or a posterior ethmoidal cell is a possible, and has been considered by some authorities as the usual, cause of the affection. The lymphoid tissue of the throat is conspicuously absent; there is often a dry pharyngitis and laryngitis, and sometimes the crusting extends to these parts, or even down the trachea. Catarrhal and suppurative otitis are common, and the disease is thought by many to predispose to pulmonary phthisis.

Prognosis.—As the ciliated epithelium can never be replaced, the affection is not truly curable, though regular treatment can keep it in an inoffensive condition, and it is common to see a suggestive degree of atrophy of the turbinals in young people with rhinitis completely disappear under treatment.

Also, the crusting tends to become less troublesome as time goes on and ultimately to cease, a state of things which is difficult of explanation.

Treatment.—The nose must be kept clean by regular syringing with a mild alkaline antiseptic lotion, of which a large quantity should be used with a Higginson syringe provided with a fine nozzle which cannot block the nares. An oily, stimulating or emollient application, such as oleum eucalypti 15 minims to 1 ounce of paraffinum liquidum, or a 25 per cent. solution of glucose in glycerine, may be painted or sprayed into the nose. The crusting can be prevented by excluding the air, and when syringing is insufficient, this should be done by introducing a plug of gauze or cotton wool loosely into the anterior nares. After some weeks of treatment the packing may be omitted, but resumed in the event of a relapse. On removal of the plug the discharge is seen to be a clear mucus; if pus is found, it must be traced to its source in an accessory sinus. Paraffin wax may be injected under the mucosa, to narrow the nasal passages, but it is liable to slough out, and a piece of costal cartilage has been implanted with the same object. Recently a plastic operation has been devised to shift the antro-nasal wall inwards and has given encouraging results. The treatment of anæmia is important: good food and an open-air life, especially at the seaside, are beneficial.

MEMBRANOUS OR FIBRINOUS RHINITIS

The Klebs-Loeffler bacillus produces in the nares two very different clinical conditions: a true nasal diphtheria which is then usually of a severe type, and a purely local affection known as fibrinous rhinitis. This latter occurs in children and is not associated with any marked constitutional disturbance nor followed by paralysis; it appears to be slightly infectious, as such, but not to give rise to true diphtheria, and therefore does not require notification.

Treatment.—The treatment consists in cleansing the nares with the usual mild alkaline lotion, and a spray of liquid paraffin; strong antiseptics and forcible removal of the membrane only do harm, and antitoxin is useless.

EPISTAXIS

Ætiology.—The causes of epistaxis may be classified as follows:

Local causes.—Traumatism, including blows on the nose, fracture of the base of the skull, surgical operations, foreign bodies; the small septal erosion of rhinitis sicca, which is the commonest of all causes; malignant disease; angio-fibroma, or “bleeding polypus,” of the septum; multiple telangiectasis, a curious hereditary affection characterised by numerous minute dilations of the capillaries on the face and mucous membranes of the nose, mouth and throat; the general congestion caused by adenoids; and syphilis, lupus and the rarer granulomata, though in these the bleeding is usually an insignificant symptom.

General causes.—High blood-pressure, as in arterial disease, chronic nephritis, cirrhosis of the liver, violent exertion, extremes of heat and cold, congestion at the menstrual period, or “vicarious menstruation”; venous congestion, as in mitral stenosis, tumours in the thorax or root of the neck,

emphysema, bronchitis and whooping-cough; toxic blood conditions, as pernicious anæmia, leukaemia, purpura, scurvy, and all the acute infectious fevers, especially in the prodromal stage. To these may be added rarefaction of the air, as in aeroplane ascents and mountaineering, and poisoning by some drugs, especially salicylates and quinine.

The *source of the bleeding* is, in the large majority of cases, a small spot, called Little's or Kisselbach's area, situated on the front and lower part of the septum just beyond the vestibule.

Treatment.—Epistaxis, of sufficient severity to call for the attention of the doctor, should always be treated, though it is of course of comparatively little importance in healthy young people; in older patients with high blood-pressure the loss of blood may be beneficial, but the occurrence is so distressing and alarming to the patient that other means to lower the pressure should be adopted.

The source of the bleeding is so far forward that a pledget of wool introduced for less than an inch into the naris, and held by compressing the nostrils, will generally control it temporarily. To arrest it and prevent recurrence, the bleeding spot must be found, started if necessary with a probe, controlled by application of cocaine and adrenalin on a plug of wool, and sealed by the galvano-cautery at dull-red heat. The use of an emollient ointment during the separation of the scab is advisable. In obstinate cases the bleeding may recur from another spot or from the opposite naris, when the treatment must be repeated. As in other forms of hæmorrhage, a rapid excited heart's action, associated with restlessness and fright, is often present, and an injection of morphine is of great value. Calcium lactate is often recommended and may be given in 20-grain doses three times a day for 2 or 3 days; or colloidal calcium may be injected subcutaneously. If the bleeding is from the usual situation, formal plugging of the nose is seldom called for; but sometimes the bleeding proceeds from farther back in the nose, or is so profuse that its situation cannot at first be determined. In such cases the naris should be evenly packed with ribbon-gauze introduced on forceps under inspection. The older method of plugging the posterior nares is seldom or never required. Nasal plugs quickly become septic, and should ordinarily be removed in 24 hours; but they may be kept sweet for several days, should it be necessary to retain them, by moistening them frequently with peroxide of hydrogen.

MUCOUS POLYPUS

Ætiology and Pathology.—Nasal polypi are rare before puberty and are somewhat commoner in men than in women. They never grow from the septum, inferior meatus or inferior turbinal, but only from the ethmoidal region. They are not neoplasms, but are essentially due to a local œdema of the mucous membrane; the swelling thus produced is acted upon by the expulsive forces of the nose, and, being so pulled down and elongated, the return flow of its blood vessels and lymphatics is further impeded and a greater degree of œdema results. All stages of polypus formation may be found, ranging from an œdematous fringe along the border of the middle turbinal to enormous pedunculated masses which block the nose and expand its bony walls. In the great majority of cases the œdema is due to inflam-

matory infiltration of the muco-periosteum of the ethmoidal labyrinth and is often associated with suppuration in the ethmoidal cells ; sometimes, however, the cause is vasomotor disturbance, for polypi are found in cases of hay fever and paroxysmal rhinorrhœa. There is also another form, the so-called "choanal polypus," in which a large single polypus hangs into the nasopharynx from a long pedicle attached within the antrum and passing through the ostium into the nose.

Symptoms.—The cardinal symptoms are nasal obstruction and discharge, which is profuse and watery. The symptoms are worse in damp weather. Cough, headache and asthma are not infrequent, and a loss of the power of mental concentration often occurs.

Polypi are smooth, shiny, white, translucent bodies, pedunculated and extremely soft and movable to the probe ; their appearance is so characteristic that they cannot properly be mistaken for anything else. If they project into the nostril they become pinker and more opaque.

Treatment.—The best method of removal is in most cases with a wire snare, a process which can be rendered quite painless with skilful manipulation and the application of cocaine. Any polypoid mucosa in the neighbourhood should be removed with punch-forceps, but the application of caustics or the cautery only does harm. Recurrence is common, but becomes less rapid if the new polypi are removed at regular intervals before they have grown large. Suppuration in the ethmoidal cells and other sinuses must, of course, receive treatment. In the worst cases, the polypi are so numerous and return so rapidly that the snare cannot deal with them adequately ; in such they should be removed with a ring-knife or suitable forceps under general anæsthesia, together with the softened ethmoidal tissue, and any suppurating sinuses be opened at the same time.

PAROXYSMAL OR VASOMOTOR RHINORRHOEA

In this condition fits of sneezing are associated with a profuse watery nasal discharge, irritation of the nasal and conjunctival mucosa, nasal obstruction, and often marked depression and prostration. The discomfort is usually worse in the morning, in overheated rooms, or on going out into the cold. The rapidity with which the attacks come and go are sufficient to distinguish them from an ordinary coryza. The affection usually shows itself in early adolescence and tends to improve with advancing age ; it is distinctly hereditary and may be associated, either in the patient or in his relations, with asthma, urticaria or chilblains. Males and females are equally affected, and it is most frequent among the cultivated classes ; a mental shock is sometimes the starting-point of the attacks.

Of these cases, *hay fever* is the best known and most marked variety, and is due to specific susceptibility to a proteid substance contained in the pollen of certain grasses ; in this country, attacks begin about the end of May and terminate in August. Hay-fever subjects are affected by very minute quantities of this toxin, whereas ordinary people are completely immune. Other individuals are susceptible to the pollen, seedlets or scent of other plants and flowers, and others again to the emanations from horses, cats, dogs and other animals ; and recent researches show that asthma, urticaria

or rhinorrhœa may be variously produced by many kinds of proteid substances, including common and uncommon articles of diet, such as eggs or lobsters, in certain people who are specifically susceptible to these substances.

Treatment.—The determining factors, which should receive attention, are heightened irritability of the nervous system, occasionally some intranasal abnormality which increases the sensitiveness, and the specific irritant. Nervine tonics, strychnine, arsenic and valerian, are indicated, and attention to the general health. Hay-fever patients are better in a locality as free as possible from pollen; some remain comparatively well at the seaside, others only on board ship, while some have to spend the best days of the year in a darkened room. Occasionally great good results from the removal of some nasal abnormality, a polypus or a sharp spur impinging on the turbinal, but the result of operative treatment is uncertain. In most cases the nares are normal, and in many of these a light cauterisation of the most sensitive areas is very helpful; the sites usually chosen are on the upper anterior part of the septum, and on the anterior part of the inferior turbinal. True hay-fever patients may have their susceptibility to pollen lessened by inoculation with diluted extract of pollen; the use of these extracts, standardised under the name of *pollaccin*, gives excellent results in a large proportion of cases, and, more recently, the attempt has been made to test susceptibility to, and to immunise against, other proteid poisons.

ACCESSORY-SINUS SUPPURATION

Ætiology.—In the large majority of cases infection reaches the accessory sinuses from the nasal cavity, and may result from a simple coryza or from one of the acute infectious fevers. Influenza is especially liable to produce disease of the sinuses, which may also be caused by measles, scarlet fever, erysipelas, enteric, pneumonia or small-pox. In addition, antral suppuration is caused by infection from the teeth, particularly the second bicuspid and first two molars, whose sockets are in closest proximity to the antral floor. The discharge from one sinus readily enters and infects another, so that disease of several cavities often coexists.

Symptoms and Diagnosis.—If the ostium of a suppurating sinus be occluded the pus is secreted under pressure, and the local symptoms are severe, whereas if the secretion can escape freely there may be no symptoms except discharge. The former class of case has been called "closed" and the latter "open" empyema. The difference between the two is, however, only relative, and many cases are alternating, the severe symptoms being relieved by periodical discharge. As the pressure of the pus in the cavity depends on the rapidity of its secretion, and the degree of occlusion of the ostium by inflammatory swelling, it follows that the closed and open cases correspond generally to acute and chronic suppuration; acute suppuration is usually fairly obvious, but some chronic cases with scanty secretion are only to be detected after very careful examination and may be for long the undiscovered cause of post-nasal catarrh, pharyngitis or chronic toxæmia.

The symptoms, then, are swelling, pain, tenderness and discharge, together with the secondary effects of the suppuration. Swelling is rare; the

bony walls are not bulged by an empyema, and this is a point of distinction between it and a tumour or cyst, but occasionally spread of the inflammation causes periostitis outside the cavity, or a fistula is formed leading to an abscess. Thus, in frontal sinusitis a swelling may appear at the junction of the inner and upper walls of the orbit, displacing the eye downwards and outwards, or an abscess may form here and, after opening, leave a fistula. Similarly, ethmoidal disease may produce a swelling farther back on the inner wall of the orbit, displacing the eyeball outwards. In antral empyema, a little œdema of the cheek, or slight swelling in the canine fossa, may be found, but a swollen cheek is more likely to be due to dental periostitis, while any definite bulging of its bony walls is an indication of a tumour. Pain is often severe in acute cases, and in chronic suppuration there may be considerable neuralgic pain. Pain of an intermittent character, relieved by a sudden gush of discharge from the nose, is highly characteristic of sinus disease. The pain may be of a local inflammatory character, or may be referred to various parts, and of a neuralgic type. In antral suppuration it is over the cheek, or may be referred to the supra-orbital region or to the teeth. The pain of frontal sinusitis is over the cavity or along the supra-orbital nerve; that of ethmoidal disease is over the nasal bridge, behind the eye or in the temple, and in sphenoidal suppuration, in the middle of the head, behind the eye, on the vertex or in the occipital region. Tenderness can usually be elicited in frontal empyema by percussion over the anterior wall, and especially by pressing upwards against the floor of the cavity: it is less marked in antral disease, in the canine fossa. Discharge into the nose is the most important, and often the only, symptom. A localised stream of pus in the nose, which reappears after removal, is, in the absence of a foreign body, conclusive evidence of suppuration in an accessory sinus. The differentiation of the affected sinus is made by following the pus to its source with a probe and, in the case of the antrum, by tapping with a trocar and cannula. The antrum, frontal and anterior ethmoidal cells open into the middle meatus, and the posterior ethmoidal and sphenoidal into the superior meatus. Further assistance is afforded by transillumination and skiagraphy. Fœtor, both subjective and objective, is often present, and a serious degree of anæmia and ill-health frequently results.

Complications.—These include pharyngitis, laryngitis, bronchitis, and otitis media; the swallowed pus causes various forms of gastric and intestinal disorders, including appendicitis. Acute septicæmia and pyæmia are rare, but symptoms of chronic poisoning, such as arthritis and fibrositis, are common. A very important series of complications results from extension of the inflammation to surrounding parts: orbital abscess or cellulitis, osteomyelitis of the frontal bone, cerebral abscess, thrombosis of the cavernous sinus, paralysis of the oculo-motor nerves and, from the sphenoidal sinus, papilloedema and atrophy.

Treatment.—This, in acute cases, consists in rest in bed, hot fomentations to the affected part, aperients, a light diet, and a few doses of aspirin. Inhalations of mentholised steam at frequent intervals are of value, and may be prepared by adding 10 drops of 25 per cent. solution of menthol in a pint of steaming water in an inhaler. In recent cases of antral suppuration, the cavity should be tapped with trocar and cannula and washed out with a warm saline lotion; this should be repeated daily or every

other day, and will effect a cure in a proportion of cases in an early stage. Frontal sinusitis has a greater tendency to spontaneous cure; the anterior end of the middle turbinal should be amputated and occasionally a cannula can be passed and the cavity washed out. Cases which fail to recover under such treatment, and those of chronic suppuration, must be submitted to operation.

SYPHILIS

CONGENITAL SYPHILIS

The *early form* appears at any time within 3 months after birth, usually within the first few weeks. The symptoms, frequently called "the snuffles," are those of nasal discharge and obstruction; the former may be thin and ichorous, or purulent and bloodstained, and is often associated with cracks and excoriations about the nostrils, upper lip and angles of the mouth; the obstruction may cause attacks of choking and frequently prevents the baby from taking the breast, and so produces wasting and malnutrition. These symptoms are not pathognomonic of syphilis, but may also be caused by catarrhal and purulent rhinitis, therefore the diagnosis must be established by the concomitant lesions.

The *late form* appears usually about the period of puberty, but may occur at any time after the age of about 5 years. It is characterised by a slow destructive gummatous infiltration and ulceration, and the symptoms are those of nasal catarrh and obstruction, frequently with fœtor and crusting; this chronic rhinitis destroys the ciliated epithelium, and may thus cause a true atrophic rhinitis which persists after the syphilis has become quiescent or cured. Congenital syphilis is apt to produce a very characteristic "saddle-back" flattening of the bridge of the nose.

ACQUIRED SYPHILIS

Primary chancre is sometimes seen on the ala of the nose, and is accompanied by bubo of the submaxillary and pre-auricular glands, and by much induration and swelling.

Secondary syphilis does not produce noticeable symptoms in the nose; there may be rhinorrhœa and obstruction associated with hyperæmia of the mucosa.

Tertiary syphilis occurs usually in the form of a diffuse gummatous infiltration and ulceration, which may proceed to necrosis of any of the bony or cartilaginous walls of the nose; there is profuse purulent discharge, often bloodstained, which tends to dry into greenish-black crusts, the odour of which is extremely offensive. A localised gumma may occur on the septum, where it forms a smooth round swelling projecting into both nostrils which, by its contraction after healing, produces a steep depression of the bridge just below the nasal bones. Syphilitic ulceration sometimes attacks the external parts of the nose, causing perforation of the ala or destruction of the columella, with a characteristic depression of the nasal tip.

Diagnosis.—This seldom presents much difficulty; the form with crusting and ozæna imitates atrophic rhinitis, but in the latter there is never

necrosis or decided ulceration—indeed intranasal necrosis may be considered pathognomonic of syphilis. A septal gumma has an appearance identical with that of a hæmatoma, but without the sudden onset and history of traumatism. Syphilitic perforations nearly always involve the bone, whereas those due to rhinitis sicca or lupus never do. Some cases of diffuse infiltration resemble lupus; but in the latter there is no necrosis or offensive odour, the characteristic nodules are usually to be seen at the edges of the lesion, and other patches of lupus may be found on the skin or in the fauces. The chief difficulty of diagnosis lies between severe syphilitic infiltration and malignant disease, but it can usually be determined by the clinical appearance, especially by the characteristic edge of the syphilitic ulcer, by the examination of an excised portion, by the Wassermann reaction, and by the results of anti-syphilitic treatment.

Treatment.—General treatment must be very prompt and energetic to prevent irremediable deformity, and should ordinarily be begun with the injection of salvarsan or of one of its congeners. Of local treatment, the lesions should be kept clean by frequent syringing with a saline lotion, to which sanitas, lysol or listerine may be added when the odour is offensive, and any necrosed bone must be removed as soon as it is loose.

LUPUS AND TUBERCULOSIS

Ætiology.—With the exception of the rare occurrence of tuberculous ulceration as a terminal infection in advanced phthisis, the lesions produced in the nose by lupus and by tuberculosis are indistinguishable; it appears that the tubercle bacillus finds in the nasal mucosa a medium unsuitable for its development, its virulence is diminished, and it can only produce the modified lesions known as lupus. It is possible, also, that this modification of the bacillus by its sojourn in the nose is the ordinary cause of lupus; at any rate it is frequently primary in the nares, whence it spreads to the fauces and larynx and on to the face and hands. The disease begins most frequently between the ages of 15 and 30, is twice as common in females as in males, and is usually seen in badly nourished people of the poorer classes.

Symptoms.—The early lesions are found on the antero-inferior part of the septum, the nasal floor and the front end of the inferior turbinal, within reach of the finger-nail, which probably conveys the infection. The characteristic "apple-jelly" nodules are seen, with or without ulceration, the latter with rounded slightly raised margins, and tending to spread in some directions and cicatrise in others. The lesions are covered by small adherent scabs, and perforation of the septal cartilage is common. The alæ often become involved with destruction of the margin or with perforation, and the nostrils may be much narrowed and deformed by scarring, while the lachrymal duct is frequently involved. The progress of the disease is extremely slow and may continue over many years. The subjective symptoms are nasal obstruction with a slight sticky discharge.

Diagnosis.—The nares should be examined in all cases of cutaneous lupus, for, if the disease remain unhealed in the nose, relapses will continually occur. In the majority of cases of nasal lupus the diagnosis is cleared up

by the presence of lesions or scars on the face, fauces or larynx. The difficulties of diagnosis are from rhinitis sicca with perforation, and from syphilis. The typical brownish nodules are pathognomonic and can always be found by careful examination when the lesions are progressing; they can be made more conspicuous by blanching the mucosa with adrenalin. The scabbing of rhinitis sicca quickly clears up under simple emollient treatment, while the lesions of syphilis are more rapidly progressive and tend to involve bone.

Treatment.—The affected areas are defined by the application of adrenalin and thoroughly and carefully scraped away with a sharp spoon, a general anæsthetic being employed if the lesions are at all extensive; small lesions and recurrences are destroyed with the galvano-cautery. Nascent iodine by Pfannenstiel's method may be employed; sodium iodide is given in 7-grain doses six times a day, while the nose is packed with gauze kept moist with peroxide of hydrogen, 10 volume strength, with 5 per cent. of acetic acid added; when a marked reaction has been obtained this solution should be diluted to half its strength, the iodine being continued as before; the treatment may have to be persisted in for several months. Radium is still under trial, and tuberculin has not established its value in this affection.

Of general treatment, arsenic in full doses, fresh air, cod-liver oil and fattening foods are of value. Lupus does not show the same tendency to spontaneous cure in the nose as in the larynx; it is easy to obtain improvement, but complete cure is very difficult.

TUMOURS

Papilloma occurs on the skin lining the vestibule and differs in no respect from cutaneous warts elsewhere. On the nasal mucosa it is excessively rare, occurs usually on the septum, has a narrow pedicle, a rough red or greyish surface, and bleeds readily when touched; occasionally the growths are multiple, and, when large, are difficult to diagnose from a malignant growth, but they do not erode the bones; they tend to recur locally after removal.

Fibroma, similar to the naso-pharyngeal fibromata, occurs, though very rarely, as a smooth pink growth attached to the posterior region of the nares. It bleeds readily and spontaneously and demands great caution in removal.

Angio-fibroma, or "bleeding polypus of the septum," is less uncommon. It varies from the size of a pin's head to that of a filbert, is red or purple, smooth or finely lobulated, sessile or pedunculated, and grows from the anterior part of the septum. The prominent symptom is epistaxis, for the tumour bleeds freely and spontaneously. When pedunculated, it may be removed with the snare and the base cauterised; when sessile, it should be stripped off the underlying cartilage with an elevator. Recurrence is common.

Osteoma and *enchondroma* are extremely rare, and usually grow from the ethmoid region and produce obstruction and deformity.

Cysts.—Mucous polypi are occasionally cystic; the so-called "ethmoidal cyst" is an enlarged cell in the anterior part of the middle turbinal pressing

on the septum and causing obstruction and headache. True cysts are sometimes seen on the anterior part of the nasal floor, and arise from the roots of incisor teeth. When small, they may be treated by intranasal removal of part of the wall; when large, they should be dissected out from the gingival fold.

Malignant tumours, also, are somewhat uncommon in the nose; sarcomata and endotheliomata are more often found than carcinoma. Though they sometimes appear on the septum or nasal floor, the usual site of origin is the ethmoidal region. They tend to expand the bones of the face, producing a characteristic frog-like deformity, and they frequently invade the antrum and expand its walls, constituting a common variety of tumour of the upper jaw. The facial, palatine and orbital walls of the antrum may each be bulged outwards, the latter with displacement of the eyeball, and egg-shell crackling can sometimes be elicited. Sanious discharge and free spontaneous hæmorrhage are prominent symptoms and important for diagnosis. Access to the deep parts of the nose for the removal of these tumours is obtained by lateral rhinotomy, or Moure's operation, by which an incision is made in the line of junction between the nose and face and the nasal process of the superior maxilla removed. Good access to the lower part of the nose without scarring is attained by Rouge's operation, in which an incision is made in the gingivolabial fold from the molar teeth of one side to the other and the soft parts raised. A formal excision of the upper jaw rarely fits the case. A small proportion of cases have remained free from recurrence over long periods; in a much larger number the relief of nasal obstruction and pain has made the operation well worth while, and the whole area being thrown into one large cavity by removal of bony partitions enables it to be kept clean and diminishes pressure-pain. The implantation of radium needles has given encouraging results.

HAROLD S. BARWELL.

DISEASES OF THE NASO-PHARYNX

ADENOIDS

Ætiology.—By this term is implied a chronic enlargement of the lymphoid tissue of the naso-pharynx, the "pharyngeal tonsil." This normally is present in childhood and disappears by the age of 20 or thereabouts, but if chronically enlarged may remain up to any age. The precise stage at which the enlargement becomes pathological can only be determined by the symptoms which it produces; these usually become manifest between the ages of 3 and 8, but occasionally show themselves at or soon after birth. The incidence of adenoids is universal, but they are most common in damp temperate climates, and there is no doubt that chronic or repeated attacks of nasal catarrh are the principal factor in the causation; the infectious fevers, particularly measles, scarlet fever and diphtheria, are also a frequent cause of the hypertrophy.

Pathology.—The adenoid, as it should really be called, or enlarged pharyngeal tonsil, is a mass of lymphoid tissue of definite anatomical shape; it is thickest above and tapers away below, and presents a series of ridges which

radiate from below upwards and slightly outwards. In older patients the mass is firmer and more fibrous, and the ridges are often adherent in places, leaving deep clefts and furrows in which secretion can collect and decompose.

Symptoms.—The symptoms of adenoids are many and various and include those due to nasal obstruction, those caused by infection and by the extension of inflammation, and reflex processes attributable to irritation and lowered vitality. In infants the nasal obstruction interferes with sucking and a serious degree of malnutrition will result unless the baby be carefully spoon-fed. Older children snore at night, breathe heavily in the day, and either bolt their food or eat very slowly owing to the necessity of breathing through the mouth. Owing to lack of oxygen the patients sleep restlessly wake unrefreshed and often suffer from a peculiar inability to concentrate the attention sometimes called "aproxia." Persistent nasal obstruction during the period of growth mechanically produces permanent deformities of the jaws and face which narrow the nasal passages, prevent the mouth from closing naturally and thus perpetuate mouth-breathing. When the mouth is habitually held open, the *alæ nasi* are pulled downwards with the cheeks, and become narrow and slit-like and fall in like valves with each inspiration; this "alar collapse" is an important cause of obstruction in neglected cases of adenoids. The palate is narrow and highly arched; the dental arch is narrow and V-shaped, so that the upper incisors, crowded and prominent, look outwards rather than forwards, and are not covered by the short upper lip; the lower jaw retains its infantile obtuse angle, and the lower incisors lie behind the upper; the chin is receding and, in the worst cases, when the molar teeth come into contact on biting, the incisors cannot meet. Only a proportion of cases of adenoids show these deformities, and undue softness of the bones, such as occurs in rickets, is doubtless an additional factor in their causation, as also in that of the malformations of the chest which result from the obstruction to the entry of air. The long narrow unexpanded chest with acute costal angle and prominent scapulæ is the commonest deformity. Harrison's sulcus, a transverse depression corresponding to the attachment of the diaphragm; pigeon-breast, a prominent sternum with depressed costal cartilages; and funnel-breast, a sharp depression at the lower end of the sternum, are also encountered.

Various infective processes result from the spread of inflammation and, if the naso-pharynx be large, are not necessarily associated with nasal obstruction. The terribly common catarrhal and suppurative affections of the ear in children are, in an overwhelming majority of cases, the result of adenoids. Blepharitis and phlyctenular conjunctivitis are also associated with adenoid vegetations. Feverish attacks, often with tender enlargement of the cervical glands, are caused by infection of the pharyngeal and faucial tonsils, and tuberculous disease of the glands is usually due to passage of the bacilli through these portals; in such cases the tonsils and adenoids may remain unaffected or may themselves show tubercles under the microscope. Chronic or recurrent bronchitis frequently results from the infection spreading to the lower air-passages. The mucus secreted by the adenoids is swallowed in large quantities, and produces derangements of stomach and intestines with failure of growth and general health. Finally, mouth-breathing undoubtedly predisposes to dental caries. The irritation of these vegetations,

and their effect on respiration and the general health, account for numerous reflex and nervous disturbances. Among them may be enumerated laryngitis with spasm called "laryngitis stridula," spasm of the glottis without laryngitis or "laryngismus stridulus," stammering, reflex cough, asthma, night terrors and nocturnal enuresis; it should be stated that the latter disorder is by no means always to be cured by removal of the concomitant adenoids, and that in general too much stress must not be laid upon the presence of adenoids as the causative factor in these reflex disturbances.

Diagnosis.—In the majority of tractable children a view of the naso-pharynx can with patience be obtained with a good light and a very small rhinoscopic mirror, when the upper part of the septum and the concavity above it are seen to be occupied by an irregular convex mass. Where this is impossible a rapid digital examination may be required; this is extremely unpleasant to the little patient, and may be postponed, in those cases where the tonsils are sufficiently large to call for removal, until the child is anæsthetised. Similarly, in very frightened intractable children, if the symptoms point strongly to adenoids it is wiser to give an anæsthetic for examination, being prepared to remove the vegetations if present. In the Mongolian type of idiocy the tongue is large and the mouth persistently open, and in microcephaly the extremely undeveloped naso-pharynx causes nasal obstruction; cases of both these types of maldevelopment are often brought to the doctor in the hope that removal of their adenoids will cure their "backwardness," and care should be taken not to fall into the error of performing a useless operation, though if a well-marked adenoid be present it should be removed under a guarded prognosis. On the other hand, adenoids can be present and produce serious secondary effects without causing nasal obstruction or any appearance of the typical "adenoid facies."

Treatment.—The normal naso-pharyngeal tonsil becomes swollen during a coryza and such temporary swelling should not be diagnosed as "adenoids," by which term chronic hypertrophy is understood, and does not call for removal provided that it subsides promptly, does not frequently recur and is not associated with otitis media or other important complications. In such cases, and when the only symptom is a mild catarrh, the regular use of a simple warm saline lotion with a rubber ball-syringe (see p. 987) will often effect a cure; in children below the age of 5 or 6 syringing is apt to be difficult and the lotion may be used in a spray, while in infants it is best to drop it into the nostrils from a small pipette like the filler of a fountain-pen. This treatment should be combined with open air—if possible a change to the seaside or a bracing country district—cod-liver oil, iodide of iron or arsenic. Breathing exercises are of great value in these slight catarrhal cases, but only do harm where there is marked obstruction.

When the enlargement frequently recurs or has gone on to chronic hypertrophy, operative removal is the only treatment, and this is especially called for when any aural symptoms supervene, or when cervical adenitis is present. After operation the general treatment referred to above is valuable, but the nose should on no account be syringed until healing is complete, as this encourages aural complications. If the *alæ nasi* are collapsing, or the chest narrow, breathing exercises are of use, but healthy open-air occupations are more useful still. In patients in their teens, or upwards, turbinal hypertrophy has not infrequently resulted; the surgeon should be prepared to snare off

enlarged posterior ends of the inferior turbinals at the time of the operation, and intranasal cauterisation may be required later.

TUMOURS

Innocent tumours in the naso-pharynx are exceedingly rare; the so-called "choanal polypus" is a variety of nasal mucous polypus which hangs into the naso-pharynx from a long pedicle attached within the naris.

Fibroma of the naso-pharynx, or naso-pharyngeal polypus, occurs usually in males between the ages of 10 and 25, grows by a broad pedicle from the periosteum of any part of the walls of the naso-pharynx, usually from the basi-sphenoid, and forms a smooth, rounded, pink mass which fills the naso-pharynx and sends prolongations into the nasal cavities. The palate is pushed downwards, the bones of the face expanded, and the eyeballs separated and displaced, producing the "frog-face" deformity. The cardinal symptoms are nasal obstruction and discharge, with headache and severe epistaxis; aural complications may follow, or the eyes may be involved with diplopia, exophthalmos and compression of the optic nerve; and, finally, death results from exhaustion, hæmorrhage, sepsis or cerebral invasion. Histologically the tumour is composed of fibrous tissue containing numerous thin-walled blood vessels and a variable admixture of round or fusiform cells, so that in some cases it might be described as a fibro-sarcoma; but it is not truly malignant, for it neither involves the glands nor becomes disseminated, though there is a tendency to local recurrence after removal.

During surgical removal the bleeding is terrific, but quickly ceases when once the pedicle has been detached; rapid operation is therefore important. The tumour must be removed by separating the pedicle from its attachment with special stout elevators, and may be reached through the mouth, or through the nose after lateral rhinotomy has been performed, according to its site of origin. It cannot be approached satisfactorily through the anterior nares and, on the other hand, division of the soft palate is unnecessary. A preliminary laryngotomy is advisable. Radium has proved of considerable value in reducing the size and vascularity of these growths, as a preliminary to operation.

Dermoid tumours occur as pathological curiosities in the naso-pharynx.

Malignant tumours are not common in the naso-pharynx, but epithelioma, sarcoma and endothelioma all occur. The early symptoms are chiefly pains of a neuralgic character and those produced by Eustachian obstruction; later, epistaxis, nasal obstruction, secondary involvement of glands and affections of the eye and cranial cavity may appear. Removal by operation is rarely feasible, but occasionally a growth of limited size may be attacked through the lateral rhinotomy route. Sarcomata and endotheliomata in this region sometimes yield remarkably to treatment by radium.

DISEASES OF THE LARYNX

ACUTE CATARRHAL LARYNGITIS

Ætiology.—The affection ordinarily occurs as part of a coryza, or cold, the inflammation spreading downwards from the nose or naso-pharynx. It is also caused by over-use of the voice, especially with faulty voice-production, and frequently a slight catarrh is made worse by using the voice during a cold. It occurs in many infectious fevers, *e.g.*, influenza, measles, scarlet fever, typhoid and small-pox, and it is occasionally a result of traumatism, instrumentation, or the inhalation of irritating fumes in chemical works or of the gases used in warfare. Predisposing causes are chiefly those factors which favour attacks of coryza, such as nasal obstruction or discharge, sedentary occupations and overheated rooms; apart from local tuberculous lesions, consumptives are very subject to laryngeal catarrh.

Symptoms.—The symptoms consist of hoarseness or aphonia, local discomfort varying from dryness or tickling to a burning sensation or actual pain, and sometimes an irritable cough. There is little expectoration, unless the trachea is involved. At the onset there may be slight feverishness and malaise. The degree of hoarseness is by no means proportionate to the objective appearances; the voice may be quite good in cases of decided hyperæmia, and may be completely lost when little abnormal is to be seen. This depends largely on the neuro-muscular tone; a muscular man will retain a strong voice with a degree of inflammation which would render a weakly woman completely aphonic, indeed, some women lose the voice with every slight cold, so that it becomes difficult to differentiate between laryngeal catarrh and “functional aphonia.” On the other hand, in some voice-users redness of the cords appears to be the normal condition and causes no interference with function. This variable effect on the voice is to be observed in all forms of laryngeal disease. In children, acute laryngitis is a serious affection. They show a far greater tendency to œdema and to spasm, and as the glottis is not only absolutely but relatively smaller than in adults, a dangerous dyspnœa may ensue with great rapidity. The larynx is reddened, and this is most obvious on the parts usually pale—the epiglottis and vocal cords, the vessels on the former being unduly prominent. The cords may be red, pink, yellowish, or merely have lost their bright pearly lustre. A small amount of mucous secretion is generally present, but no large accumulations of strings of mucus, such as are seen in chronic laryngitis; a minute globule of mucus may sometimes be seen standing on the centre of the cord during phonation, and resembles a little nodule. There is often a little swelling of the cords so that, on phonation, their edges come into contact at the centre; this explains how singers’ nodules are caused by use of the voice during a laryngitis.

Treatment.—People suffering from the slighter degrees of laryngitis rarely apply for treatment, unless they are professional voice-users. The patient should remain in a warm (65° F.), well-ventilated room, preferably in bed, and must not attempt to use the voice. The coryza, if present, should be treated at the same time. Steam inhalations are of value and may be used from an inhaler or from a jug round the mouth of which a towel

has been wrapped in the shape of a cone. The water should be at a temperature of 130° to 140° F., and one of the following medicaments may be added in the proportion of one drachm to the pint: Compound tincture of benzoin (Friar's balsam) $\mathfrak{z}\text{i}$, with or without menthol, grs. x-xv; or benzoic acid, grs. ij, kaolin, grs. xij, tincture of tolu, \mathfrak{m} xvij, and water to $\mathfrak{z}\text{i}$, these being sedative, while oleum pini sylvestris, \mathfrak{m} xl, magnesii carb. levis, grs. xx, water to $\mathfrak{z}\text{i}$ is mildly stimulating. Steam inhalations should only be ordered when the patient can remain in a warm room; when he is not confined to the house, or in a later stage, an oily solution from an atomiser is preferable, such as menthol, grs. vij, camphor, grs. ij, chloretone, grs. v, liquid paraffin, $\mathfrak{z}\text{i}$. Internally, expectorants are indicated; vinum ipecacuanhæ, \mathfrak{m} x, or vinum antimoniale, \mathfrak{m} v, potassium iodide, grs. ij or iij—singly or in combination—or ammonium chloride, grs. v, or oil of cubebs, \mathfrak{m} v in syrup, every 4 or 6 hours. If cough is severe it should be restrained; a lozenge of morphine and ipecacuanha is useful, or a linctus containing heroin hydrochloride, gr. $\frac{1}{2}$, or liquor morphinæ, \mathfrak{m} ij to iv.

The acute laryngitis of children calls for prompt treatment. One or two grains of calomel may be given every 3 hours until the bowels have acted freely, after which it may be continued in $\frac{1}{2}$ gr. doses three times a day. Hot fomentations to the neck and a steam-kettle are advisable, and in acute febrile cases, 1 minim each of tincture of aconite and vinum antimoniale every 3 hours. If dyspnœa occurs, an emetic dose of ipecacuanha often gives prompt relief; 1 drm. of the vinum followed by $\frac{1}{2}$ -drm. doses every half-hour until vomiting occurs: in very young or weakly children, 15 minims every quarter-hour may be preferred.

SPASMODIC LARYNGITIS (LARYNGITIS STRIDULA)

This is simply catarrhal laryngitis with spasm of the glottis as a marked feature. It is a disease of childhood and is predisposed to by general ill-health, rickets and adenoids. The onset is that of an ordinary cold, with slight feverishness, hoarseness and a frequent cough, and during the evening or night the respiration becomes embarrassed. There is inspiratory stridor, recession of the epigastrium and lower ribs and, in some cases, an alarming degree of asphyxia. The symptoms tend to subside towards morning and, though they may recur on the next few nights, it is usually with diminishing severity. The condition should be distinguished from laryngismus stridulus, a purely spasmodic affection, with no hoarseness or other symptoms between the attacks. The evanescence of the symptoms serves to distinguish it from cedematous laryngitis and from diphtheria, in which the attacks become increasingly severe. The general health requires attention, and adenoids, if present, must be removed after recovery takes place.

CEDEMATOUS LARYNGITIS

Ætiology.—Oedema of the larynx is not a disease but a pathological condition due to a variety of causes. Non-inflammatory oedema may be mentioned here for the sake of completeness; it occurs, though rarely, as part of the general anasarca of renal and cardiac disease. Angio-neurotic oedema sometimes occurs in the larynx, in which event it produces rapid and

1004 DISEASES OF THE RESPIRATORY SYSTEM

severe dyspnœa (see p. 978). The swelling which occasionally results from administration of potassium iodide in susceptible subjects may be placed in the same category.

Inflammatory œdema seldom results in adults from a simple catarrh, but it may do so in children ; it more often occurs as part of an acute septic pharyngitis, and is often associated with "angina Ludovici." Œdema may follow various forms of traumatism, the drinking of corrosive poisons in attempted suicide, inhalation of irritating vapours, such as the poison gases of the Great War, the lodgment of foreign bodies, or rough or unduly prolonged bronchoscopy. Scalding, from attempts to drink from a kettle-spout, is a common cause among children. In other cases it is a sequela of typhoid fever, pneumonia, scarlet fever or small-pox, and is a local complication of syphilitic, tuberculous, cancerous or traumatic ulceration.

Symptoms.—If part of a septic pharyngo-laryngitis, the general symptoms are severe. The chief local symptom is dyspnœa with inspiratory stridor and the associated symptoms of asphyxiation ; there is hoarseness or aphonia, local discomfort and tenderness, and sometimes dysphagia. The aryteno-epiglottidean folds are enormously swollen, appearing as pale or purple translucent flask-shaped masses ; if the epiglottis be œdematous it forms a sausage-shaped swelling of the same appearance. The mucosa of the vocal cords is too adherent to permit much swelling, and "œdema of the glottis" is therefore a misnomer. The subglottic region is lax and may become swollen ; indeed, the œdema may be confined to this region and then appears as a red swelling below each vocal cord. In children œdema may be inferred from the steadily increasing dyspnœa without the rapid increase and decrease typical of spasmodic laryngitis.

Angio-neurotic œdema is a very rapid condition and has proved fatal.

Treatment.—In slight cases, the swelling may be reduced by sucking ice and by the application of an ice-bag to the neck ; the latter is inadmissible in young children. A spray of adrenalin, 1 in 1000, may be used. Hypodermic injections of pilocarpine, gr. $\frac{1}{2}$, are recommended and, for the œdema produced by iodides, large doses of bicarbonate of soda. Free scarification of the œdematous tissues at the upper aperture should be practised without undue delay ; in adults this should be done with a laryngeal lancet under guidance of the mirror, but in children it is best performed with a curved bistoury guarded to near the point with strapping and passed down along the left forefinger as a guide. If this does not give quick relief, or if the dyspnœa be severe, tracheotomy should be performed without delay, in adults under local anæsthesia. Intubation is not suitable for cases of œdema of the upper aperture of the larynx, though it may be employed for subglottic cases, provided that skilled attention be immediately available should the tube be coughed out. Angio-neurotic œdema should be treated by a spray of adrenalin, and the same drug may be injected hypodermically ; tracheotomy may here also be required.

MEMBRANOUS LARYNGITIS

The formation of false membrane in the larynx is nearly always part of an attack of diphtheria, which is discussed elsewhere, but by the term "mem-

branous laryngitis " is implied a formation of membrane of non-diphtheritic origin. Apart from traumatic cases, in which the membrane is due to irritating chemicals and scalds, inflammation of the larynx accompanied by membrane may be caused by a variety of streptococci and staphylococci. The affection occurs especially in children between the ages of 2 and 8 years. The first symptom is hoarseness, soon followed by a brassy cough and the signs of dyspnoea; the patient is restless and the temperature rises rapidly to 103° or 104°. In some cases, however, the disease takes a subacute form, the attacks of dyspnoea being worse at night and abating towards morning. The diagnosis from diphtheria is only possible by bacteriological examination, and pending the report the case should be treated with antitoxin; but it may be noted that the pharynx is nearly always involved in diphtheria, whereas in membranous laryngitis the disease is often primary in the larynx. The prognosis is grave, worse than that of diphtheria since the introduction of antitoxin. An emetic dose of ipecacuanha should be given, and a steam-bath and hot fomentations to the neck are advisable. Calomel treatment is recommended; 1 or 2 grains every 3 hours until the bowels have acted freely and subsequently 1 grain three or four times a day. Tracheotomy or intubation must not be delayed when there is serious dyspnoea.

PERICHONDritis

Ætiology.—This, an inflammatory exudation beneath the perichondrium of one of the laryngeal cartilages, usually going on to suppuration, is most frequently the result of infection with pyogenic organisms in the course of tuberculous, syphilitic or malignant disease of the larynx. It is found as a complication of typhoid fever, small-pox, or other infectious fevers, or of septic laryngitis; and it is also caused by traumatism from without or by a foreign body within, by the rough passage of the stomach tube, or by the introduction of a tracheotomy tube through the larynx.

Symptoms.—In acute cases there are the usual general feverish symptoms. Locally, there is pain and tenderness, with a variable degree of hoarseness, dysphagia or dyspnoea, depending on the site and severity of the inflammation. External swelling and abscess formation occur when the thyroid or cricoid cartilages are attacked.

Arytenoid perichondritis appears as a unilateral rounded swelling of this region; the infection generally enters at the vocal process, where the mucosa is thin and adherent and, when pus forms, the abscess ruptures here. When necrosis occurs, the entire cartilage may be exposed in a deep triangular cavity, which opens on its inner aspect. This form is a common complication of tuberculous laryngitis. Epiglottic perichondritis produces a rounded red swelling, accompanied by severe dysphagia. In thyroid perichondritis, there is diffused swelling of the lateral wall of the larynx and ventricular band of the affected side, with early fixation of the vocal cord and hoarseness. Externally there is a tender swelling over the ala. The abscess may rupture into the larynx or ramify widely in the neck. Cricoid perichondritis usually affects the posterior plate, causing a swelling of the posterior laryngeal wall, frequently with subglottic œdema and severe dyspnoea.

Treatment.—This depends largely on the cause. Abscesses should be

opened when they form, either internally or externally, and necrosed cartilage removed when possible. Dyspnœa may call for tracheotomy and, later, cicatricial stenosis may demand treatment. When pain is present, aspirin and small doses of opium are required; insufflations of orthoform, 3 grains, or of orthoform and anæsthesin in equal parts, 15 minutes before meals, are helpful in relieving the pain of swallowing.

CHRONIC LARYNGITIS

Ætiology.—The causation is similar to that of acute catarrhal laryngitis; indeed, chronic laryngitis is often the result of recurrent or persistent acute catarrh. The principal factors which predispose to chronicity are nasal obstructions and discharges, dusty occupations and lack of fresh air, over-use of the voice and faulty voice-production, and the abuse of alcohol or tobacco; consumptives are particularly liable to non-specific catarrhal laryngitis, and oral sepsis must not be omitted. Almost any cause of general ill-health may be included among the predisposing causes, such as gout, rheumatism, anæmia, and gastro-intestinal, cardiac and hepatic disorders.

Symptoms.—The only constant symptom is impairment of the voice, which is hoarse, easily tired or even, though rarely, completely aphonic; it is sometimes weakest when tired in the evening, but is often at its worst on rising in the morning or after a rest. There is frequently a sensation of aching, dryness, tickling or of a lump in the throat, and there is usually some cough, but little expectoration, unless the trachea and bronchi are involved.

The objective appearances vary with the severity of the affection. The larynx generally is of a deeper red than usual, and the vocal cords have lost their normal pearly lustre and are pink or grey; they are usually somewhat thickened at the edges, and enlarged vessels may be visible on their surface; the vocal processes are often prominent and may be reddened or show up white against the hyperæmic cord. Strings of sticky secretion may stretch between the cords, or a little globule of mucus may form on the centre of the cord during phonation; adduction is frequently imperfect. When the epiglottis is reddened, its yellow edge stands out clearly and enlarged vessels are seen on the surface; the ventricular bands are often swollen so as to hide the outer part of the cords. The mucous membrane in the interarytenoid space, thickened and relaxed, is seen to be thrown into folds on adduction of the cords, and may form a mass large enough to prevent their approximation.

Atrophic rhinitis usually produces a form of inflammation, *laryngitis sicca*, in which small brown scabs adhere to the cords and posterior commissure, but occasionally the disease itself spreads to the larynx, which is covered by large greenish or brownish-black foetid crusts; more rarely still the crusts extend into the trachea and cause severe dyspnœa, which may prove fatal.

Pachydermia laryngis is a somewhat rare variety of chronic laryngitis, occurring principally in middle-aged men. It is frequently ascribed to alcoholism, perhaps on insufficient grounds, to syphilis and to tubercle; the diagnosis between pachydermia and these two diseases is, however,

often a matter of difficulty. The characteristic epithelial thickenings are probably of the nature of corns, resulting from frequent cough and continued irritation. There is hoarseness of a rough raucous character, but no particular discomfort. The epithelial thickening is pink or whitish and occupies the posterior or cartilaginous region of the glottis from the vocal processes backwards to the posterior commissure. A circumscribed swelling appears on each vocal process, with a small cup or depression at the apex; the approximation of the cords is better than would be expected, because the prominence on one vocal process fits into the depression at the other. The epithelium of the inter-arytenoid space is thrown into ridges, which fill up the angles between the arytenoid and the posterior commissure, but leave a depression in the middle line. These firm opaque symmetrical swellings, without ulceration, are distinguishable from the soft irregular granulations of a tuberculous lesion; and the even cup-shaped swelling on the vocal process, even when more marked on one side, should not be mistaken for an early epithelioma.

Treatment.—The detection and correction of the ætiological factors are the most important part of treatment. Any constitutional disturbance, such as anæmia, rheumatism, gout or dyspepsia, should receive attention. Over-indulgence in tobacco, or alcohol, lack of ventilation and exposure to dust must be considered, and with teachers the black-board chalk is a common source of irritation.

Incorrect voice-production is a factor of great importance especially, but by no means exclusively, among those who use the voice largely in their occupations; in such, a course of lessons in voice-production often works wonders. In a large proportion of cases the primary cause of the laryngitis is to be found in the nose, therefore any source of nasal obstruction, catarrh or suppuration must be carefully looked for and treated; any concomitant pharyngitis should also receive attention.

Locally, treatment must begin with rest of the voice, which should be absolute in the case of professional voice-users. Where there is much secretion a saline lotion may be used in a spray—sodium bicarbonate, sodium bichlorate, sodium chloride, 10 grains of each, thymol water, 2 drms., glycerine, 1 drm., water to 1 ounce. Oily solutions are usually preferred, such as menthol, 5 grains, camphor, 2 grains, chlorotone, 5 grains, or oil of eucalyptus, pine or gaultheria in similar proportions to an ounce of liquid paraffin. The direct application of pigments is not often called for, and is to be recommended only when pachydermatous changes are present; in such cases the cautious application of a solution of nitrate of silver on a cotton-wool mop once a week may be tried, beginning with 5 grains to the ounce and increasing the strength gradually to 50 or more grains; Dundas Grant advises an alcoholic solution of salicylic acid, beginning with 1 per cent. and increasing to 6 or 8 per cent.

Internally, small doses of potassium iodide, 2 or 3 grains, or the yellow proto-iodide of mercury, $\frac{1}{16}$ grain, three times a day over long periods, are of value.

CONGENITAL LARYNGEAL STRIDOR

In this condition there is an exaggeration of the infantile shape of the upper aperture of the larynx; the epiglottis is sharply folded laterally, the

1008 DISEASES OF THE RESPIRATORY SYSTEM

ary-epiglottic folds are almost in contact, and the opening is thus reduced to a narrow vertical slit. As these parts are very flaccid in infancy, they become sucked together during inspiration and, by their vibration, produce the characteristic stridor. This stridor is noticed very soon after birth, it is inspiratory, of a peculiar purring or even musical character, and is most marked during active breathing and crying. The voice is unaffected, and there is remarkably little sign of dyspnoea or distress. These characteristics distinguish the condition from other forms of obstruction found in infants, such as laryngeal webs or papillomata, or "thymic asthma." It tends to disappear during the second year of life, but the prognosis must be guarded in early infancy, for an attack of bronchitis is more than ordinarily dangerous and even kills a proportion of these patients.

SYPHILIS

CONGENITAL SYPHILIS

The early, or secondary, form appears in the first few months of life and is rarely recognised, but it may be suspected when the cry is hoarse in an infant with active syphilitic lesions.

Tertiary lesions are rare, and usually make their appearance about puberty, less often during the second dentition. The disease takes the form of diffuse infiltration with or without ulceration; the swelling may produce obstruction or, later, cicatricial stenosis may ensue. The symptoms are stridor with hoarseness, and tracheotomy may be required.

ACQUIRED SYPHILIS

Symptoms.—Secondary lesions are superficial, cause no symptoms but hoarseness, and seldom come under observation. The commonest manifestation is an erythema which differs from that of catarrhal laryngitis by being more uneven and patchy in its distribution, and may affect one cord, leaving the other normal. Mucous patches are occasionally found on the cords or on any part of the larynx, appearing as superficial erosions with a smooth greyish base and a sharply defined hyperæmic margin. The fauces are nearly always affected at the same time.

Of tertiary lesions, the superficial serpiginous ulcer is occasionally seen with the same characters with which it more commonly appears on the fauces. Diffuse infiltration may attack any part of the larynx, but chiefly, in contra-distinction to tuberculosis, the anterior regions, such as the epiglottis and the front parts of the vocal cords. Subglottic infiltration is fairly frequent and abduction of the cords often limited, so that stenosis is much commoner than in tuberculous disease. The typical circumscribed gumma is distinctly rare; it is single, unilateral, and attacks especially the epiglottis and arytenoids, and usually breaks down rapidly to form a deep excavated ulcer, which may result in perichondritis, exfoliation of cartilage, and, ultimately, in severe cicatricial stenosis. The subjective symptoms are hoarseness, of a peculiar rough, "raucous" character, and sometimes dyspnoea with stridor; pain is in general not a prominent symptom, but a gumma on the upper aperture may cause severe dysphagia.

Diagnosis.—From tuberculous disease the diagnosis is discussed under that heading (see p. 1010). From epithelioma a gumma is distinguished by its more rapid evolution; the edge of an epithelioma is thick and everted and its base nodular, whereas these characters are less marked in syphilitic ulceration, the margin of which is hyperæmic and frequently sharply cut; while other parts of the larynx or fauces often show syphilitic lesions. The hard infiltration of secondarily involved glands is characteristic of malignant disease.

Treatment.—General treatment is urgently called for to prevent perichondritis and stenosis. Local treatment is not often required. Tracheotomy should be performed when decided dyspnoea is present; it seems to aid the recovery of the larynx, and the tube can often be omitted in a short time, when anti-syphilitic medication has removed the obstructing lesion. Necrosed pieces of cartilage must be removed by internal or external operations, and insufflations of orthoform are indicated when dysphagia is present.

LUPUS

Lupus in the larynx is comparatively rare, and is probably always secondary to the disease in the nasal passages.

Symptoms.—The lesions begin on the epiglottis and slowly spread along the aryteno-epiglottic folds; the interior of the larynx is less often attacked and the cords usually escape. The infiltration is composed of tiny red nodules, which develop the typical "apple-jelly" centre and break down to form multiple coalescent shallow ulcers, the smooth base covered by a scanty secretion and with indefinite uninflamed margins. Cicatricial contraction goes on during the progress of the affection, and the epiglottis, if not destroyed, is usually much deformed; but the scars are less thick, and the contraction less severe than in syphilis, and marked stenosis is uncommon.

Treatment.—The disease shows a decided tendency to spontaneous cure, and in many cases of cutaneous lupus the scars of healed disease can be seen in the larynx. Open-air treatment, as carried out in a sanatorium, with good food, moderate exercise, and cod-liver oil suffice to cure most cases. Arsenic, in large doses, appears to have a specific effect, starting with 5 minims of liquor arsenicalis 3 times a day and increasing the dose gradually to 15 or more minims. Local treatment should be reserved for those cases which general measures fail to cure. If the lesions are confined to the epiglottis, this may be removed; for more diffuse infiltration repeated galvanocautery puncture gives the best results, but over-zealous application will promote stenosis. Good results have recently been reported from the use of radium, applied externally to the neck in the form of plates.

TUBERCULOSIS

Ætiology.—Primary tuberculosis of the larynx is so rare as to be of no practical importance; in the overwhelming majority of cases the disease is secondary to pulmonary tuberculosis, of which it is a common and important complication. It is probably caused by infection from the sputum,

is two or three times commoner in men than in women, and is most frequent between the ages of 20 and 40. St. Clair Thomson finds that the difference in sex-incidence is occupational, and that women working in office and factory are as susceptible as men.

Symptoms.—The disease attacks, in order of frequency, the vocal cords, arytenoid region, inter-arytenoid space, ventricular bands and epiglottitis; in general the lumen is invaded before the upper aperture, and the posterior rather than the anterior parts of the larynx. The typical infiltration is finely nodular, pallid and soft in appearance; ulcers are shallow, with a smooth speckly base and pale ill-defined margin. On the vocal cord the disease chiefly attacks the posterior half and especially the vocal process, where ulceration readily reaches the underlying cartilage and may produce a deep triangular excavation. Thickening in the inter-arytenoid region is common; infiltration of the arytenoids results in typical pale semi-translucent flask-shaped swellings, while the epiglottitis appears as a firmer red sausage-shaped mass.

Of subjective symptoms, the hoarseness is very characteristic, being weak and effortless and very different from the raucous voice of syphilis. Cough and expectoration are mostly due to the pulmonary disease and not in any considerable degree to the larynx. Pain on swallowing is common and often very intense; there may also be actual obstruction to deglutition and, in a late stage, entry of food into the larynx. Dyspnoea is rare.

Diagnosis.—Although signs of pulmonary tuberculosis are helpful in diagnosis, it is obvious that any kind of laryngeal disease may occur in a consumptive patient.

From simple laryngitis.—In the earliest stage of invasion tuberculous laryngitis may exactly resemble catarrh, but redness of one cord only is certainly not due to catarrh, and the latter quickly improves under treatment. The swollen arytenoids of oedematous laryngitis are less pale and more transparent, while the affection is acute and the entire larynx inflamed. Inter-arytenoid infiltration somewhat resembles pachydermia, but the latter is opaquely white, firm and symmetrical.

From lupus, typical tuberculosis differs completely. The former is painless, affects first the epiglottitis and upper aperture, is never accompanied by oedema, and tends to cicatrization. But there is a chronic "lupoid" form of tuberculous laryngitis which attacks the epiglottitis and is very similar to lupus.

From syphilis.—The tuberculous ulcer has an ill-defined margin without surrounding hyperæmia; the base has a yellow speckled appearance, and on healing there is little scarring or contraction. The superficial syphilitic ulcer has a well-defined hyperæmic margin, with a smooth, flat base; the deep ulcer is "crateriform," with thickened punched-out edge, and, on healing, leaves a dense scar and marked deformity. In general, syphilitic lesions attack the anterior half of the larynx, tuberculous the posterior; the former look firm and dense, the latter soft, translucent and ill-defined.

From neoplasms.—Only the rare tuberculomata resemble innocent tumours. Occasionally tuberculosis attacks one vocal cord in an elderly patient and may then easily be mistaken for epithelioma (see p. 1014).

Prognosis.—Any tuberculous lesion of the larynx renders the prognosis of a case of pulmonary tuberculosis much more serious. A considerable

number of the superficial lesions become healed ; but it is doubtful if any cases of extensive infiltration recover, with the exception of a few rare instances where it is confined to the epiglottis and can be entirely removed.

Treatment.—Tuberculous laryngitis is but a complication of pulmonary tuberculosis, and by far the most important part of the treatment is that of the general infection. For the laryngeal lesions the most valuable remedy is complete silence, but it is a severe and depressing measure and should not be insisted on unless there is a prospect of cure ; the pain and irritation in advanced cases are, however, often relieved by vocal rest. Any concomitant catarrh should receive attention ; an oily spray containing menthol and chloretone (7 grains of each in an ounce of liquid paraffin) is valuable, and irritable cough should be relieved by a simple lozenge, or, if severe, by heroin, $\frac{1}{2}$ gr. or less in a lozenge or linctus. Attempts to cure by active local treatment must only be made when the pulmonary lesions are quiescent or progressing towards arrest, the general health good, and the local lesions not very extensive. Of these methods the galvano-cautery is the most generally useful, and may be employed to the surface of superficial ulcers, or as multiple puncture of infiltrated areas. Chemical caustics may be applied to ulcerated surfaces, especially on the cords and posterior commissure ; lactic acid, 50 to 80 per cent., may be used, or Lake's mixture of lactic acid 50 per cent., formalin 7 per cent., and phenol 10 per cent. Ulcers covered with sprouting granulations may be curetted, and occasionally infiltration of the epiglottis or arytenoid may be removed with punch-forceps.

In advanced cases the dysphagia is so distressing that its relief is of great importance. For this purpose the most valuable drug is orthoform, which may be combined in equal proportions with anæsthesin ; it is an insoluble non-toxic powder and is used as an insufflation in doses of 3 to 5 grains, 30 to 60 minutes before meals ; patients readily learn to inhale it into the throat through a glass tube. Cocaine and morphine should be reserved to the last stages. When the dysphagia is due to a greatly swollen epiglottis, the greatest relief is afforded by its removal under cocaine with special punch-forceps ; and when the pain is caused by a tense swollen arytenoid, the removal of a piece with punch-forceps relieves tension and gives similar relief. Injection of alcohol into the superior laryngeal nerve is a useful method of alleviating pain in cases of extensive disease. Tracheotomy is seldom required, and tuberculous infection of the wound is common after this operation.

TUMOURS

INNOCENT TUMOURS

Singer's nodules are inflammatory epithelial thickenings, and may be considered as a form of pachydermia. They are found in teachers and speakers, rather than in singers, and are caused by faulty voice-production and, especially, by forcing the voice when the cords are inflamed. The appearance is that of a minute pink or whitish nodule on the edge or upper surface of the vocal cord, surrounded by a varying amount of injection ; there is usually a nodule symmetrically placed on each cord, but it is frequently

larger on one side than on the other. The place where the growth occurs, and which is also the "seat of election" for other innocent tumours, is at the junction of the anterior and middle thirds of the glottis, that is, in the centre of the true vocal cord, for the posterior third of the glottis is cartilaginous. It is here that the maximum vibration occurs, and here that the cord, if swollen, comes into contact with its fellow on phonation.

Fibromata occur usually on the vocal cord on the same site as the singer's nodule, of which they are in some cases probably a development, or at the anterior commissure. They are pedunculated, smooth and round, white, pink or brown from extravasation of blood, and vary from the size of a pin's head to that of a bean. These growths not infrequently become oedematous, when they appear translucent like a nasal polypus and have been incorrectly described as *myxomata*.

Papillomata are reddish, papillary, pedunculated growths, and occur anywhere on the larynx, but, when single, generally occupy the "seat of election" on the vocal cord, and are seldom found on the posterior half of the glottis. Multiple papillomata occur in childhood and, as they present special characteristics, will be considered separately later.

Cysts.—A fibroma may degenerate with the formation of a cystic space in its interior. Apart from this, cysts, which may reach a large size, are found as a rarity on the upper aperture of the larynx, especially on the anterior surface of the epiglottis. They are thin-walled and translucent, with ramifying vessels running over the surface.

Angiomata occur, though rarely, on any part of the larynx either as a flat patch or a raised purple mass resembling a blackberry.

All innocent neoplasms are uncommon; in addition to those already mentioned, *lipomata*, *chondromata* and *thyroid-gland tumours* have been observed.

Symptoms.—A tiny growth situated on the vocal cords, or in such a situation as to prevent their approximation, causes hoarseness and a variable amount of aching and discomfort, but even a large tumour elsewhere may cause no symptoms to attract attention. Dyspnoea results in rare cases when a neoplasm is large enough to block the air-way, but it is astonishing how slight a disturbance may be produced by a large tumour if it has grown slowly; inspiration is more difficult than expiration, except when the tumour lies below the glottis. Angiomata cause hæmorrhage, which may be slight or very severe.

Diagnosis.—This is usually easy on inspection, but a growth in the anterior commissure, or one that drops down below the cords, may be readily overlooked. The rare tuberculoma may so exactly imitate an innocent neoplasm as to be only recognisable under the microscope. The important matter of diagnosis from a malignant neoplasm will be referred to under the latter disease.

Treatment.—Tumours situated away from the glottis and causing no symptoms should be left alone. Cysts are best treated by making a large hole with punch-forceps or the cautery, for they refill after simple incision. Angiomata, especially if diffuse, are best left untouched, unless bleeding calls for interference, in which case it can usually be checked by the cautery at dull-red heat; diathermy puncture with a fine terminal through a direct laryngeal spatula, or by suspension-laryngoscopy, is a preferable method;

if repeated hæmorrhage becomes a danger, it can be excised by an external operation, but is usually more widely spread than appears on laryngoscopic examination. Singer's nodules, if quite small and sessile, frequently disappear under prolonged rest of the voice; the smaller nodules may be lightly touched with the galvano-cautery; larger ones should be removed with forceps. Fibromata and papillomata are removed with forceps; it causes far less disturbance to the patient if this be done under cocaine anæsthesia by the "indirect method," i.e. under guidance with the laryngeal mirror, provided that the operator has acquired the necessary skill, but since the introduction of the "direct method" they are often removed through the tube-spatula. After the little operation, absolute rest of the voice should be enjoined for a few days; in cases of singer's nodule a longer rest is necessary, with training in voice-production and avoidance of dust and conditions of vocal strain.

Multiple papillomata.—This rare but serious condition occurs almost exclusively in children and generally attracts attention between the ages of 2 and 4. The warts may be very numerous, fill the lumen with a cauliflower-like mass, and extend to the subglottic region, down the trachea and even on to the pharynx. The first symptom is hoarseness, and long-continued hoarseness in a child should suggest the possibility of papilloma; dyspnœa ensues later and becomes gradually more severe until tracheotomy is necessary. The growths may disappear after tracheotomy, or spontaneously, or after an acute illness, and tend to vanish or cease to recur about puberty. The modern treatment is to remove the growths through the tube-spatula, or by suspension-laryngoscopy, under general anæsthesia; a preliminary tracheotomy is advisable if there is much dyspnœa; several sittings may be required, and the operation must be repeated as often as the growth recurs.

MALIGNANT TUMOURS

Ætiology and Pathology.—Epithelioma is by far the commonest malignant growth in the larynx, but spheroidal-cell carcinoma and sarcoma also occur. Malignant disease of the larynx proper is rare below the age of 40, and is seldom seen in women; but there is a post-cricoid epithelioma, which of course originates on the mucous membrane of the pharynx, which is relatively common in women, and at such an early age as 23 or even younger. Secondary or metastatic growths are practically unknown in the larynx; on the other hand, owing to the fact that the laryngeal lymphatics do not anastomose freely with other systems, cancers confined to the lumen of the larynx rarely become disseminated and do not readily infect the glands. Therefore, Krishaber's classification into *intrinsic* and *extrinsic* is valuable for treatment and prognosis; the former are those situated within the cavity of the larynx, while the latter affect the upper aperture, epiglottis and arytenoids, and the outer walls, such as the posterior surface of the cricoid plate.

Symptoms.—Unfortunately, intrinsic malignant tumours do not cause severe symptoms at an early stage and, particularly in hospital practice, frequently do not present themselves for treatment until they have become extrinsic by extension; hence the importance of a laryngeal examination in all patients over 40 with hoarseness which does not rapidly yield to treat-

ment. Hoarseness is the most general, and usually the only early, symptom ; owing to the deep infiltration characteristic of malignant disease, it is often more marked than the size of the tumour would appear to warrant. Cough is not a common symptom. Pain is absent in the early stages of intrinsic cancer, but is severe in the later stages and in the extrinsic forms ; it radiates to the ear and side of the head, and is made worse by swallowing, speaking, and coughing. The later symptoms include involvement of the glands, fœtor of the breath, salivation, hæmorrhage, dyspnœa, dysphagia and general cachexia ; often the patient dies of septic pneumonia.

On a vocal cord, epithelioma may appear as a definite tumour resembling a papilloma or angioma, or it may begin as a diffuse infiltration, or even as a mere area of thickening and congestion. On the ventricular band or posterior commissure it usually shows itself as an irregular papillary dusky-red swelling ; cancer of the epiglottis ulcerates early and appears as a dirty-white or reddish tumefaction. Often the only sign of a post-cricoid growth is a swollen and fixed arytenoid ; sometimes the upper edge of the growth is visible, but it is frequently necessary to pass a tube-spatula or to pull the larynx forward with a probe passed down to the glottis before it can be inspected.

Diagnosis.—In the earliest stage the diagnosis obviously is a matter of extreme importance and sometimes one of great difficulty. The unilateral character of the infiltration is ordinarily sufficient to exclude a simple inflammatory lesion ; though pachydermia may be more marked on one side, the smooth cup-shaped swelling on the vocal process is characteristic. The difficulties of diagnosis are generally between an innocent neoplasm on the one hand, and a tuberculous or syphilitic infiltration on the other. A papilloma or a fibroma on a vocal cord should be regarded with suspicion in a man over 40, and especially if, after removal, the site fails to heal promptly. An innocent neoplasm has a fine pedicle, moves freely in the air-current on phonation, there is no tumefaction at its site of origin, and it is found at or in front of the middle of the vocal cord. A malignant growth may occur in any situation ; it is less movable and pedunculated, the cord in the neighbourhood is frequently swollen and may show a leash of tiny vessels running to the tumour ; a white spiky appearance of the papillæ is suggestive of malignancy ; a sluggish delayed movement of the cord is an important sign, insisted on by Semon, but its absence by no means excludes malignancy, for it only occurs when somewhat deep infiltration has occurred, and is absent in a considerable proportion of early cases. Epithelioma beginning as a flat infiltration may resemble a tuberculous or syphilitic lesion, but usually other signs of these diseases are present to aid the diagnosis ; in the latter the Wassermann reaction and, still more, the results of vigorous anti-syphilitic treatment will clear up the doubt. There is a form of senile tuberculosis in which infiltration of one vocal cord may closely imitate epithelioma, more especially as the pulmonary signs are merely those of bronchitis and tubercle bacilli are very scanty in the sputum. Sometimes a piece may be removed for examination, but frequently the growth is too sessile to permit it ; the piece removed must not be very small, and a negative finding is of little value, for the tip of a malignant growth cannot always be distinguished microscopically from a papilloma. This removal should never be performed in inoperable cases, for it only stimulates the growth and does harm.

Extrinsic epithelioma is most likely to be mistaken for tertiary syphilitic ulceration. A gumma grows and ulcerates more quickly, its edge is smoother and sharper, and its base often covered by a yellow slough. Pain has little diagnostic value, for a gumma of the upper aperture may cause severe dysphagia. Palpation with the finger is of great service, for the firm hard feel of an epithelioma is very characteristic.

Treatment.—Malignant disease cannot be removed with certainty by the natural passages. Thyrotomy, or laryngo-fissure, is the operation of choice for removal of intrinsic cancer; it consists essentially in wide removal of the disease from the interior of the larynx after splitting the thyroid cartilage in the middle line. The results in suitable cases are probably better than those of removal of malignant disease in any other part of the body; there is now practically no immediate mortality in skilled hands, statistics show from 70 to 80 per cent. of permanent cures, and a useful husky voice remains. When, however, the growth has spread at all extensively to the arytenoid, or to the subglottic region, or across the anterior commissure to the opposite cord, laryngo-fissure is no longer possible and a very different picture is presented. Hemi-laryngectomy is performed in some cases in which the cancer is limited to one side, but it is impossible to protect the lungs from septic discharges and the mortality is very high. In most cases, too advanced for removal by thyrotomy, if operation is feasible, a total laryngectomy is preferable, for the trachea is sutured to the skin at the lower end of the neck and aspiration of sepsis thus avoided; in the last few years the mortality has been much reduced and the results, as regards freedom from recurrence, greatly improved. The operation leaves the patient in a condition very different from that after thyrotomy; as he breathes through the tracheal opening in the neck he cannot cough or strain and has no natural voice. Nevertheless he can often produce a faintly audible whisper by means of the air in the pharynx, or with the aid of a tube leading from the tracheotomy wound into the mouth or nose, and a number of cases succeed in passing a surprisingly happy and useful existence. Subhyoid pharyngotomy and, more recently, lateral pharyngotomy are operations designed to obtain access to cancers at the upper aperture of the larynx; the latter operation gives very good results in strictly limited tumours of this region. The technique of therapy by means of X-rays and radium has now been put on a reliable basis by determination of the appropriate dosage and by adequate screening; in many cases of malignant tumours of the larynx, great improvement can now be obtained by both these agencies, and a considerable proportion of cures has been effected. Radium, or its emanation, is enclosed in needles or small seeds of platinum and buried, accurately spaced, in and close to the tumour; or plates containing radium are embedded in wax and applied as a collar to the neck: the two methods may be combined in the treatment of any particular case. Great care and judgment are required in the selection of cases for these various operations, and very many come under observation too late. In these much can be done by palliative treatment; careful attention to the hygiene of the mouth and teeth is of great importance, together with mild antiseptic laryngeal sprays containing hydrogen peroxide, listerine, sanitas or carbolic acid. For dysphagia, insufflations of powdered orthoform, with or without anæsthesin, is the most reliable remedy; cocaine is disappointing, for its effect is very transient and

the resulting numbness interferes with swallowing ; the judicious administration of morphine or heroin is eventually necessary, but the local application of these drugs is useless. Palliative tracheotomy or gastrostomy may be called for, and partial removal or curettage gives relief in some cases of cancer at the upper aperture.

PARALYSIS

Paralysis of a vocal cord is a frequent symptom of various diseases of the thorax and of the nervous system, and the laryngoscope is therefore of great value to the physician as an aid to diagnosis ; this is more especially the case in that the common early form, abductor paralysis, causes no symptoms, and can only be recognised by laryngoscopic examination.

The larynx has two more or less antagonistic functions ; that of respiration, aided by abduction, and that of phonation, associated with adduction of the vocal cords. Of the two, the latter is the more recently acquired and, being directly controlled by the will, has a definite cortical centre situated bilaterally in the lower part of each ascending frontal convolution. On the other hand, the respiratory function is more vital, less under conscious control and is mainly represented in the medulla. Accordingly, functional disturbances always paralyse the adductors, while organic lesions affect first the abductor muscle.

ORGANIC PARALYSIS

In paralysis of the superior laryngeal nerve the affected cord remains slack and wavy and sags up and down with respiration. Owing to the short course of these nerves, isolated paralysis of the crico-thyroid is extremely rare ; it results from surgical or suicidal wounds, or by pressure from glands, but most often occurs after diphtheria. In lesions of the vagus above the origin of this branch the signs of this paralysis are obscured by that of the other muscles of the cord. The recurrent laryngeal nerves supply all the other muscles. In any progressive lesion of the nerve-path the muscles become paralysed in a definite order, the enunciation of which is known as Semon's law ; the abductors are first affected, then the tensors or thyro-arytenoidei, and finally the adductors.

In *abductor paralysis* the affected cord lies in the middle line ; during phonation the sound cord adducts to meet it and the larynx appears normal, but on inspiration it is drawn outwards and backwards and appears longer than its paralysed fellow, which remains unmoved. As would be expected from the course of the recurrent nerves, the left cord is far more often affected than the right. The voice is unaltered, but, although the glottic aperture is reduced by half, there is usually dyspnoea only on exertion, except in children, in whom the narrowing of the naturally small glottis may produce sufficient obstruction to necessitate a tracheotomy.

When the thyro-arytenoid fails, the edge of the cord is concave on phonation, the cord appears narrower than its fellow, and the voice gradually becomes husky. Finally, when total recurrent paralysis has occurred, the cord assumes the "cadaveric position" between the middle line and the normal position of rest. On phonation, the healthy arytenoid crosses the middle line and pushes the paralysed cartilage aside ; sometimes the latter

drops forward and exposes its broad posterior surface, which may be mistaken for a swelling. As the cords are still able to approximate, the voice is not necessarily lost, but is hoarse and easily tired, with a characteristic breathy quality, from waste of air, or a diphonic character, due to unequal vibration of the two cords.

In cases of *bilateral abductor paralysis* the cords lie together near the middle line. The voice is good, but the inability to take a full breath gives the speech a peculiar character; dyspnoea is a marked symptom accompanied by inspiratory stridor and severe paroxysmal exacerbations. When the disease progresses to complete *bilateral recurrent paralysis*, both cords remain in the cadaveric position, the dyspnoea passes off and the voice is reduced to a whisper.

Diagnosis.—The diagnosis is almost entirely a matter of accurate inspection. Obliquity of the laryngoscopic image, due to faulty position of the mirror, may cause confusion. In nervous subjects the cords are sometimes adducted on inspiration, but they will abduct naturally during the involuntary inspiration which follows a prolonged phonation. The only condition which really imitates paralysis is the fixation of the arytenoid cartilage which results from disease in or around the joint; its complete immobility with the presence of swelling or scarring often aids the diagnosis, but in old-standing cases of paralysis secondary fixation frequently occurs.

Ætiology.—The ætiology is of some importance, for it is on our knowledge of their causation that the diagnostic value of these lesions depends. The movements of the cords are represented bilaterally in the cortex cerebri, and stimulation of either centre produces movement (adduction) of both cords, from which it follows that no unilateral lesion above the bulbar nuclei can paralyse the larynx, and clinically we find that it is never affected in cases of hemiplegia. The bulbar centres lie in the floor of the fourth ventricle, and here a lesion of one centre causes paralysis of the cord at the same side which, in a gradually progressive lesion, attacks first the abductor muscle. Thence the nerve fibres pass in the roots of the bulbar-accessory to the vagus and recurrent laryngeal nerve; the cause of the paralysis may, therefore, be situated (1) in the medulla, (2) at the base of the skull, (3) in the vagus, or (4) in the recurrent laryngeal nerve.

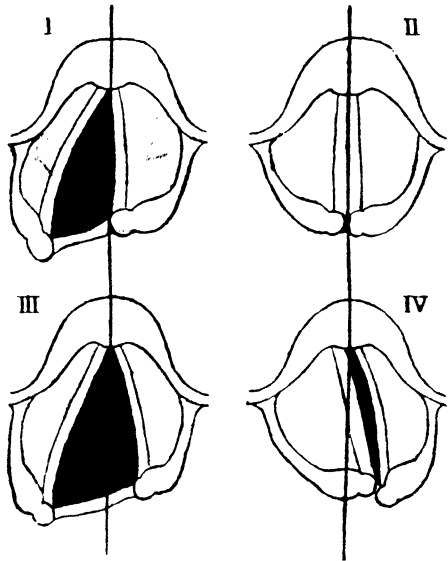

FIG. 113.—Organic Paralysis: I. Abduction paralysis of left cord on inspiration; II. Abduction paralysis of left cord on phonation; III. Total paralysis of left cord on inspiration; IV. Total paralysis of left cord on phonation. (*Lancet*.)

Paralyses of bulbar origin are often, but by no means always, bilateral. In lesions here and at the base of the skull neighbouring nerves are liable to be involved; thus, paralysis of a cord and of the same side of the palate may coexist (syndrome of Avellis), or paralysis of cord, palate, trapezius and sterno-mastoid from involvement of the spinal accessory roots, or persistent frequency of the pulse due to damage of the cardio-inhibitory centre or nerves. Tuberculosis dorsalis is the most frequent cause of paralysis of central origin; it may affect one or both cords and may be associated with anaesthesia, paræsthesia or the spasmodic attacks called "laryngeal crises." In general paralysis of the insane laryngeal palsy is not uncommon. It is the rule in bulbar paralysis, and is usually bilateral, but appears late in the disease. Syphilitic nuclear disease, pachymeningitis and gummata at the base of the brain are frequent causes, and here the ocular muscles, especially the external rectus, are often attacked.

Peripheral causes usually act by compression of the recurrent nerve, the most frequent causes being aneurysm, enlarged glands, usually tuberculous, and cancer of the œsophagus. Other causes are thyroid tumours, usually but not necessarily malignant, mediastinal tumours, cancer of the lung, pleurisy, and pulmonary tuberculosis in which the nerve, usually the right, may be involved in a lesion at the apex of the lung, or by tuberculous bronchial or tracheal glands. Neuritis is a cause of laryngeal paralysis; it may be produced by the toxins of the infectious fevers, usually diphtheria, or by organic poisons, especially lead, and more rarely arsenic and alcohol. Finally, the condition is sometimes the result of traumatism, more especially surgical operations on the thyroid gland and œsophagus.

Prognosis.—Paralysis of one cord is not in itself dangerous to life; but when the cause is undiscovered the prognosis must be guarded, for this paralysis may be for a long time the only sign of serious disease; on the other hand, the recurrent nerve may be involved in some non-progressive lesion, such as a fibrotic bronchial gland, and such cases of paralysed cord have been under observation for 20 or 30 years without change.

Treatment.—This depends on the cause. In most cases it is but a symptom of disease elsewhere and does not call for special treatment. In traumatic cases, however, the nerve may sometimes be found and sutured; afterwards, and in cases due to neuritis, strychnine and the local application of the faradic current by means of an intra-laryngeal electrode are indicated. Tracheotomy is advisable in bilateral abductor paralysis, but a plug may usually be worn in the tube, and removed at night and whenever dyspnoea threatens.

FUNCTIONAL PARALYSIS (FUNCTIONAL APHONIA)

Ætiology.—Functional aphonia is a common manifestation of hysteria, and has been a very frequent symptom of war-neurosis or "shell-shock," but it should be clearly stated that the majority of cases are not purely hysterical. Anything which increases the effort of phonation, such as debility or laryngeal catarrh, predisposes to this affection, which is characteristic rather of feeble neuro-muscular tone than of hysteria; this explains how some women lose the voice completely with every slight cold, while other patients can produce a loud if hoarse voice with severe laryngeal disease.

Symptoms.—Paralysis of the adductors presents a totally different clinical picture from the organic paralysis. It is always bilateral; the larynx appears normal while at rest, but, on attempts at phonation, it is seen that the cords do not adduct into the position necessary for the production of the voice. Very commonly the thyro-arytenoidei are the only muscles which fail to act; the cartilaginous glottis is then properly closed, but an elliptical chink is left between the cords. If the crico-arytenoidei are paretic, the entire glottis remains open to a variable extent, and, very rarely, the arytenoideus is affected alone, when a triangular aperture is left behind the vocal processes. The paralysis is hardly ever complete; indeed a considerable amount of movement is usually seen, though insufficient to produce phonation. In purely hysterical cases the onset and recovery are sudden, the cough is usually not aphonic and the voice when regained is not hoarse. In some hysterical patients there is also inability to whisper.

Treatment.—In patients suffering from debility the cause should be found and treated; chronic phthisis is such a common cause of functional aphonia that it should always be thought of in this connection. There is frequently a slight degree of laryngitis and in some the failure of adduction is "myopathic," or due to inflammation of the muscles; in these the local condition must receive appropriate treatment. When the larynx is normal the voice can nearly always be temporarily restored by any powerful local stimulation, such as the intra-laryngeal application of chloride of zinc, or any similar drug, or of the faradic current; but the aphonia usually recurs again, and succeeding applications are less effective, so that the most difficult cases to cure are those who have had much local treatment. Far better results are obtained by moral suasion, explaining to the patient that there is no serious disease; but that he is not using his muscles correctly, and that he can produce a good voice quite easily when the laryngeal mirror or tongue-depressor is in position. With a little elementary instruction in voice-production this is usually successful, the patient's confidence is restored and the voice does not again fail; in obstinate cases some perseverance in lessons on production is required. These methods have been extraordinarily successful with gassed and shell-shocked soldiers, but it must be confessed that such certain and rapid results are not always obtainable in hysterical women.

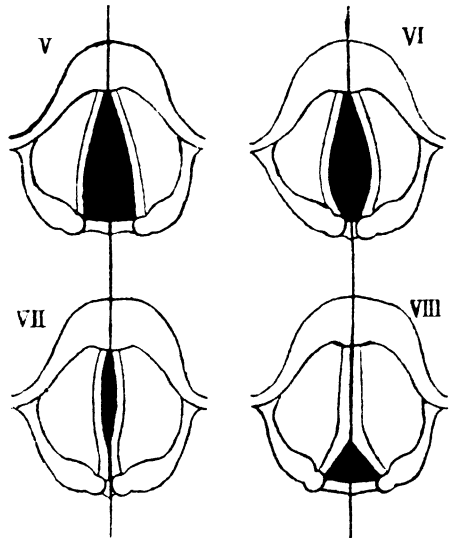

FIG. 114.—Functional Paralysis; all during attempted phonation: V. Paresis of all the adductors; VI. Arytenoideus still active; VII. Paresis of internal tensors; VIII. Paresis of interarytenoideus. (*Lancet*.)

SPASMODIC AFFECTIONS

GLOTTIC SPASM

Spasm of the laryngeal muscles produces adduction of the cords, for, though the abductors are probably affected, they are overpowered by the stronger adductor muscles.

Ætiology.—(1) In the majority of cases the spasm is a reflex set up by local irritation: foreign bodies, including the laryngoscopic mirror, irritating gases; inflammation, ulceration or tumours in or near the larynx, children being much more liable than adults to spasm from local irritation. (2) Spasm is also caused by irritation of the recurrent laryngeal nerves by enlarged glands, mediastinal tumours and, especially, by aneurysm. (3) Central nervous lesions, especially tubercles. (4) Functional disturbances, frequently hysterical, often associated with globus hystericus, and sometimes excited by sexual disturbances.

Symptoms.—The attacks vary much in different subjects in severity and duration. The patient is usually aware of its onset, and clutches some support or rushes to the window. The respirations are rapid and shallow, with loud inspiratory stridor, and, in the height of a severe attack, are completely arrested with all the signs of asphyxia. The subjective sensations include a horrible feeling of anxiety, but consciousness is not lost. Many cases are less acute but persist longer, even for several hours.

Prognosis.—The attacks are practically never fatal, unless a foreign body or tumour be present.

Treatment.—During the attack amyl nitrite or chloroform may be inhaled, and ampoules of these drugs should be kept on hand. Between the attacks sources of irritation should be sought for and removed, the upper air-passages brought to a healthy condition, and the general health and mode of life should receive attention. Administration of bromides may be required when the attacks recur frequently.

LARYNGISMUS STRIDULUS

Ætiology.—This is a condition, clinically similar to glottic spasm, occurring in children. It is far commoner than the spasm of adults, and it has been suggested that the asphyxial attacks of laryngismus are caused by collapse of the soft and yielding cartilaginous framework of the larynx. It is commonest between the ages of 6 months and 2 years, but may persist later; it occurs in ill-nourished, unhealthy children, usually in association with rickets, and practically always in association with adenoids.

Symptoms.—The onset is sudden and usually at night. The child wakes gasping for breath, and a series of short noisy inspirations are followed by complete cessation of breathing and terminated by a long, crowing inspiration. There are retraction of the lower ribs and epigastrium, cyanosis and great terror and distress, and in severe cases, carpo-pedal contractions, convulsions and evacuation of urine and feces. When the attack is over the child is perfectly normal and there is no hoarseness. Slighter and less typical attacks often occur.

Diagnosis.—This is easy if the symptoms are carefully noted; the sudden attack of dyspnœa, with complete absence of symptoms in the intervals, is quite distinctive.

Prognosis.—The prognosis is somewhat grave in severe cases; an infant rarely dies in an attack, but is often worn out and succumbs to collapse of the lungs.

Treatment.—During the attacks the face and chest may be freely sponged with cold water, and the inhalation of amyl nitrite from a capsule broken in a handkerchief may be tried. The quickest relief can usually be obtained by drawing the tongue forward with a finger passed into the mouth to its base, a manœuvre easily performed by the mother or nurse. The attacks are so short and sharp that there is no time for a hot bath or the administration of bromides frequently recommended.

Prevention involves general tonic treatment, fresh air, wholesome food and correction of digestive disturbances. The removal of adenoids is of great importance, even if not large enough to be definitely obstructive, as is the treatment of naso-pharyngeal catarrh with the usual saline lotion which, in small children, may be dropped into the nostrils from a pipette. Bromides are to be avoided if possible as depressing, but 10 to 30 drops of liquid extract of grindelia may be given 3 or 4 times a day in milk or sweetened water as recommended by Eustace Smith.

CICATRICIAL STENOSIS

Ætiology.—Suicidal and other wounds, gunshot injuries and scalds frequently produce cicatricial narrowing of the lumen of the glottis. After thyrotomy a web may form across the anterior commissure. In the haste of an emergency tracheotomy, the wound has often been made too high and the cricoid cartilage cut through; in these cases it generally happens that, after the subsidence of the acute condition, dyspnœa follows every attempt to remove the tube, and a stenosis is found to have resulted from swelling and narrowing in the subglottic region. Similarly, a proportion of cases intubated for diphtheria are unable to breathe without the tube, by reason of a subglottic stenosis. Lupus and tuberculosis of the larynx can produce cicatricial stenosis, but extensive cases of the latter disease rarely progress far enough towards healing for this to occur. Syphilis is the most fruitful cause of this condition, and the great difficulty of obtaining a cure at this stage is a powerful reason for early and thorough treatment of syphilis of the larynx. Leprosy and scleroma cause stenosis, but are rarely seen in this country. The perichondritis which is an occasional complication of enteric fever, small-pox and diphtheria, commonly ends in severe stenosis.

Symptoms and Diagnosis.—The principal symptom is naturally dyspnœa, but in chronic cases it is remarkable how great may be the narrowing before dyspnœa becomes severe. The obstruction and the stridor are most marked on inspiration, in contra-distinction to tracheal stenosis where the stridor is both inspiratory and expiratory. The larynx moves downwards with each inspiration; this "respiratory excursion" of the larynx is a further diagnostic sign of laryngeal obstruction, but is not always present. The patient sits upright, with the head thrown back; whereas in tracheal obstruction he bends forward to relax the trachea.

Treatment.—In all cases with decided dyspnoea tracheotomy should be first performed, and in syphilitic cases it is important that all active disease should be arrested by thorough treatment before any attempt at dilatation be begun, and the stenosis itself will often be greatly improved by such treatment. The administration of iodides is dangerous in these cases, for the increased secretion is pent up behind the stenosis and may overwhelm the lungs. Difficulty in dispensing with the tube after tracheotomy is sometimes due to nervousness on the part of the child, and can then be surmounted by using a fenestrated tube which is plugged occasionally and by encouraging the patient to breathe through it by blowing soap-bubbles or sounding a whistle. When the tracheotomy wound is too high, a low tracheotomy should be performed and the original wound allowed to close; this is often sufficient to overcome the difficulty.

The successful treatment of severe cicatricial stenosis demands the greatest skill and perseverance on the part of the surgeon as well as the patient co-operation of the sufferer. The whole circumstances of the case should be carefully considered before advising difficult and prolonged treatment. Adult patients can live active lives with a permanent tracheotomy opening. If the stenosis be not too extreme, a fenestrated tube may be worn which can be kept plugged during the day, so that the patient may have the use of speech and respiration by the natural passages. In children and young people a permanent tracheotomy is more harmful, and the prospect of cure by dilatation is better. The best method of dilatation is by the use of intubation tubes: under anaesthesia increasing sizes are passed until the stricture is dilated as far as possible, when the largest is left in position. This must have an especially large swell to prevent its being coughed out, or, better, is fixed by a special clamp passed through the tracheotomy fistula. In this way safety is assured, and the tube in these cases may be retained for 3 or 4 months without becoming foul; at the end of this time it is replaced, if necessary, by one of a larger size until dilatation is complete.

HAROLD S. BARWELL.

DISEASES OF THE TRACHEA

INFLAMMATION OR TRACHEITIS

ACUTE TRACHEITIS

Acute tracheitis may occur from any condition leading to irritation of the mucous membrane of the trachea. When it occurs as a result of bacterial or chemical agency, the whole of the upper air-passages are usually involved in greater or less degree, and the clinical manifestations are not confined to the trachea. In some cases, however, the stress of the resultant reaction falls upon this tube, and the condition therefore requires separate consideration.

Ætiology.—1. *Microbic invasion.*—This is the commonest cause. The bacteria usually found associated with tracheitis are the so-called catarrhal organisms, such as the *Micrococcus catarrhalis*, the pneumococcus, the Friedländer pneumo-bacillus and Pfeiffer's *Bacillus influenzae*. Less frequently

a member of the streptococcus group may be found, either alone or in association with one or more of those just mentioned. As with catarrhal inflammation of other parts of the upper air-passages, damp, cold or foggy climatic conditions predispose to tracheitis. It is more common in young and middle-aged adults than in infancy or in old age. Mouth-breathers are more liable to this condition. Exposure to sudden changes of temperature may be a factor in its onset.

Tracheitis may also occur as part of the clinical picture in some of the acute specific diseases, such as enteric fever, diphtheria, whooping-cough and measles. It is often a troublesome and distressing association or sequel of true influenza.

2. Chemical agencies.—Irritating or poisonous fumes and vapours may lead to a very acute form of tracheitis. It may, therefore, occur in certain occupations, unless adequate precautions are taken. The use of "poison gases" in warfare has drawn widespread attention to this form of the condition, since tracheitis was an almost constant result of certain forms of "gassing." The chief chemical irritants used in the Great War were chlorine, phosgene and yperite, or dichlorethyl sulphide, commonly known as yellow cross or mustard gas. Of these the latter was perhaps the most irritant to the trachea, and fatal cases invariably showed tracheal lesions. Direct inhalation of steam may also induce an acute tracheitis.

3. Mechanical causes.—The presence of a foreign body, or the invasion of the trachea by extension from malignant growth in adjacent structures may lead to a local or even to a general tracheitis. It is noteworthy, however, that the trachea is frequently spared in occupations involving the respiration of dusty air, which lead to deposits in the lungs and bronchial glands with resulting pneumokonioses. Although a coal miner's lungs are black, yet his trachea may be practically normal.

Pathology.—The changes found in the trachea vary from simple catarrhal inflammation to intense destructive changes with ulceration, and in some cases croupous or membranous exudate. In the catarrhal forms, the mucous membrane shows changes similar to those in bronchitis. It is at first swollen, red and dry, the vessels running across the trachea being engorged and clearly visible. Then, owing to increased activity of the mucous glands, excessive mucoid secretion occurs and the mucous membrane becomes moist, after which resolution may take place, or the process may proceed to a mucopurulent stage, when the fluid on the membrane coheres to form yellowish or green tenacious pellets. Occasionally numerous red blood cells are extruded and the tracheal exudate becomes streaked, tinged or uniformly pinkish.

In some inflammations, such as those induced by poison gases or inhaled steam, the mucous membrane may be intensely engorged and actual destruction may occur, involving even the deeper structures and the cartilages, so that greyish yellow sloughs result, which on separation leave ulcers. In diphtheria the characteristic false membrane composed of necrosing fibrin, leucocytes and bacilli may be found loosely attached to the mucous membrane, as in other localisations of this process. It may be primary or secondary to faucial or laryngeal diphtheria, either by direct extension or through diphtheritic infection of a tracheotomy wound.

In influenza the pink appearance of the trachea is of such constancy in fatal cases that it has come to be regarded as one of the most characteristic

1024 DISEASES OF THE RESPIRATORY SYSTEM

post-mortem changes found in this disease. The bright injection generally involves the lower half of the trachea, but it may occur along the whole length of this tube.

In whooping-cough the inflammatory reaction is usually less acute.

In typhoid fever small ulcers may occasionally be found in the trachea similar to those occurring more commonly in the larynx.

Symptoms.—Acute catarrhal tracheitis usually begins more or less acutely, like the common “cold,” of which it is to be regarded as one form, with malaise, slight headache, and a mild degree of fever, the temperature being usually between 99° and 100° F., rarely 101° F. The patient soon experiences a sensation of irritation behind the sternum, rapidly leading to a harsh, dry cough of noisy character. The cough aggravates the retrosternal discomfort, which develops into a sensation of rawness or soreness, making the cough very painful and distressing. If the larynx is involved at the same time, the voice becomes hoarse and sometimes lost, or reduced to a raucous whisper. In tracheitis alone the voice is usually unaffected. After from 12 to 24 hours the condition passes into the mucoid stage. The cough becomes looser and less painful, and small pellets of tenacious mucus are coughed up, usually greyish or black in town-dwellers, whitish in those in rural conditions; in either case, the mucus may be streaked with blood or even tinged a uniform pink colour; in the more acute forms, it sometimes becomes yellow and more purulent. In the mucoid stage, the retrosternal soreness becomes less, the constitutional symptoms abate, while the temperature subsides and becomes subnormal. The patient often feels weak and out of health for some days, and is sometimes left with a noisy morning cough and tracheal irritation which may last for days or weeks. The aspect of the patient shows nothing characteristic. There is the general appearance of fever, malaise and discomfort. The rise of temperature and increase in pulse-rate are usually moderate. In the early stages physical examination of the chest shows no abnormality, but when exudation occurs a coarse wheeze may be audible over the trachea, particularly when the patient takes a deep breath or just before a cough occurs.

Diagnosis.—The association of catarrhal symptoms with a dry, harsh cough and retrosternal soreness, without signs of bronchitis, is almost pathognomonic. In some cases the diagnosis can be established with the laryngoscope or by endoscopy, but in most the discomfort which these examinations entail is unnecessary.

Prognosis.—This is almost invariably good, except in debilitated subjects or in those with cardiac or renal disease, in whom the process may spread to the larynx, bronchi or lungs. The usual course is from 2 days to a week, though cough and expectoration may persist for days or weeks. The condition may become chronic. To some extent the prognosis depends upon the care and treatment in the initial stage. Cases that are neglected are liable to become chronic.

Treatment.—The prophylactic and remedial treatment of acute tracheitis is practically identical with that of acute bronchitis of the larger tubes. Even in mild cases the patient should go to bed, though this may be necessary only for 1 or 2 days; but he should keep to his room till his temperature has become normal. There may be less need for expectorants than in bronchitis, and a simple saline diaphoretic mixture, with the addition later of vin. ipecac.

and tinct. camphoræ co., may be all that is necessary. Sedative inhalations, such as vapor benzoini, are specially useful, and counter-irritation to the sternal region is comforting and grateful to the patient. When a chronic noisy cough develops, a mixture containing small doses of apomorphine and tinct. chloroform. et morphin. co. often gives relief.

When tracheitis occurs as part of some specific disease, such as diphtheria or influenza, the treatment should be that appropriate to the primary disease.

In "gassing," every effort should be made to relieve the distressing and painful symptoms, and for this purpose morphine, either alone or in combination with atropine and strychnine, may be required. Various inhalations may be tried, and useless cough should be checked by sedative mixtures or by a linctus of heroin, morphine or codeine.

CHRONIC TRACHEITIS

Ætiology.—Chronic tracheitis may follow an acute attack, or it may develop insidiously in patients suffering from chronic laryngitis or bronchitis. Inhalation of cigarette smoke is a not infrequent cause. It is also sometimes a sequel of chronic rhinitis, especially with the atrophic form or *ozæna*. A certain degree of chronic tracheitis accompanies the specific lesions of syphilis and tuberculosis, which are described below.

Pathology.—Various degrees of chronic inflammatory lesions may be found. In chronic catarrhal tracheitis, the vessels are distended or engorged, and the mucous membrane of the trachea becomes thickened and more or less covered with mucoid or muco-purulent secretion, the histological changes being those of chronic catarrhal inflammation, namely, shedding of the ciliated epithelial cells, overactivity of the mucous glands, and sometimes thickening and induration of the submucous tissues from proliferative changes. A condition of perichondritis of the tracheal cartilages may, in this case, be observed, and this may result in a mammillated appearance in the internal aspect of the trachea. In *ozæna*, crusts similar to those in the nose and pharynx may form on the tracheal mucosa.

Symptoms.—The symptoms of chronic tracheitis are similar to those of the acute form. There is a sense of discomfort and irritation about the trachea and a chronic, almost dry cough, often worse in the morning. There is generally some scanty, sticky expectoration, mucoid or muco-purulent, darkened by carbon particles and occasionally blood-tinged.

There are practically no physical signs of this condition, except that the tracheal changes can be observed by the laryngoscope or by endoscopy of the trachea.

Diagnosis.—This is concerned chiefly with its differentiation from chronic changes in the trachea due to syphilis, tuberculosis or leprosy and to the effects of new growths. It must largely be made by endoscopic examination.

Prognosis.—The prognosis depends upon the cause. When this can be removed, as by treatment of predisposing conditions in the nose and throat, the outlook is good. When the tracheitis is due to other conditions, such as syphilis and tuberculosis, it depends upon the situation and extent of the other lesions and upon the treatment adopted.

Treatment.—This is, in its main features, similar to that of acute tracheitis, but climatic treatment may be of great importance. The patient may perhaps

spend the winter months in a warm or equable and clear climate with great advantage. Vaccine treatment may also yield good results. When other conditions are concerned, such as *ozæna*, syphilis or tuberculosis, the treatment appropriate to them should be employed as well.

CYSTS AND TUMOURS

These are rare conditions, but require careful consideration.

CYSTS

Owing to weakening of the wall of the trachea, local bulging may occur, giving rise to a cystic, air-containing swelling in the neck, in direct communication with the lumen of the trachea. Such cysts are known as "tracheoceles" or "aeroceles." They are resonant to percussion and can often be temporarily reduced by pressure.

Small retention cysts may occur in the posterior wall of the trachea, from obstruction of the ducts of the mucous glands as they pass through the trachealis muscle. They are of pathological interest only, and do not give rise to symptoms.

SIMPLE TUMOURS

The most important is papilloma. It occurs chiefly in children and is usually pedunculated. When it grows in polypoid form it may lead to obstruction of the trachea low down, in which case tracheotomy may fail to give relief, and death results.

Other innocent tumours occur, but are rare. They include enchondrosis from localised overgrowth of cartilage, multiple enchondroma, and osteoma from ossification of a pre-existing enchondroma. Lipoma and aberrant thyroid tumours may occur, but are very rare.

Symptoms.—These tumours produce varying degrees of tracheal obstruction, and can usually only be recognised by endoscopy. Treatment is considered under that of tracheal obstruction.

MALIGNANT TUMOURS

A few cases of primary carcinoma of the trachea have been recorded. Secondary growths are not common, but the trachea is often involved and infiltrated by primary carcinoma in adjacent structures, such as the œsophagus, the thyroid, the larynx, or by the extension of secondary deposits in the cervical or mediastinal glands.

Primary sarcoma of the trachea is also very rare. The growth is usually smooth and not pedunculated. Secondary deposits of sarcoma in the trachea may occur from sarcoma of distant organs, such as the kidney; or it may be invaded directly by sarcoma originating in the thymus or other mediastinal structures, and especially by lympho-sarcoma of the mediastinal glands.

Symptoms.—The tracheal symptoms and signs are usually those of ob-

struction, accompanied by pain. When the primary growth is in the oesophagus, antecedent dysphagia and sometimes laryngeal paralysis reveal the origin of the tracheal symptoms when they occur. In this case, copious frothy mucoid expectoration is frequent, and when ulceration develops, food particles may enter the trachea, excite cough and soon lead to inhalation broncho-pneumonia or gangrene. When the growth is near the bifurcation, urgent dyspnoea is the rule, and spasmodic attacks may occur, causing the most extreme distress. In most cases of tracheal growth the characteristic clanging brassy cough (gander cough) of tracheal obstruction can be heard. The trachea may be pushed to one side and its lumen distorted and obstructed by growth in the cervical glands. In mediastinal new-growth invading the trachea, the pressure signs and symptoms characteristic of that disease usually render the explanation of the tracheal symptoms apparent.

Course.—This is generally rapidly progressive.

Diagnosis.—Intratracheal growths have to be differentiated from other causes of tracheal obstruction and the diagnosis is considered in detail under that condition. Endoscopy would afford valuable confirmation if it is practicable or desirable. In oesophageal and mediastinal new-growths invading the trachea, X-ray examination may assist in diagnosis.

Prognosis.—This is hopeless, death occurring from asphyxia or from some complication or by asthenia.

Treatment.—Treatment can be palliative and symptomatic only. In obstruction, it may be possible in rare cases to give temporary relief by a low tracheotomy, but as a rule this is impossible, owing to the presence of obstruction below any point where the trachea is accessible.

THE INFECTIVE GRANULOMATA

SYPHILIS

The trachea may be affected in both the congenital and acquired forms.

In congenital syphilis, a progressive cicatrisation may occur, leading to stenosis. In acquired syphilis, during the secondary stage, the mucous membrane of the trachea may become generally hyperæmic, or small raised mucous patches may develop locally. In the tertiary period, gummata may occur in the trachea, the commonest site being towards the lower end. Degenerative processes, leading to necrosis and softening, eventually result in ulceration, sometimes with local sloughing of parts of the tracheal rings. In the process of cicatrisation a progressive stenosis may develop.

Symptoms.—Symptoms are those of chronic tracheitis and tracheal irritation in both the secondary and tertiary manifestations, but in the latter, signs of tracheal stenosis may develop when scarring and healing are in progress. Laryngeal involvement occurring at the same time tends to distract attention from the tracheal lesions or to obscure them.

Diagnosis.—The diagnosis of syphilis of the trachea depends upon a careful study of the history of the case, indications of tracheal irritation, laryngoscopic or endoscopic examination, the coexistence of other manifestations of syphilis, and in their absence, a positive Wassermann reaction.

Prognosis.—If the condition is recognised early, excellent results may

1028 DISEASES OF THE RESPIRATORY SYSTEM

be obtained by treatment, but it is obvious that where deep destructive changes have resulted, medicinal measures can only palliate.

Treatment.—Anti-syphilitic treatment should be administered vigorously, and after a course of neo-salvarsan or novarsenobillon, mercury should be given. Inunction seems sometimes of special value in such cases. In cases of stenosis of the trachea from cicatrization, dilatation of the stricture by means of bougies introduced through an endoscope may be practicable and afford useful help.

TUBERCULOSIS

Tuberculosis of the trachea is occasionally found post mortem in advanced cases of pulmonary tuberculosis, usually in those with extensive laryngeal involvement. Primary tracheal tuberculosis is unknown. The rarity even of secondary lesions in this tube is probably to be explained by the ciliated epithelium preventing lodgment of the bacilli.

Pathology.—Tuberculous lesions may occur at any part of the trachea, but they are more frequent in the lower part and on the posterior wall. When they occur they are usually numerous. There may be some general hyperæmia, or small tubercles, varying in size from a pin's head to a split pea, may be visible. Later, superficial ulceration occurs, forming irregular punched-out ulcers. Occasionally, the process may extend deeper, and erosion of the cartilages may occur, with the formation of sinuses and even fistulous communication with the œsophagus.

Symptoms.—Since tracheal tuberculosis is usually a late manifestation of advanced disease, its clinical indications are slight and are usually obscured by the more obvious laryngeal and pulmonary symptoms and signs, though if the process extends deeply and produces sinuses and fistulous tracks, it may become apparent. The actual tracheal symptoms are those of cough and retrosternal soreness.

Diagnosis.—This condition has to be distinguished from other chronic tracheal lesions, and a diagnosis can only be made from a careful review of the history, the general evidence of tuberculous disease and by the tracheal involvement which may be visible by endoscopy.

Treatment.—This must, from the nature of things, be largely palliative, and is in effect practically identical with that of laryngeal tuberculosis, notably intratracheal insufflation with orthoform and anæsthesin.

LEPROSY

In some cases of this disease, granulomatous lesions occur in the trachea, and these may eventually give rise to tracheal stenosis, owing to the contraction of new-formed fibrous tissue. The diagnosis can only be made from the occurrence of tracheal symptoms in a case with established lesions of leprosy in other parts.

The treatment is symptomatic.

SCLEROMA

Although in most cases this condition affects the nose only, scleromatous lesions may be found in the trachea as a pathological curiosity. The disease

in any form is rare in England, and occurs chiefly in Poland and Austria. The nodules of granulomatous tissue in the trachea may cause partial obstruction mechanically, or, on contraction, lead to actual stenosis.

TRACHEAL OBSTRUCTION

Obstruction to the lumen of the trachea may be produced by foreign bodies, by conditions originating in the trachea, and by pressure from without.

FOREIGN BODIES IN THE TRACHEA

The commonest route by which foreign bodies enter the trachea is through the mouth and larynx, in the acts of breathing, laughing, yawning, sighing, or before and after coughing, when food or some foreign substance is in the mouth. A piece of bone, a stud, button, false teeth, chewing gum, peas, articles of food, nuts, grains of wheat, beads or blades of grass are among the substances which may gain entrance to the trachea in this manner. Surgical operations in the mouth and throat may lead to the inhalation of a tooth, a piece of tonsil or a mass of adenoid tissue. Material vomited from the stomach, such as food, blood clot or intestinal worms, may be inhaled into the trachea. A large blood clot in hæmoptysis may temporarily obstruct it. Foreign bodies may also gain access through the tracheal wall, such as small projectiles in wounds of the neck, a piece of new growth or tuberculous glands by ulceration through the wall.

Unless it becomes impacted, or is too large to enter one of the two main bronchi, a foreign body rarely remains long in the trachea. It either causes death with dramatic rapidity, is coughed out again, or passes down into one or other of the large bronchi or their secondary divisions, where it produces results which are described in the section on diseases of the bronchi.

Symptoms.—These depend upon the mode of entry, the size of the foreign body, and the degree of obstruction to the air current which it induces, but in general the tracheal symptoms are less urgent than those of laryngeal obstruction, and less serious than those of obstruction of one or other main bronchus. There may be intense dyspnœa, with great discomfort and alarm during the actual passage through the larynx of a small foreign body, especially if it is temporarily arrested there; but when it enters the trachea there is an almost instantaneous cessation of the acute distress, though some degree of dyspnœa may persist. The type of dyspnœa is inspiratory in the main, though a minor degree of expiratory difficulty may be apparent if the foreign body is of considerable size. There may be a definite stridor with both phases of respiration, but it is more pronounced in inspiration. If the foreign body remains loose in the trachea, which may occur if it is rounded and too large to engage in one of the main bronchial divisions, a sound of vibratory character may be heard on auscultation of the trachea, sometimes described as the *bruit de grelottement*. This may be produced by friction of the foreign body against the tracheal wall, or more commonly by the air passing over it during respiration. A paroxysmal cough may occur, caused by the foreign body irritating the sensitive posterior wall of the trachea, and during such an attack the foreign body may be forced up to the larynx,

obstruct it, or cause reflex spasm with intense dyspnœa and cyanosis and a risk of suffocation, unless it drops back, is coughed out, or removed. When sudden rupture of caseous material into the trachea occurs, the lumen may be blocked and death take place rapidly.

Course.—A foreign body impacted in the trachea may give rise to septic inflammation of its walls, with subsequent cicatrisation after removal, or it may lead to secondary infective processes in the lungs, such as purulent bronchitis and broncho-pneumonia.

Diagnosis.—The history of disappearance of some object from the mouth during coughing, breathing or laughing should give rise to suspicion of an inhaled foreign body, and this may be confirmed by seeing the object directly by endoscopy, or indirectly by means of the X-rays.

Prognosis.—This depends in the main on the nature of the foreign body, and the time elapsing before its removal. An irregular, rough or soft foreign body is more likely to induce septic complications than a smooth, hard substance. Apart from rapidly fatal results, the prognosis is better with intratracheal foreign bodies than with those reaching the bronchi. If removal is effected within 24 to 36 hours, recovery is usually rapid and complete.

Treatment.—Treatment consists in rapid removal with as little damage to the trachea and larynx as possible. This may be effected by means of forceps passed through a Killian's bronchoscope, either by the mouth or through a tracheotomy wound, a method requiring expert manipulation, or by tracheotomy alone, when the foreign body may be coughed out through the opening or be easily removed by forceps. The tracheotomy wound should be kept open by means of a dilator instead of the usual tracheotomy tube. Inversion of the patient in the hope that gravity may assist the expiratory efforts of cough is dangerous and should only be attempted after tracheotomy has been performed. Where rupture of a caseous gland or softening new-growth occurs into the trachea, an immediate tracheotomy may be necessary.

OBSTRUCTION FROM CICATRISATION OF THE TRACHEAL WALLS

Ætiology.—This may result from any condition leading to ulceration of the tracheal walls, with subsequent healing, such as a syphilitic gumma, or less commonly other granulomata, such as tubercle, leprosy or scleroma. Another cause is cicatrisation from wounds of the trachea, accidental, suicidal or after tracheotomy, when the incision has been made too near the cricoid, or when the wound has become infected or the tube left in too long. Scarring from damage to the trachea by the inhalation of boiling or caustic liquids or even by inhaled gases may lead to stenosis.

Pathology.—The deformity of the trachea and the obstruction of its lumen depend upon the situation and the extent of the cicatricial contraction of its walls. It may be local, producing an hour-glass constriction, or involve a long extent of the tube. Occasionally, especially in syphilitic lesions, stenosis may occur at two different levels.

Symptoms.—These depend upon the degree of stenosis, the rapidity with which it develops, and the condition of the larynx, bronchi and lungs. When the stenosis is produced gradually, as in cicatrisation, a degree of obstruction may result, greater than would be compatible with life if suddenly

induced. In the early stages of a progressive stenosis, slight dyspnoea may be present on exertion, and during sleep a faint stridor may be audible, disappearing when the patient is awake. As the contraction progresses, the dyspnoea becomes more marked, and a definite and persistent stridor develops, at first inspiratory only, though expiration may become both noisy and obstructed. The patient may experience a sensation of obstruction referred to the neck or under the sternum, accompanied by pain and irritation, leading to cough, which may be dry, noisy and metallic, or accompanied by more or less frothy sputum, if the primary condition is associated with widespread tracheitis. The voice may lose tone and volume, and the patient talk more quietly than normal and with some evident effort. In advancing stenosis, sudden and alarming attacks of dyspnoea may occur, leading to cyanosis and threatening suffocation. These attacks are usually due to an accumulation of mucus at the site of the stenosis. The patient in advancing degrees of obstruction cannot lie down, and generally sits leaning forward with chin depressed. It may be noted that the extraordinary muscles of respiration contract forcibly, and yet the laryngeal excursions may be small or hardly noticeable, in contrast with those of laryngeal obstruction in which they are maximal. This distinguishing sign was first pointed out by Gerhardt, and is of value, but unfortunately it is not absolute and cannot, therefore, be regarded as pathognomonic. On auscultation over the trachea, a noisy roar may be audible, of maximum intensity near to the obstruction, whereas the breath sounds over both lungs may be deficient, although the stridor may be conducted bilaterally.

Course.—The course of cicatricial stenosis is usually progressive, unless arrested by treatment, and the dyspnoeic attacks become more frequent and alarming.

Diagnosis.—Tracheal obstruction from cicatrization has to be distinguished from laryngeal obstruction, in which the symptoms are usually more acute and more urgent. Gerhardt's sign described above may also be suggestive. It must also be differentiated from obstruction due to pressure from without (*vide infra*). The only reliable method of distinction is by direct inspection with the bronchoscope.

Prognosis.—Early syphilitic stenosis may be arrested by appropriate anti-syphilitic treatment. Obstruction due to other granulomatous conditions varies with the severity and extent of the primary lesions. Caseous material or degenerated growth ulcerating into the trachea is usually immediately fatal, or leads to death within a few days from pulmonary complications.

Treatment.—Rest, avoidance of exertion, smoking and alcohol should be advised. The patient's fears should be allayed and symptomatic treatment ordered, such as sedative inhalations or a linctus to check useless cough. In syphilitic stenosis vigorous anti-syphilitic treatment with salvarsan¹ should be given. A low tracheotomy may be necessary for an intractable stricture high up in the trachea. In some cases where an ordinary tracheotomy cannot be performed below the stricture, it may be possible to insert Koenig's long tracheotomy tube through an opening in the trachea made above it. In

¹ According to Mr. Harold Barwell, administration of potassium iodide is very dangerous, as it increases the secretion which is pent up behind the stenosis. It may be given in combination with belladonna, but it is better withheld until the severity of the condition has been relieved by salvarsan.

1032 DISEASES OF THE RESPIRATORY SYSTEM

other cases, dilatation of a fibrous stricture by bougies passed through an endoscope may be feasible.

OBSTRUCTION FROM EXTERNAL PRESSURE

Pressure on the trachea may occur in the neck or in the mediastinum.

Causes of pressure in the neck.—Strangulation, throttling or garotting leads to death by occlusion of the trachea and suffocation. Enlargement of both lobes of the thyroid body may cause lateral compression of the trachea, until eventually its lumen is reduced to a narrow slit—the so-called “scabbard trachea.” Irregular or unilateral enlargements on the other hand cause deviation of the trachea, with kinking of its lumen. Other less common causes of compression of the trachea are enlargement of the cervical glands from tuberculosis, malignant disease, Hodgkin’s disease or leukæmia. The trachea may be pressed on from behind by a foreign body impacted in the œsophagus, or by a bony tumour arising from the vertebræ.

Causes of pressure in the mediastinum.—An aneurysm of the aortic arch may press directly upon the trachea at, or near, the bifurcation and cause obstruction. Similarly deep pressure may be caused by a retrosternal goitre, a persistent and enlarged thymus, or a thymic abscess, mediastinal glands enlarged from any cause, usually malignant disease, a dermoid cyst or a bony tumour originating in the sternum.

Symptoms.—The symptoms are in the main identical with those of stenosis of the trachea from intrinsic causes, with the special symptoms due to the primary external condition superadded.

Diagnosis.—This may be simple and obvious, as in those cases due to pressure from tumours in the neck, whereas, in those due to mediastinal pressure, it is usually only possible after a careful survey of all the symptoms, and is in brief identical with that of aneurysm or mediastinal new-growth, to which reference should be made. In some cases X-ray examination may give valuable information.

Prognosis.—This is good in obstruction due to causes in the neck other than malignant disease, but it is almost uniformly bad, indeed hopeless, in obstruction due to mediastinal causes, with the exception of abscess and some thymic conditions.

Treatment.—The treatment is that of the primary condition. In goitre and tuberculous glands, in simple tumours and some thymic conditions, operation may be possible and may effect complete cure. In those due to mediastinal pressure, especially from aneurysm or new-growth, treatment, in most cases, can be only palliative or symptomatic, and directed to the relief of pain, dyspnœa, cough and distress.

INJURY

Direct violence to the trachea has been known to cause rupture when the chin is raised upwards and the trachea is, therefore, extended.

R. A. YOUNG.
G. E. BEAUMONT.

DISEASES OF THE BRONCHI

BRONCHITIS

Inflammation of the bronchi, or bronchitis, is one of the commonest maladies and may be induced by a variety of causes. These, in the main, fall into three groups, bacterial, chemical and mechanical, similar to the causes of tracheitis, which is, indeed, in many cases, a concomitant or antecedent of bronchitis, so that tracheo-bronchitis would be a more accurate designation of the majority of cases. At the same time it should be recognised that the trachea may be alone or predominantly affected, while, on the other hand, in many cases of bronchitis of the smaller tubes, the trachea may escape, or be only slightly involved.

Bronchitis is so varied in its extent and in the form and severity of its manifestations that a satisfactory classification is somewhat difficult to formulate. Fowler's classification into (1) acute bronchitis, (a) of the larger tubes, and (b) of the smaller tubes; (2) chronic bronchitis; (3) secondary bronchitis; and (4) plastic or fibrinous bronchitis, is convenient as a combined clinical and pathological grouping, but fails to separate what appear to be clinically distinct entities. We propose to consider the clinical manifestations of bronchitis according to the following classification:

1. ACUTE FORMS—(a) Catarrhal bronchitis, (1) of the larger tubes, (2) of the smaller tubes; (b) ~~suppurative~~, (c) secondary bronchitis; (d) bronchitis due to mechanical and chemical agencies; (e) ~~fibrinous~~.

2. CHRONIC FORMS—(a) Catarrhal, (b) suppurative, (c) secondary, (d) due to mechanical agencies, and (e) fibrinous.

ACUTE BRONCHITIS

ACUTE CATARRHAL BRONCHITIS OF THE LARGER TUBES

Synonyms.—This condition is often called Bronchial Catarrh, or Acute Tracheo-bronchitis.

Ætiology.—*Predisposing causes.*—Climate and latitude undoubtedly play an important part. Catarrhal bronchitis is rare in polar and arctic regions and near the equator, but is very prevalent in damp and foggy climates. In England attacks are common in late autumn, winter and early spring. It is probable that some degree of hereditary predisposition occurs, since "weakness of the chest" is common in some families. Owing chiefly to greater exposure, the disease occurs more frequently in men than in women. It is most common at the extremes of life, infancy and old age, but it is not infrequent at any age. Fatigue and privation play their part, and exposure to cold, wet or fog so frequently seems to initiate the attack that it is often regarded as the exciting cause. Scoliosis, kypho-scoliosis and other malformations or deformities of the chest predispose to bronchitis, and some of them are induced or aggravated by bronchitis early in life. Chronic cardiac and renal disease both render their subjects more liable to bronchitis, as do also conditions of the nose and pharynx which lead to mouth-breathing, in consequence of the inhalation of air which is unwarmed and

unfiltered by the nose. In childhood, dentition seems to be a frequent predisposing condition.

The exciting cause is usually one of the catarrh-producing organisms, and one or more of the following may be found in the sputum: the pneumococcus, Friedländer's pneumo-bacillus, streptococci, *Micrococcus catarrhalis*, staphylococci, *M. tetragenus*, and occasionally *Bacillus coli communis*. It may also be caused by the *Spirochaeta bronchialis* (see p. 189). In health, the bronchial mucosa is in all probability sterile, though this has been disputed, and it is possible that a "carrier" condition may occur here as in the upper air-passages.

Pathology.—The changes induced in the bronchi are similar to those in the nasal mucosa in coryza and in the trachea in tracheitis. Three stages may be described: An initial dry stage, when there is active hyperæmia of the bronchial mucosa, with exudation into the submucous layer, causing temporary diminution of the bronchial secretion from occlusion of the mucous ducts. The second or mucoid stage is associated with copious discharge of mucoid secretion, owing to increased activity of the mucous glands, this secretion being mixed with shed ciliated epithelial cells and scanty leucocytes. Sometimes in acute cases a few red blood corpuscles are present. The third stage is that of resolution, though not infrequently a muco-purulent stage occurs, when the sputum becomes less copious and greenish in colour from large numbers of pus cells.

In fatal cases the lung tissue may appear slightly distended and red, while the bases may be sodden from œdema. On section, the bronchi appear injected and the mucosa is swollen. On squeezing the lung, beads of mucoid fluid or muco-pus exude from the cut ends of the bronchi. There is no consolidation and the lung tissue floats in water.

Symptoms.—An attack of acute bronchitis generally begins suddenly, with malaise, aching in the limbs, and a sense of oppression in the chest. If the trachea is also involved, there is the characteristic feeling of rawness under the sternum. The temperature rises, varying from 99° to 100° F. in mild cases to 103° F. in more severe ones. The cough is at first dry, irritating and ineffective, but in a few hours it becomes looser. The sputum in the early stage is scanty, tenacious and sometimes streaked with blood; it then becomes copious, mucoid and frothy in character, and is found to contain mucus, shed epithelial cells, leucocytes and red blood corpuscles; later it lessens in quantity and may become thick, yellow and muco-purulent. With the onset of expectoration there is generally an abatement in the symptoms, the rawness under the sternum disappears, and the feeling of pain or soreness about the pectoral muscles and the costal attachments of the diaphragm lessens. The febrile reaction may last only 3 or 4 days, but the cough and expectoration may go on for 10 days or longer, gradually diminishing, until they are present only night and morning, and then cease completely.

In the early stage the patient is flushed and the breathing may be slightly increased in rate, but it is rarely or never laboured, unless emphysema co-exists. Vocal fremitus is unaltered, but rhonchal fremitus may sometimes be felt over one lung or both. The chief physical signs are discovered only on auscultation. The breath sounds may be harsher and higher-pitched, particularly in infants and children, but they remain vesicular, and expira-

tion may be prolonged. The voice conduction is unaltered. As a rule rhonchi, either sonorous or sibilant, according to the size of the bronchus in which they are produced, are audible over both lungs and during the mucoid stage bubbling râles may be heard, especially at the bases.

Complications and Sequelæ.—Bronchitis may go on to bronchopneumonia or may be followed by lobar pneumonia, fibroid induration or bronchiectasis. It may lead to chronic bronchitis, or be followed by active tuberculosis. Occasionally acute interstitial emphysema may result from violent coughing.

Course.—This is variable. The patient may be convalescent in from 7 to 14 days, but cough, expectoration and a condition of debility may continue for several weeks, though, in this case, the possibility of pulmonary tuberculosis should always be considered.

Diagnosis.—The diagnosis of bronchitis is usually easy, owing to the characteristic rhonchi, but it is important to differentiate primary bronchitis from bronchitis occurring as a secondary condition in acute specific fevers and other diseases.

Prognosis.—Bronchitis of the larger tubes is rarely fatal, except when it occurs in infants or the aged, or as a complication of advanced cardiac or renal disease.

Treatment.—*Prophylactic.*—This consists in the avoidance of stuffy, ill-ventilated rooms and places of entertainment when catarrhal infections are rife. In mouth-breathers, steps should be taken to deal with the conditions of the naso-pharynx inducing this habit, and instruction in normal breathing given. In dusty occupations, suitable measures should be taken to minimise the irritant particles in the air, as is now done in most factories and workshops. Where poisonous gases have to be encountered the excellent form of gas-mask evolved during the war should be utilised.

Prophylactic inoculation by vaccines, either from stock mixtures such as are now available, or from autogenous cultures, are now being extensively used, and with some success. Detoxicated vaccines are also used for this purpose, so that larger doses can be administered. An autogenous vaccine is usually to be preferred, if possible. The dose given depends upon the organism and varies from 1 to 50 or 100 millions. Two or three doses at intervals of 7 to 10 to 14 days are usually given in the case of the stock vaccines, whereas with the autogenous a course of 6 to 12 gradually increasing doses is given at intervals of about a week.

General.—No matter how mild the attack may be at the onset, the patient should be kept in bed. This may only be necessary for 1 or 2 days, but he should keep to his room till his temperature has returned to normal. The Turkish bath taken by some patients at the first onset is unwise and should be discouraged. The room temperature should be kept at 60° to 65° F. While the temperature is raised the diet should be the ordinary, simple, liquid diet suitable to febrile conditions, namely, milk, weak tea, cocoa and simple gruels, broths or one of the many invalid foods. The patient is often thirsty, and warm or hot demulcent drinks, such as toast and water, fruit juices in hot water, and linseed tea sometimes afford great comfort. The air of the bedroom may be moistened by means of a steam kettle in the dry stage, but the use of a steam tent is to be avoided. Local applications over the sternum, acting as counter-irritants, seem to give some relief to the

distressing soreness so often complained of. A mustard leaf or one of the medicated wools is the most easy to apply, but a linseed poultice, anti-phlogistine or a liniment, such as camphorated oil or the acetic turpentine liniment, may be ordered. Some patients find a cold or hot compress to the neck comforting. Medicated inhalations may be used, either in a special inhaler or in a domestic substitute, such as a jug. At first vapor benzoini—1 drachm to the pint—is the most comforting, but in later stages vapor olei pini sylvestris or a dry inhalation of creosote, terebene and spirits of chloroform may be useful. It is often wise to start treatment with an aperient, unless this is contra-indicated. In the dry stage, a simple saline diaphoretic mixture may be given, with vin. ipecacuanhæ or vin. antimoniale in small doses. One-drop doses of tincture of aconite are also sometimes given. When expectoration starts it may be encouraged by saline and stimulating expectorants, such as ammonium chloride and carbonate, combined with squills and flavoured with syrup of tolu or of Virginian prune. For the first night it may be well to give 10 grains of Dover's powder to relieve discomfort and secure sleep.

During convalescence the patient should take care to avoid chill and should be given a more liberal diet. A mixture of strychnine and phosphoric acid may be given for a few days, and a linctus or lozenge containing small doses of heroin or other sedative, to lessen the ineffective cough, which not infrequently occurs. Convalescence is usually shortened by a few days' stay at the coast, especially the south.

When bronchitis occurs as a part of some specific disease, such as diphtheria or influenza, the treatment should be that appropriate to the particular disease.

CATARRHAL BRONCHITIS OF THE SMALLER TUBES

Synonym.—Capillary Bronchitis.

It is open to question whether this condition exists as a separate entity. When the finer bronchi and bronchioles are inflamed the alveoli invariably become involved, since very little swelling of the bronchiolar walls is sufficient to occlude the lumen of the tube, with the inevitable production of an area of lobular collapse. The transition from this condition to actual lobular pneumonia is a very small one. In any case, the causes, the symptoms and the treatment of capillary bronchitis and broncho-pneumonia are identical. (See Secondary Broncho-pneumonia.)

ACUTE SUPPURATIVE BRONCHITIS

Synonyms.—Sometimes called Acute Purulent Bronchitis, or Suffocative Catarrh.

This condition was brought into prominence during the recent Great War. In 1916 and 1917 it appeared in epidemic form amongst the British troops in England and France. Although it was then regarded by some observers as a new disease, it is more probable that it was, in reality, an epidemic form of a condition usually rare and sporadic and previously termed "suffocative catarrh." That name has unfortunately been applied loosely to a number of conditions associated with acute dyspnoea.

Ætiology.—*Predisposing causes.*—The exceptionally severe winter of 1916-17, together with conditions of overcrowding in huts and billets, were undoubtedly concerned in the epidemic just mentioned. The condition affects young adults chiefly, and is much more common in men. Over-exertion, fatigue and debility predispose to it, but the disease may occur in robust and healthy persons. A history of chill may be given, but often no obvious cause can be discovered.

Exciting cause.—The organisms usually found are the pneumococcus and Pfeiffer's *Bacillus influenzae*, the latter being reported in 90 per cent. in some series of cases. The *Micrococcus catarrhalis* is also sometimes present.

Pathology.—A very intense inflammation occurs in the medium-sized and small bronchi, leading to an exudate rich in leucocytes. The inflammatory process may extend to the alveoli, which then contain a fibrinous fluid, with entangled red cells. The condition occurs in both lungs and is usually almost universal, no portion being spared. Post mortem the lungs are heavy and red in colour. On section the bronchi are found to contain a thick yellow purulent fluid. Small areas of collapse and sometimes of broncho-pneumonic consolidation are seen, and there is usually œdema of the bases. Plastic pleurisy is not infrequent, and the glands at the root of the lung are enlarged.

Symptoms.—The onset is usually abrupt, often in young people apparently in robust health. A definite chill may occur, or only coryza and general malaise, with aching of the muscles. The temperature rises quickly and may reach 104° F. early in the disease. A cough soon develops and extreme dyspnoea is a characteristic feature. Expectoration starts early, often on the second or third day. At first it may be streaked with blood, but it soon becomes yellowish green and nummular; it consists of almost pure pus; there is often as much as 5 or 6 ounces in 24 hours. In most instances there is great prostration. In grave cases the patient becomes unconscious and loses control of the sphincters.

There is intense cyanosis, the face, lips and ears being purple. Respiration is rapid, 30 or 40 per minute, and the accessory muscles are often in full action. Palpation and percussion may not show any abnormality, though slight dullness is sometimes present at the bases. At first no signs may be discovered on auscultation, but soon the breath sounds become largely obscured by medium-sized bubbling râles, often audible from apex to base, both front and back. The pulse is frequent, the right heart may dilate and the heart-sounds become weak.

Complications and Sequelæ.—In severe cases recurrent bronchitis, broncho-pneumonia, fibroid disease or emphysema may follow.

Course.—In favourable cases complete restoration to health results. In severe cases the course is rapid, the patient becomes comatose from toxæmia, expectoration ceases and death occurs from exhaustion in 2 or 3 days from the onset. In other cases the disease may last for weeks and proceed to recovery or death.

Diagnosis.—The occurrence of marked dyspnoea and cyanosis early, the expectoration of copious pus, and the widespread râles without dullness are very suggestive of acute suppurative bronchitis. The disease must be differentiated from other conditions described as acute suffocative catarrh, that are associated with extreme dyspnoea and cyanosis.

Acute pulmonary œdema is usually afebrile, and the sputum is albuminous, frothy and copious. The condition leading to it, such as cardiac or renal disease, may be apparent.

Capillary bronchitis or broncho-pneumonia may give rise to difficulty, but in these conditions the sputum is scanty, tenacious, sometimes rusty, and but rarely purulent; moreover, cyanosis and dyspnœa develop late and depend upon the extent of the disease and the condition of the right side of the heart.

Pneumonia of the wandering type may simulate this condition, but the character of the signs, with dullness and tubular breathing, and the rusty sputum, usually render diagnosis easy.

Prognosis.—This is very grave. The mortality is high, often as much as 50 per cent. Cases extending to 3 weeks or more with swinging temperatures usually recover.

Treatment.—Cases of this disease should be isolated. If there are indications of an epidemic spread, prophylactic inoculations with a vaccine made from the special strain of pneumococci concerned may be useful in limiting it. When once the disease has set in, unfortunately little except symptomatic treatment is available. The steam tent and the inhalation of medicated vapours, such as vapor benzoini, may give a little relief to the dyspnœa. Oxygen has not been found beneficial, though it may be tried. Venesection may give temporary relief, but produces no lasting effect. Ammonium carbonate and potassium iodide are generally recommended. Stimulants, such as brandy and strychnine, should be given freely, and hypodermic injections of camphor in sterile oil up to 10 or 20 grains a day may be given. Vaccines have so far not proved of any curative value.

SECONDARY BRONCHITIS

Ætiology.—Bronchitis, usually of catarrhal type—indistinguishable as regards symptoms and signs from primary acute catarrhal bronchitis—occurs as a definite part of many acute infectious diseases and as a complication in others. Among these may be mentioned measles, whooping-cough, influenza, the enteric group, small-pox, diphtheria, malaria and plague. Acute nephritis of infective origin is often accompanied by acute bronchitis. Other conditions associated with bronchitis are pulmonary tuberculosis, glanders, secondary syphilis, pleurisy and gunshot wounds of the chest.

Diagnosis.—Bronchitis is easy to recognise, but it is important not to overlook the fact that it may not be the primary condition. In all cases of bronchitis in the early stages, the possibility of a primary acute specific infection should be borne in mind. The diagnosis is also of importance in regard to treatment—for example, in malaria, nephritis and syphilis, in which treatment directed to the primary condition may be more helpful than the ordinary treatment of catarrhal bronchitis.

BRONCHITIS DUE TO MECHANICAL AND CHEMICAL AGENCIES

Ætiology.—*Mechanical.*—Attacks of acute bronchitis may be caused by the inhalation of dust-laden air. In occupations where the worker is liable to inspire fine particles of carbon, silica, steel, iron or kaolin, acute bronchitis

may result, but more often these conditions lead to chronic bronchitis and pneumokoniosis. Pressure on a bronchus by aneurysm or new-growth, or irritation by the presence of a foreign body, may induce local acute bronchitis. The symptoms and signs are practically identical with those of the catarrhal form and need no special description.

Chemical.—Acute bronchitis may follow the inhalation of chemical irritants, either as a result of occupation, accidents, attempts at suicide, or the use of poison gases in warfare. Special attention has been drawn to this subject by the large number of cases of “gassing” dealt with in the Great War. Death not infrequently occurred, much acute suffering was caused, and some permanent damage has resulted in many cases which recovered. “Mustard gas” produces its chief effects upon the skin, the eyes and the bronchi. A fibrinous exudate forms on the mucosa as a false membrane, which separates as a slough. The suffocative gases chlorine and phosgene affect the alveoli primarily and more intensely. Chlorine inhaled in a concentration of 1 in 10,000 causes a rapid alveolar flooding with a serous and highly albuminous fluid, and if the victim does not die at once he is liable to suffer from an acute bronchitis. A condition called bronchiolitis fibrosa obliterans has been described as a sequel.

Symptoms.—These are similar to those of acute catarrhal bronchitis, but there is great pain, distress and almost constant cough, often with copious expectoration.

The treatment is referred to under the heading of Tracheitis, and is, in the main, symptomatic and directed to the relief of pain, useless cough, and distress.

ACUTE FIBRINOUS BRONCHITIS

Synonym.—Acute Plastic Bronchitis.

Definition.—A comparatively rare acute disease in which there is inflammation of the bronchi, with the formation of casts. These may be hollow or solid, and are coughed up in the expectoration.

Ætiology.—The cause of the disease is unknown. It is more common in males, and is met with both in children and in adults. It may begin as a primary catarrhal bronchitis, or develop as a complication of enteric fever, measles or pulmonary tuberculosis. Such organisms as the pneumococcus or a streptococcus may be found in the casts.

Pathology.—The casts may involve the main bronchi only, or more frequently the smaller ones and the bronchioles. They are greyish white, solid or tubular, and when large, bear the impress upon their exterior of the bronchial walls in which they have been enclosed. Thus, when a cast extends up to the lower portion of the trachea, the indentations made by the tracheal rings may be seen impressed upon it. The fine terminations generally show a spiral moulding. Chemically, they consist of fibrin or of fibrin and mucin. Post mortem, the casts may be seen in some places *in situ*; in other areas the bronchi from which they have been expelled may be recognised. The bronchial mucous membrane is at times acutely inflamed, red in colour, with the lining epithelial cells desquamating, or it may appear pale and unaffected. There is usually a certain degree of emphysema, and there may be collapse of lung tissue beyond the site of obstruction.

Symptoms.—The disease generally begins somewhat abruptly with a cough and malaise. In the course of a few days the patient becomes considerably worse, dyspnoea develops and a certain degree of pyrexia, but the temperature is often not more than 99° or 100° F. The dyspnoea becomes more intense, and is the prominent and all-important symptom. The face is seen to be cyanosed, the *alæ nasi* and the accessory respiratory muscles are in violent action, sometimes with retraction of the intercostal spaces. There may be diminished movement of the chest, either bilateral or unilateral. If there is unilateral pulmonary collapse the heart may be slightly displaced towards the same side. Vocal fremitus may be normal or locally diminished. The percussion note is somewhat hyper-resonant over the anterior chest-wall, but behind there may be some degree of dullness over one or other lobes. If the bronchi are unilaterally affected there may be dullness limited to one lower lobe, with diminution of air entry and no adventitious sounds. Vocal resonance over the affected area is lessened. There is usually some diffuse bronchitis, as indicated by the presence of rhonchi or râles. Marked stridor is sometimes heard with respiration. A special sign, the “bruit de drapau,” has been described when the cast lies free in the bronchial lumen. It is a dry clicking sound, caused by the flapping of the cast against the wall of the bronchus as the air passes over it. The ordinary sputum does not show any peculiarities. It may, however, show Curschmann’s spirals, Charcot-Leyden crystals and eosinophile cells, and it may be absent until the crisis occurs. This consists in the expectoration of the cast after a violent fit of coughing. The cast may be stained with blood, or there is sometimes actual hæmoptysis. The peculiar nature of the expectoration often escapes notice, unless it is examined by floating in water, when a large intact cast is revealed. The dyspnoea ceases immediately after the cast has been expelled.

Complications and Sequelæ.—Emphysema may occur as the result of the violent coughing, or the disease may become chronic, recurring at intervals of varying duration. The most serious complication is laryngeal obstruction, caused by the cast becoming impacted between the vocal cords.

Course.—The disease is generally self-limited, terminating with the separation and expectoration of the cast. The acute stage does not, as a rule, continue for more than 12 to 24 hours.

Diagnosis.—The stridor and respiratory obstruction are suggestive of œdema of the glottis, but auscultation will show that the site of the lesion is lower down the respiratory tract. Asthma, and all causes of laryngeal and tracheal obstruction, must be excluded. The dyspnoea and the presence of signs localised to one lobe may suggest an active lobar collapse, or a lobar pneumonia, but the dyspnoea is more intense than is met with in either of these conditions. Casts are expectorated in diphtheria, pneumonia, chronic disease of the heart, pulmonary tuberculosis and hæmoptysis. The casts of acute fibrinous bronchitis are firmer than those found in these affections, and are expectorated in long pieces, showing the many branches and bifurcations of the bronchial tree.

Prognosis.—The immediate outlook is fair. Death may occur in the first attack, or recurrences may take place, which lead to an increasing degree of emphysema, with its usual results. The ultimate prognosis is, therefore, not good.

Treatment.—The patient should be kept in bed and treated as a case

of acute bronchitis. Inhalations of medicated vapours often afford relief. Potassium iodide is believed to expedite the separation of the cast. Intra-tracheal injections of olive oil or lime water have been recommended, as the casts tend to dissolve in the latter. Tracheotomy instruments should always be at hand in case of laryngeal impaction.

CHRONIC BRONCHITIS

Chronic bronchitis is perhaps even more difficult to classify than the acute varieties, each one of which may have its counterpart in chronic form, so that the same classification may be followed. At the same time it must be admitted that, especially in the catarrhal forms, the clinical manifestations are somewhat varied.

CHRONIC CATARRHAL BRONCHITIS

Ætiology.—The causes are practically identical with those of the acute form, of which it is in most cases a sequel.

This affection may commence at any age, although it is more common in middle life and with advancing years. Men are more frequently affected than women. It seems also to have a special incidence in some families. It is more common in damp and foggy climates, and is favoured by urban conditions and by dusty occupations. It starts each winter with a more or less acute catarrhal attack, but each year the summer intermission becomes shorter, until the bronchitis persists throughout the year. It tends to produce emphysema and is aggravated in turn by this condition. It is especially favoured by cardio-vascular lesions, such as valvular defects and arterial disease; also by gout, chronic nephritis, syphilis and alcoholism. Conditions associated with chronic cough predispose to it, notably emphysema, asthma, arrested pulmonary tuberculosis, mouth-breathing and cigarette smoke inhaling.

The bacteria found are practically identical with those in acute bronchitis, the commonest being the pneumococcus, Friedländer's pneumobacillus, *Micrococcus catarrhalis*, streptococci and staphylococci. Mixtures of two or more of these may be present. A rarer cause is bronchial spirochætosis, from infection with the *S. bronchialis* (see p. 189).

Pathology.—The bronchi show chronic inflammatory changes of a catarrhal nature. The walls are thickened from chronic hyperæmia and also from productive changes in the connective tissues. The mucous glands may be hypertrophied or atrophied, and there may be widespread desquamation of the ciliated epithelial lining of the bronchi. In long-standing cases there is usually some peribronchitis, leading to cylindrical bronchiectasis and distortion of the bronchi by fibrosis. There is almost invariably a greater or less degree of emphysema, which may be generalised or only marginal. Post mortem, the lungs are generally red and somewhat engorged, but if much emphysema has resulted they may be paler than normal. On squeezing the lung after section, pus or muco-pus exudes from the cut bronchi, and there is usually some evidence of œdema at the bases.

Symptoms.—A patient with chronic bronchitis complains of his "chest." By this he means that he suffers from cough, expectoration and shortness of

breath on exertion. The cough varies greatly in its severity. During the warm weather the patient may be completely free, and yet suffer for years from a winter cough. It may occur frequently throughout the day and in attacks at night, or only in the mornings and evenings.

The expectoration varies considerably in quality and quantity, so much so that the old classifications of chronic bronchitis were based on this factor. Thus, there may be practically no sputum or only small tenacious pellets, the "crachats perlés" of Laennec, which gave rise to the name "catarrhe sec": on the other hand, there may be a profuse expectoration resembling unboiled white of egg diluted with water, constituting the form described as "pituitous catarrh" or "bronchorrhœa serosa." Usually the sputum is mucous or muco-purulent and contains greyish-black particles mixed with a frothy fluid. The dyspnoea is largely due to the accompanying emphysema, and so indicates the degree of chronicity of the disease. At first the patient may only notice that he gets out of breath on going upstairs or on mounting slopes, but later even walking on the level causes dyspnoea.

Slight rises of temperature occur in the acute exacerbations of the catarrhal process. Slight cyanosis is frequently observed, especially after exercise, when the accessory respiratory muscles are called into play. Sometimes rhonchal fremitus is felt. Movement of the chest is restricted by emphysema, and the percussion note then becomes hyper-resonant. On auscultation, expiration is prolonged and sonorous or sibilant rhonchi are heard all over the lungs, with bubbling râles if there is thin secretion in the smaller bronchi. On the other hand, rhonchi may be scanty or only occasionally heard. Voice conduction is unaffected. The fingers may be slightly clubbed, and further evidence of venous obstruction apparent in the dilated venules on the cheeks or along the costal attachments of the diaphragm.

Complications and Sequelæ.—The following changes may occur in the lungs—peribronchial fibrosis, bronchiectasis and emphysema. Asthma or attacks of bronchial spasm sometimes form a complicating factor in chronic bronchitis, especially in the cases of so-called bronchorrhœa. The increased cardiac strain may lead to right-sided dilatation, with basal pulmonary congestion, ascites and œdema of the legs. Late in the disease, as the result of the cyanosis, a peculiar form of confusional delirium is met with, which is worse at night. Trophic lesions, such as dermatitis herpetiformis and pulmonary arthropathy, are occasionally seen.

Course.—The disease once firmly established, unless relieved by suitable climatic treatment, remains chronic and becomes progressively more severe as further damage is wrought in the lungs with each hibernal exacerbation. As the emphysema develops, a vicious circle is initiated, the aerating power of the lungs diminishes, and finally cardiac failure ensues.

Diagnosis.—Chronic bronchitis must be distinguished from pulmonary tuberculosis, bronchitis secondary to heart failure, and from bronchiectasis. In tuberculosis with bronchitis there is generally wasting, and often flattening of the chest-wall, owing to fibrosis of the lungs. In all cases where the summer intermission of the symptoms fails suddenly rather than lessens gradually, tuberculosis should be suspected. The diagnosis is clinched by the presence of tubercle bacilli in the sputum. In bronchitis secondary to heart failure, in addition to the cardiac signs, the râles in the lungs are chiefly basal and the rhonchi are not so universally distributed. In bronchiectasis

the signs are usually characteristic and limited to one lobe. The X-rays may afford useful aid in diagnosis.

Prognosis.—The immediate prognosis is good, the ultimate is bad. Much depends upon the patient's social condition and opportunities for treatment, especially in respect to climate. The expectation of life of a patient suffering from chronic bronchitis is considerably shortened.

Treatment.—Those subject to chronic bronchitis should live in a warm, equable and dry climate. In England the south-western districts are best, but it is advisable to winter farther afield if possible, either on the Riviera, the north coast of Africa, or in Madeira. High altitudes should be avoided if emphysema is present or if there are cardiac complications. Exposure to wet and chill is dangerous. The question of occupation is often difficult. Much time should be spent out of doors, provided that the patient is not exposed to the inclemencies of the elements; and, further, the work undertaken must not involve severe muscular efforts, or the inhalation of dusty or irritant particles.

In England it is difficult to find an outdoor occupation conforming with these desiderata, consequently light indoor work in a good atmosphere should be advised. Clothing should be warm but light, and afford special protection to the chest without overloading, as some patients are liable to do. Excesses in diet are to be avoided, also alcohol and heavy smoking. The general nutrition should be well maintained, and many patients, especially those of spare habit, seem to derive great benefit from cod-liver oil during the winter months.

If cough is troublesome and expectoration tenacious or scanty, various combinations of expectorant remedies are useful, such as ammonium carbonate or chloride, vin. ipecacuanhæ, preparations of squills or senega, with tolu, liquorice or Virginian prune as flavouring agents. A simple saline mixture, such as the "Mist. sodæ cum æthere chlorico"¹ of the Brompton Hospital Pharmacopœia, in the morning or at night, may help to "clear the tubes" and give the patient a spell of freedom from cough. In older patients the ether and ammonia mixture may be given, and in cases with bronchial spasm potassium iodide with anti-spasmodics, such as stramonium, lobelia, belladonna or grindelia, may be of great value. Various antiseptic drugs, such as turpentine ℥ x, terebène ℥ v-x, creosote ℥ iij in capsules or perles, have been recommended, and the elixir thymi et diamorphin. ʒi. Sedative lozenges, such as the compound liquorice, heroin or codeine, are often useful in checking useless cough. Intercurrent attacks of acute bronchitis must be treated on the principles described under that condition and the patient kept indoors or in bed, as may be necessary. When an advanced degree of emphysema coexists the treatment appropriate to that condition should be applied. Sometimes benefit may follow the use of the compressed air chamber. When failure of the right heart ensues, with visceral engorgement, the treatment must be modified suitably as described under emphysema. Liniments applied to the chest wall, especially those containing camphor, turpentine or belladonna, are soothing and afford relief. Care should be taken that any tendency to constipation is checked. In some cases, especially when the predominant organism is the *Micrococcus catarrhalis* or Friedländer's

¹ R. Sodii bicarb., grs. x; sodii chlorid., grs. iij; sp. chlorof., ℥ v; aquam anisi ad ʒi.

1044 DISEASES OF THE RESPIRATORY SYSTEM

pneumo-bacillus, an autogenous vaccine prepared from the sputum ameliorates the symptoms. This should be considered especially in cases unable to undergo suitable climatic treatment.

CHRONIC SUPPURATIVE BRONCHITIS

Synonym.—*Fœtid Bronchitis*.

Ætiology.—This condition is not sharply defined and is not a specific and separate nosological entity, but it is a convenient group to include cases with fœtid purulent sputum. In some forms of chronic bronchitis the secretion may from time to time accumulate in the bronchi and prove offensive on expectoration. In some instances this condition becomes chronic and the expectoration is fœtid up to the time of death.

Pathology.—There is chronic inflammation of the bronchi, with marked peribronchial thickening. The bronchial secretion becomes purulent, and ulceration of the bronchial wall may occur. Post mortem, the lungs are soft, and on section some broncho-pneumonic areas, with œdema of the bases, may be seen. Pus of an offensive nature exudes from the cut ends of the bronchi.

Symptoms.—These resemble those found in chronic bronchitis, with, in addition, the unpleasant characteristics of the sputum. In the latter, Dittrich's plugs may be found. These are small, yellowish bodies, with an intensely offensive odour, composed of compact secretion.

Complications and Sequelæ.—Ulceration of the bronchial walls, abscess or gangrene of the lung, and areas of broncho-pneumonia may develop. As with bronchiectasis, pyæmia sometimes ensues, with the formation of secondary abscesses in the brain.

Course.—The disease is progressive, but in the early stages there may be long remissions in which the sputum is not offensive although the bronchitis persists.

Diagnosis.—The sputum is offensive in abscess and gangrene of the lung, bronchiectasis and interlobar empyema. X-ray examination of the chest is of great value in revealing these conditions, but they can generally also be recognised by their characteristic signs.

Prognosis.—As the disease becomes firmly established the patient's strength is gradually undermined from the absorption of toxins, and death ensues in the course of a few years, either from exhaustion, toxæmia or pyæmia.

Treatment.—An endeavour should be made to lessen or prevent the offensive character of the sputum. For this purpose creosote or garlic may be administered, as in bronchiectasis. Creosote vapour baths are also of great value. Apart from this, the treatment is as for chronic bronchitis.

CHRONIC SECONDARY BRONCHITIS

Chronic bronchitis is a common association of chronic cardiac and renal disease, and possibly also of gout. Its clinical characters do not need special description. It is only necessary to emphasise, as in the acute forms, the importance of recognising that the bronchitis is not the essential condition, and that treatment must be directed especially to the primary disease.

CHRONIC BRONCHITIS FROM MECHANICAL AND CHEMICAL AGENCIES

This usually proceeds to interstitial changes in the lung, and these results may be studied more conveniently under the heading of the pneumokonioses.

CHRONIC FIBRINOUS BRONCHITIS

Acute fibrinous bronchitis has been described above. In certain cases of chronic catarrhal bronchitis a fibrinous exudate may occur from time to time, with the formation of intrabronchial casts. There is then cough and dyspnoea, which abate with the expectoration of the cast. It therefore very closely resembles acute fibrinous bronchitis, and the treatment indicated is that described above.

TUMOURS OF THE BRONCHI

Tumours arising in the bronchi are somewhat uncommon. They may be (a) simple, or (b) malignant.

Simple tumours.—The following varieties occur: Adenoma, lipoma, myxoma, papilloma and chondroma. Any of these may lead to bronchial obstruction and, in consequence, to either collapse or bronchiectasis, but otherwise they rarely give rise to symptoms or physical signs, and they are for the most part only of pathological interest.

Malignant tumours.—Primary carcinoma or sarcoma may originate in the bronchi, but both are rare. In carcinoma the growth is usually of the columnar type, and presumably arises from the lining epithelium of the bronchi or from that in the mucous glands. In some instances secondary deposits of carcinoma may follow very closely the paths of the main bronchi.

Sarcoma may originate in the connective tissue of the bronchial walls. Even after death it may be difficult to establish the bronchial origin of an intrathoracic new growth. During life it is impossible to do so, since the symptoms and signs are indistinguishable from those of new growth of the lung, to which the reader is referred.

THE INFECTIVE GRANULOMATA

SYPHILIS.—During the secondary stage, a generalised hyperæmia of the bronchial mucous membrane may occur, giving rise to slight bronchial catarrh with the usual symptoms and signs, a condition that has been called syphilitic bronchitis. It is frequently beneficially influenced by anti-syphilitic treatment. In the tertiary stage, gummata may form in or near the large bronchi. They tend rather to fibrosis and contraction than to softening and ulceration, although the latter processes may occur. Contraction may lead to bronchial stenosis, with the symptoms and signs described below, or to extensive peribronchial inflammation and bronchiectasis. If the gummata extend into the lung, as may happen in rare instances, destructive lesions with cough, expectoration and hæmorrhage may result. This condition is more fully described in the section on pulmonary syphilis.

TUBERCULOSIS of the bronchi occurs as part of pulmonary tuberculosis and does not require separate description.

LEPROSY.—The bronchi may be involved in this disease, with the production of cellular infiltration and even nodule formation. At first, these lesions may produce bronchitis, but they are progressive and lead to cough, expectoration, wasting and asthenia. The general clinical picture may simulate chronic pulmonary tuberculosis, from which it is distinguished by the presence of leprous lesions elsewhere, and the absence of tubercle bacilli from the sputum.

BRONCHIAL STENOSIS AND OBSTRUCTION

Obstruction of the main bronchi or of their subdivisions within the lungs may arise from causes within the bronchi or from conditions outside them, and these require separate consideration. It is important to emphasise the fact that in both conditions the symptoms differ according to whether the obstruction is sudden and complete, in which case collapse of the corresponding lung is the rule, or whether it is partial and more gradual, when bronchiectasis usually results.

1. INTERNAL CAUSES

These are most conveniently considered in two groups—(a) **Foreign bodies**; (b) those due to cicatrisation of the bronchial walls.

(a) **FOREIGN BODIES IN THE BRONCHI.**—These usually gain access through the larynx and trachea by inhalation. Any inhaled foreign body that is small enough to pass down the trachea may reach a main bronchus, more commonly the right, or if it is small it may pass into one of the secondary bronchi. It may at once become impacted, or be moved by cough, but unless it is expelled in this way, it is sooner or later drawn into the smallest bronchus that will receive it, and there becomes impacted.

The recorded varieties of foreign body thus reaching the bronchi are very numerous, but among the more common are pieces of bone, beads, pins, coins, ear-rings, studs, pencils, fruit stones, grains, grasses, beans, nuts, teeth and pieces of tonsil or adenoid growths after tonsillectomy. Even a living fish has been inhaled into a bronchus. Foreign bodies may reach the bronchi through a tracheotomy wound, or a gland may ulcerate into the lumen of a bronchus. Broncholiths and pneumoliths, calcareous particles originating in the bronchi and lungs respectively, may be inhaled into a bronchus instead of being expectorated.

Pathology.—The pathological changes resulting from a foreign body in a bronchus depend upon the nature of the foreign body, the duration of its stay, the size of the bronchus obstructed by it, and the degree of obstruction induced. If the foreign body is smooth and comparatively little septic, and if it be removed within 24 hours or so, complete recovery after a very mild local inflammatory reaction may be expected. If, on the other hand, the foreign body is rough, or soft and laden with septic organisms, acute pneumonic processes, often septic in character, may develop very rapidly. A soft type of foreign body may swell and com-

pletely obstruct the bronchus it reaches, leading to complete collapse of the corresponding lung area, often the whole or half of the lower lobe. If the stay of any foreign body is prolonged to days, weeks, months or longer, irreparable damage almost invariably results. The forms this may take are numerous. Collapse and septic pneumonia have already been mentioned. If the obstruction is partial, septic bronchitis, with stagnation of the bronchial exudate and pus behind the obstruction, leads in turn to peribronchitis, bronchiectasis and fibroid induration of the corresponding lung area. In other cases gangrene of the lung results. Not infrequently an empyema may occur and the foreign body may be found in the empyema cavity. Suppuration round a foreign body may lead to localised intrapulmonary suppuration or abscess.

Symptoms.—During the passage of the foreign body through the larynx and trachea urgent symptoms may occur which leave no doubt as to what has happened; but this is not invariable, and the patient may not be sure whether he has inhaled or swallowed it. In any case, after a bronchus has been reached, there may be a latent period which engenders a sense of false security and leads to delay in treatment. In most cases pain, discomfort and cough develop rapidly. The cough may lead to the expulsion of the foreign body, or may cause dyspnoea if it forces it up to the larynx. The cough soon becomes noisy, often paroxysmal, and if local septic changes are set up expectoration occurs, sometimes mucoid and copious, at others muco-purulent. Pain may be absent, but is often severe. The temperature is generally normal for the first few hours, but soon rises, especially if bronchitis, pneumonia or broncho-pneumonia develop. The further symptoms are those of the reactive changes and complications which ensue.

The physical signs naturally depend upon the bronchus affected and upon the degree of obstruction. They are at first those of deficient air entry. The affected side may show less movement, and there may be some recession of the lower intercostal spaces in young people. If a large bronchus is involved and collapse results, there is some displacement of the heart to the affected side. Vocal fremitus may be diminished or absent, the percussion note impaired, and the breath-sounds and voice-sounds weak or absent over the whole or part of one lung, almost invariably the lower lobe. An "asthma-toid wheeze" has been described in America. This consists of a wheezing sound heard at the end of inspiration on listening close to the open mouth when the patient breathes deeply. When bronchiectasis, empyema or other conditions develop, their characteristic signs become apparent.

Complications and Sequelæ.—Many of these have been enumerated in describing the pathological results. Sometimes septic meningitis or cerebral abscess develops.

Course.—Spontaneous relief may occur in two ways, either by the foreign body being coughed up, as may happen within a few hours or days or after an interval of months or years, or the foreign body may track through the lungs and pleura, and be discharged in an abscess bursting through the chest wall. In both cases, if an interval of more than days occurs, irrecoverable damage may have resulted. Apart from these occurrences and from successful treatment the course is very variable. Death may occur quickly from some of the septic complications, or after a longer or shorter interval from bronchiectasis, gangrene or cerebral abscess.

Diagnosis.—The history of disappearance of some article from the mouth in the act of laughing, breathing, yawning or sighing, etc., should always arouse suspicion of an inhaled foreign body. If signs indicating bronchial obstruction are found, the diagnosis is almost certain. In every suspicious case radiograms of the chest should be taken in two different directions, in case the shadow may be merged in that of the scapula or of the ribs. The possibility of a foreign body should always be borne in mind in cases of unilateral basic bronchiectasis, especially if no obvious cause can be found. When such unilateral lung signs develop after an anæsthetic, or after operations on the mouth or naso-pharynx, the possibility of some inhaled material should always be remembered.

Prognosis.—This is grave unless the foreign body is removed within 36 hours, owing to the various dangerous complications that may ensue. Excluding the few cases in which cure occurs by spontaneous discharge of the foreign body, about 50 per cent. of cases left untreated die within 1 or 2 years.

Treatment.—This consists in removal, if practicable, as soon as possible after the diagnosis is established. If the foreign body is in a main bronchus or one of its principal divisions it can usually be removed by means of the bronchoscope and appropriate forceps. The operation requires very careful anæsthesia and expert manipulation. Where these are not available a tracheotomy may be done, when sometimes the foreign body is coughed out or can be extracted. If these methods fail the question of pneumotomy may have to be considered. If this is decided on, every effort must be made to localise the foreign body by X-ray examination. If intrapulmonary or pleural suppuration has occurred, this must be dealt with surgically, and sometimes the foreign body can be removed at the same time. The medical treatment of the cases consists in that of the various conditions resulting.

(b) **STENOSIS FROM CICATRISATION OF THE BRONCHIAL WALL.**—**Ætiology.**—The causes of this condition are those leading to ulceration of the bronchial wall, with subsequent healing, such as syphilitic processes in and around the bronchi, ulceration from injury produced by a foreign body or in its removal, or by the inhalation of severe irritants. The fibroid variety of tuberculosis may also produce it.

Pathology.—The stenosis may occur in one of the main bronchi, or in one passing to a lobe or to part of a lobe. At first partial, it may progress, until the lumen is almost completely occluded at one point. The changes occurring in the lung beyond the obstruction vary with its degree. At first there is retention of secretion in the bronchi, and air may be forced past the obstruction in inspiration, but not expelled during expiration, producing emphysema, with commencing bronchial dilatation. When the obstruction is more complete the air is absorbed, the lung tissue gradually becomes fibrotic, and the bronchi dilate further.

Symptoms.—Cough, not infrequently of paroxysmal character, is an early symptom and is usually a continuation of that caused by the primary condition. It may be dry or associated with mucoid sputum, sometimes blood-streaked. The expectoration may cause dyspnœa, by obstructing the narrowed bronchus. If bronchiectasis develops the sputum becomes fœtid.

The physical signs are those of collapse of a part of the lung and are progressive. Local limitation of movement and flattening, with displacement of the heart to the affected side, may be apparent on inspection. The

vocal fremitus is diminished, the percussion note, impaired at first, may progress to complete dullness when fibrosis develops. The breath-sounds are weak or even absent, and the voice-sounds diminished. In the early stages a bronchial stridor may be audible. Compensatory emphysema of the adjacent healthy lung tissue often develops.

Complications.—These are similar to those in stenosis from a foreign body, notably fibrosis and bronchiectasis.

Course.—Unless the primary condition causing the stenosis is one which can be arrested by treatment, the condition is progressive, and eventually the area of lung beyond the obstruction becomes permanently functionless.

Diagnosis.—Bronchial cicatrization must be differentiated from obstruction due to extrabronchial causes, such as pressure from new-growths, aneurysm and the other mediastinal conditions mentioned in the section below. The history, the physical signs and examination by X-rays and possibly by the bronchoscope may help in distinguishing. The Wassermann reaction should be investigated in every case where the stenosis is proved to be of intrabronchial origin.

Prognosis.—This varies with the cause. It is most favourable in cases due to syphilis submitted to treatment at an early stage.

Treatment.—Vigorous anti-syphilitic treatment should be employed in cases due to syphilis. In other cases the treatment is to relieve symptoms by appropriate measures.

2. EXTERNAL CAUSES

These may be subdivided into—(a) Mediastinal conditions, chiefly enlargement of the bronchial or mediastinal glands from tuberculosis, Hodgkin's disease or malignant growth, aneurysm of the aorta, mediastinal abscess, pericardial effusion and oesophageal new-growths. (b) Intrapulmonary causes, generally primary or secondary new-growths.

Symptoms.—These are practically identical with those just described, but in addition there are those of the condition causing the pressure.

Diagnosis.—This has been discussed in the previous section. The bronchoscope should not be employed where there is any suspicion of an aneurysm.

Prognosis.—This is extremely unfavourable, except in cases due to tuberculous glands and pericardial effusion, and in some cases of mediastinal suppuration.

Treatment.—This can only be palliative in the majority of cases. Useless cough may be checked by a sedative linctus of heroin or morphine. Dyspnoea when due to spasm may be lessened by inhalations of creosote and spirits of chloroform, or by administration of oxygen. Pain may be relieved by aspirin or other analgesic drugs.

ASTHMA

The term asthma has been loosely employed to denote any form of dyspnoea of expiratory type occurring in paroxysms. For all conditions other than that now to be described some descriptive qualification should be employed to avoid confusion.

Asthma or true spasmodic asthma is a paroxysmal affection, occurring most frequently in patients of neuropathic inheritance. It manifests itself in attacks of severe expiratory dyspnoea due to excessive vagal discharges, set free by peripheral irritation, chemical agencies or cerebral influences.

Ætiology.—Probably no other disease shows such a varied and complex causation, but recent studies of idiosyncrasy and anaphylaxis have served to explain many of the obscurities.

Predisposing causes.—**Age.**—The first attack may occur at any age, even as early as the period of the first dentition. The majority of cases begin before the age of 25.

Sex.—Asthma is generally stated to be nearly twice as frequent in the male sex as in the female.

Heredity.—It certainly runs in families. The heredity is not always direct, the nervous instability sometimes being evidenced in other generations by migraine, epilepsy or hysteria. The view that hypersensitiveness to certain proteins is inherited is now discredited, and it is believed that an unduly irritable bronchial centre is the factor transmitted by heredity.

Other diseases.—Gout and syphilis are said to predispose to asthma. Bronchitis not infrequently leads to paroxysms in patients with asthmatic tendencies. Tuberculosis of the lung occasionally induces it, but here again it is probably in patients with the asthmatic diathesis.

Climate and locality.—Asthmatics seem very sensitive to both of these, but no general relationship can be proved, as the effects are most variable. Some patients are better in dry, others in damp, foggy climates, and in regard to locality each patient is a law to himself.

Conditions of the nose and naso-pharynx.—Nasal obstruction from swelling of the turbinates, deflection of the septum, spurs and polypi, and conditions of the naso-pharynx, such as adenoids and enlarged tonsils, undoubtedly predispose to asthma, and may also be exciting causes of the actual paroxysm.

Exciting causes.—**Chemical substances.**—The emanations from certain animals may be the determining cause. The best known of these are the horse and cat, but rabbits, hares, guinea-pigs, deer, dogs and monkeys may have a similar effect. Even human hair appears capable of discharging the paroxysm. The dust from some substances, such as corn, rice or oats, the smell of certain drugs, such as ipecacuanha, and the scent and the pollen of grasses and flowers may act in a similar fashion, as also may articles of diet, and many drugs. This factor in causation has attracted much attention recently—in this country by Freeman and Coke, and in America by Walker. It is claimed that at least 50 per cent. of asthmatics show hyper-sensitiveness to various protein antigens obtainable from animals, grains, bacterial bodies, foods and drugs, and over a hundred are now available for routine testing of these patients. The analogy with the causation of hay fever and paroxysmal sneezing is obvious.

Peripheral irritation.—As already mentioned, irritation of the nose, naso-pharynx and bronchi may be asthmogenic in those of asthmatic tendency.

Gastro-intestinal disturbance.—This is well recognised as a cause, and most asthmatics find by experience the penalties of a heavy late meal and of indigestible articles of diet. It is possible that actual metabolic errors may be a factor, as in the so-called "week-end asthma," due to altered conditions of diet and exercise at this period.

Genito-urinary conditions, particularly in women, notably ovarian or uterine disorders, sometimes act in inducing asthma.

Cutaneous.—Asthmatics are peculiarly liable to urticaria and eczema, although these conditions usually alternate with the asthmatic attacks.

Nervous factors.—Fatigue, emotion and nervous shock may precipitate an attack. This factor cannot be ignored, even in cases due to protein hyper-sensitiveness, as is shown by a well-known case in which a patient susceptible to roses developed asthma when handed an artificial rose.

Pathology.—Numerous theories have been propounded to explain the asthmatic paroxysm. Among these may be mentioned vascular turgescence of the bronchial mucous membrane, spasm of the bronchial muscle, and increased secretion of the mucous glands. Spasm of the diaphragm or of the inspiratory muscles has also been suggested. That bronchial spasm plays the major part seems to have been established by the experiments of Brodie and Dixon, and this view is strongly supported by their observations on the effects of drugs on the bronchial musculature. Muscarine, pilocarpine and physostigmine produce bronchial constriction and asthmatic symptoms in animals, while atropine, hyoscyamine and chloroform abolish these effects.

There can now be little doubt that the broncho-constrictor fibres of the vagus are the channel by which the impulses discharging the asthmatic paroxysm reach the bronchi, although the possibility that impulses leading to vaso-dilatation and to increased bronchial secretion are also concerned, must be admitted.

ANAPHYLAXIS.—The important part played by extraneous proteins in the genesis of asthma and the obvious analogy between the asthmatic paroxysm and the symptoms of anaphylactic shock have suggested that in many cases, if not in all, asthma is an anaphylactic phenomenon. Evidence is accumulating in support of this view. It has been shown that the lungs of the guinea-pig killed in anaphylactic shock show extreme constriction of the bronchioles. Asthmatics are well known to show anaphylactic tendencies, and especial care in the administration of antitoxic serums is necessary with them. It is of some interest to note that Eppinger and Hess' group of vagotonics show urticaria, dermatographia, eosinophilia and liability to anaphylactic shock, all conditions which occur in asthmatics. It is tempting, therefore, to assume that the foreign protein or toxin produces the asthmatic attack by inducing vagotonicity. Lastly, the observations of Freeman, Coke and the American workers have demonstrated the cutaneous hyper-sensitiveness of many asthmatics to special foreign proteins. Further research is needed before it can be accepted that anaphylaxis accounts for all cases of asthma, but it is almost certainly an important factor in many.

Asthma is rarely fatal apart from complications, so little can be stated about its morbid anatomy.

Symptoms.—The asthmatic paroxysm most commonly commences about 2 a.m. or later, but it may sometimes develop in the daytime. There are often preliminary indications some hours beforehand, constituting the "asthmatic aura." These include restlessness, irritability, mental exaltation, less frequently depression, itching of the nose or chin, flatulence or polyuria. Some attacks are ushered in by coryza. Such warnings are not constant, and the sufferer usually wakes from sleep with a feeling of suffocation. In early attacks great restlessness, anxiety and alarm occur. The difficulty

in breathing and the sense of suffocation increase; the patient sits up in bed, or gets up to throw open the window, and fixes his arms to bring into action all possible muscles of respiration. Respiration, although laboured and difficult, is often slow, inspiration being short while expiration is greatly prolonged. Both are accompanied by loud wheezing sounds, audible at a distance from the chest. The patient appears pale, but the lips are dusky and the expression is anxious and distressed. The jugular veins are distended and prominent. The accessory muscles of respiration are seen to be in violent action, notably the sterno-mastoids, scalenes and pectorals. The skin is moist and there may be marked sweating. The chest is much distended, and at each violent attempt at inspiration very little further enlargement occurs, while there is often sucking-in of the supra-clavicular and lower costal regions.

Percussion reveals marked hyper-resonance and encroachment on the cardiac and hepatic dullness. On auscultation inspiration is short and high-pitched, expiration very prolonged, and both are obscured by abundant sonorous and sibilant rhonchi, and later by bubbling râles at the bases. The pulse is small, quick and sometimes irregular. There is usually marked epigastric pulsation. A differential blood count during an attack may show an eosinophilia of as much as 35 per cent. Cough does not develop until late in the paroxysm, and is quickly followed in many cases by the expectoration of small pellets, called "perles" by Laennec, and often likened to boiled sago or tapioca. These were carefully studied by Curschmann, and when examined on glass on a black background, prove to consist of a central highly refractive mucinoid coil, with masses and threads of mucin wrapped spirally around it. Microscopically leucocytes, mostly eosinophils, may be seen entangled in the mucus. The sputum frequently contains Charcot-Leyden crystals, which are not now regarded as spermin phosphate but more probably as tyrosin. With the onset of expectoration the dyspnoea quickly lessens, and the attack subsides. The patient often passes a large quantity of pale urine and then may sleep until morning, awaking in apparent comfort. More frequently he appears pale, tired and anxious.

Course, Complications and Sequelæ.—Such an attack may last from a few minutes to several hours, and may remit and then return. More often the attacks recur at the same time each night for a considerable period extending to weeks, and then pass off, after which the patient may enjoy a period of freedom of weeks or months. The intermissions may become shorter with successive attacks, and increasing emphysema may develop. This in turn leads to secondary bronchitis, which persists, together with some degree of permanent oedema of the bases. Later still the cardiovascular changes incidental to emphysema occur as sequels, namely, engorgement of the right heart, tricuspid regurgitation, venous stasis, ascites and oedema. Chronic asthmatics frequently present a characteristic appearance. Of thin build, with sallow complexion, anxious expression and nervous manner, they often have a long neck, high straight shoulders, and a forward stoop. Asthma necessarily imposes limitations upon those who suffer from it at all severely, although many asthmatics lead active, useful lives in spite of their disease.

Diagnosis.—This involves the differentiation from other forms of dyspnoea, particularly those of spasmodic expiratory type. The chief forms of paroxysmal expiratory dyspnoea are :

1. *Bronchial asthma or spasmodic dyspnoea complicating chronic bronchitis and emphysema.*—This condition is sometimes a late result of true asthma, but may occur independently. The dyspnoea is more persistent and is more definitely related to the bronchitic attacks, being therefore more common in the winter.

2. *Cardiac dyspnoea or cardiac asthma.*—This, like true asthma, is often nocturnal, but the signs of failure of compensation in association with valvular or myocardial disease usually make the nature of the dyspnoea clear.

3. *Uræmic dyspnoea or renal asthma.*—This is also not infrequently nocturnal and may be almost indistinguishable from true asthma. Examination of the urine and the presence of cardio-vascular changes with high blood-pressure enable the distinction to be made with certainty, although the latter is not invariable.

4. *Hay asthma* is probably only a severe form of hay fever and is to be regarded as a variety of true asthma.

5. *Pulmonary tuberculosis may be associated with asthmatic dyspnoea.*—The differentiation may not be easy during the attack, but the persistence of apical signs in the interval may give a clue. It is a wise precaution to examine the sputum for tubercle bacilli in all cases of asthma. A low blood-pressure in an asthmatic should also arouse suspicion of tuberculosis.

The dyspnoea of laryngeal or tracheal obstruction and of mediastinal pressure can usually be recognised by the fact that it is chiefly of inspiratory type, and may be associated with stridor, instead of wheezing. In all cases of doubt the chest should be examined with the X-rays to exclude aneurysm or new-growth.

Prognosis.—When the disease starts in childhood or in early adult life it may stop spontaneously or be relieved permanently when some causal condition is discovered and treated. During a severe attack the aspect of the patient may be so alarming that a fatal issue may seem imminent, yet death very rarely occurs. In chronic cases, the ultimate prognosis is made more serious by the complicating emphysema and bronchitis, and in spite of popular belief, the asthmatic has less than the normal expectation of life.

Treatment.—(a) *During the attack.*—The list of anti-spasmodic drugs and measures employed is a long one, and it is impossible to foretell which will be efficacious, for asthmatics vary as widely in their response to drugs as they do in regard to asthmogenic causes. Drugs may be administered for this purpose by inhalation, by nasal sprays, by the mouth or by hypodermic injection. Adrenalin hydrochloride, in doses of 2 to 5 minims of a 1 in 1000 solution hypodermically, may act with dramatic efficacy if administered sufficiently early, but it should be given cautiously to elderly asthmatics. It may also be combined with pituitary extract, as in the special preparations *evatmine*, *pitrenalin* and *asthmolysin*. It sometimes proves helpful as a nasal spray, especially in combination with chloretone. A weak solution of cocaine and atropine in an oily excipient has been much employed as a nasal spray, but it is not devoid of risk if used indiscriminately. The fumes of burning nitre paper, or of a powder composed of tobacco, stramonium and nitre, sometimes help to relieve the distress, but they should be avoided in cases with bronchitic complications. Smoking a cigarette or a cigar may be helpful in patients who do not smoke habitually; others are helped by cigarettes containing stramonium. Inhalations of amyl-nitrite, ethyl-

K9, Hypertension, Belladonna, (Stramonium, Lobelia)
(Grindelia)
1064 DISEASES OF THE RESPIRATORY SYSTEM

iodide or chloroform may be tried in some cases. Various drugs have been employed, of which potassium iodide and bicarbonate with tincture of stramonium, hyoscyamus, lobelia or belladonna are the most useful. Twenty or 30 minims of liquid extract of grindelia every 20 minutes for three doses have been found useful in some cases. Other drugs which have been recommended are chloral hydrate, phenacetin and the other coal tar antipyretic drugs, euphine (caffeine tri-iodide) in drachm doses, and an emulsion of benzyl benzoate, 2 drachms every 2 hours. Other measures include drinking a cup of strong coffee, the application of a mustard leaf over the sternum, and placing the feet in hot water and mustard. In very severe cases, if all else fails, it may be necessary to inject morphine or heroin, but this should only be done after careful consideration, owing to the danger of inducing the morphine habit.

(b) *Between the attacks.*—The greatest care should be taken to discover and deal with any predisposing or exciting causes. The patient should live in that locality which his experience shows to be most suitable for him, and at present no rules can be formulated in advising on this matter.

Diet requires careful consideration. Any article of diet to which the asthmatic is susceptible should be entirely eliminated, and only the lightest of meals should be taken after midday. Fatigue, over-work and emotional stress are to be avoided. Care should be taken to see that the bowels act efficiently. The general health should be maintained by every possible means. Arsenic may be given by the mouth, or subcutaneously as sodium cacodylate (gr. $\frac{1}{2}$ in m xv water). During the period when the patient is having a series of attacks, iodide of potassium with one or more of the anti-spasmodic group of drugs, such as stramonium, lobelia, belladonna and grindelia, may be given regularly with great benefit. Any local source of irritation in the nose or naso-pharynx should be dealt with adequately. Sometimes touching the nasal septum with the galvano-cautery may alone be efficacious. In cases complicated by bronchitis, the sputum should be examined bacteriologically, and a vaccine may be made from the predominating organisms. If these prove to be *Micrococcus catarrhalis*, or Friedländer's pneumo-bacillus, great benefit may result, but the patient should be told that the vaccine can only help the asthma by lessening the accompanying catarrh. Some cases associated with marked emphysema obtain considerable relief from compressed air baths, at first on alternate days, then daily, the course extending to 1 or 2 months.

Careful investigation of the question of protein hyper-sensitiveness should be undertaken, and the recent method of testing by means of the cutaneous application of various antigens is worth consideration. For this purpose, the particular protein antigen, or a series of such antigens, may be applied to the skin of the forearm in the form of powder, solution or paste, and superficial scarification is then effected by means of a sterile needle or scalpel. A positive reaction is shown by the development of an urticarial wheal surrounded by a hyperæmic area. A control scarification with normal saline or a paste free from protein should be made at the same time. A positive result may be expected in about 50 per cent. of asthmatic patients. If such a condition is established to one or more such substances, they should be avoided if possible; if not, the methods of desensitisation may be tried, but the results are frequently disappointing. The specific antigen may be employed in very minute doses by injection, starting, for example,

with 1 minim of a $\frac{1}{100,000}$ solution and gradually increasing. Auld has endeavoured to achieve the same effect by intravenous injections of peptone. In adults $\frac{1}{10}$ gr. of Armour's No. 2 peptone is given for the first dose, successive doses being given every fifth day, increasing by $\frac{1}{50}$ gr. each time for 6 injections, when the dose is kept stationary for another three or four injections. In cases which fail to respond to such injection, he has recently suggested the use of "new serum peptone" injections, which consist of a mixture of the patient's own serum with agar solution and Armour's No. 2 peptone. These injections should not be given during an asthmatic attack.

Recently Storm van Leeuwen has emphasised the importance of dust and of some moulds, notably the genus *Aspergillus*, in the genesis of asthma. He tries the effect of putting the patients in rooms supplied with air relatively dust free.

BRONCHIECTASIS

Definition.—Bronchiectasis is a condition of permanent dilatation of one or more bronchi. When it occurs in the finer divisions it is sometimes described as bronchiolectasis.

Ætiology.—Bronchiectasis is invariably secondary, and may result from disease of the bronchi, the lung parenchyma or the pleura. Even the rare congenital cases are probably consequent on malformation, atelectasis or intra-uterine disease.

1. The bronchial conditions which may progress to dilatation are bronchitis, and any affection leading to partial bronchial obstruction, such as inhaled foreign body, stenosis from cicatrization and external pressure from new growth or aneurysm. In children, measles and whooping-cough are not uncommon causes, especially when they follow one another in rapid succession, although either alone, if severe, may lead to it.

2. Conditions of the lung parenchyma which may cause bronchiectasis are unresolved pneumonia, broncho-pneumonia, collapse, syphilis and tuberculosis. Syphilis is rare and usually acts by leading to bronchial obstruction or stenosis. Fibroid tuberculosis is a common cause, but the clinical manifestations are as a rule masked by the primary condition. The pulmonary complications of influenza are not infrequently followed by bronchiectasis.

3. The pleural conditions which are followed by bronchiectasis are those which lead to pleural adhesion and are associated with pulmonary fibrosis, notably chronic pleural adhesion, or empyema leading to prolonged or permanent collapse of the lung.

In a lesion with such diverse antecedents the age relations are necessarily indefinite. It may occur at any age, but is commonest in the third and fourth decades. It frequently commences in childhood, although the characteristic clinical manifestations may not develop until adult life.

Sex.—In most recorded statistics there is a striking preponderance in the male.

Social state.—It is noteworthy that bronchiectasis in its fully developed form is much more common in the poor than in the well-to-do.

Pathology.—Three factors in the pathogenesis of bronchial dilatation have to be considered. (1) Weakening of the bronchial walls. This is admittedly the most important. Most of the conditions preceding bronchiec-

tasis tend to induce severe bronchitis and peribronchitis, and thus render the walls more yielding. Where stagnation of secretion occurs, putrefactive and other organisms develop, producing tryptic ferments which may act injuriously upon the lining membrane. (2) Increased pressure on the walls thus weakened is the determining factor. This is generally expiratory in origin and due to the strain of cough. The actual pressure of secretion accumulating behind an obstruction may promote yielding of the bronchial walls. In cases of bronchiectasis following on collapse of the lung the force of inspiration has been regarded as contributory, but this is doubtful and in any case is less important than the expiratory strain of cough. (3) The third possibility is the traction exerted upon the walls of the bronchi by contracting connective tissue in the surrounding fibroid lung. This obviously postulates the existence of pleural adhesion, which is not invariably present. While this must be admitted as a possible contributory factor, its importance is certainly less than that of the preceding ones.

Congenital bronchiectasis is a pathological rarity. It is usually unilateral, and the bronchi involved are of small size, although in some cases the lung may show a large central cavity, with smaller spaces around it. Bronchiol-ectasis is also more of pathological than of clinical interest. It occurs chiefly in children, as a result of acute broncho-pneumonic processes. It is said sometimes to follow influenza and possibly tuberculosis. The lung has a peculiar spongy appearance, to which the name "honeycomb" has been applied.

Bronchiectasis of the larger tubes may be either cylindrical or saccular. In the former condition several of the bronchi are more or less uniformly dilated, and when opened out they appear like the fingers of a glove. Sometimes the dilatations are fusiform, at others they show a beaded arrangement, described as moniliform. These forms of dilatation are usually associated with emphysema and chronic bronchitis. Saccular bronchiectasis is generally localised and may be found in any part of the lung, but is most common in the lower lobes and near the base. This is partly due to the fact that the antecedent processes fall with special stress on the bases of the lung, and partly to the influence of gravity in leading to retention of secretions in these parts. Although it may be unilateral in origin, it often spreads and may involve both bases or even all the lobes. There may be one large irregular cavity, or a series of smaller globular dilatations involving the whole or part of the walls of one or more bronchi. The cavities are usually filled with the foetid secretion, to be described under expectoration. When this is washed away the walls are found to be thin, smooth and formed of thinned-out mucous membrane. In places this may have ulcerated, owing to the tryptic action of the secretion, and the lung tissue is thus exposed. An abscess may then form, and an aneurysm sometimes develops, as in a tuberculous cavity. The openings of the smaller bronchi, derived from that dilated, can often be recognised in its walls. In doubtful cases the histological demonstration of cartilage and muscle in the walls establishes the bronchial origin of a cavity. The surrounding lung tissue is usually airless and fibroid, and sometimes is almost of leathery consistence. Occasionally, however, it is emphysematous, congested or pneumonic. In the great majority of cases there is dense pleural adhesion over the area of lung involved.

Other morbid conditions found post mortem include lardaceous disease,

gangrene of the lung, empyema, pyo-pneumothorax, suppurative pericarditis and cerebral abscess. Owing to the obstruction of the pulmonary circulation which may result, engorgement and dilatation of the right side of the heart, tricuspid regurgitation and the results of systemic venous stasis are often found.

Symptoms.—The onset is usually insidious, the symptoms developing during the course, or as a sequel, of one of the acute or chronic affections mentioned above. In some few cases, however, they develop rapidly in patients previously in good health. This is particularly the case where bronchiectasis results from an inhaled foreign body, and a rapid onset should lead to the suspicion of this. The cough in well-developed cases is somewhat characteristic and occurs in paroxysms. These are frequently induced by change of posture—for example, bending forward or lying down. They occur with special frequency on rising, and are usually associated with the expectoration of large quantities of sputum, due to the overflow of the secretion, accumulated in the cavities during the night, into a sensitive or relatively healthy bronchus, which excites cough reflexly. They also occur on retiring to bed and at long intervals during the day. The sputum frequently amounts to as much as 20 or 30 ounces in the 24 hours. It is generally extremely foetid, although in the earlier stages this is not invariable. The patient's breath is also often malodorous, and the stench may pervade the room or even the house in which he lives, although it is not persistent. The patient is himself much distressed by the unpleasant character of the sputum, of which he is, as a rule, acutely conscious. On standing in a glass vessel it can be seen to settle into three layers—a surface scum of light frothy mucus, an intermediate stratum of thin, turbid, greenish fluid, and a deep layer of brownish colour consisting of muco-pus, bacteria, and putrefactive products, including foul-smelling organic acids. Foetid yellow bodies called Dittrich's plugs can usually be found in the deep layer. Elastic tissue is only present when erosion of the wall has occurred. Hæmoptysis is not infrequent, and may occasionally be fatal. Dyspnœa is not, as a rule, apparent unless the condition is widespread, or unless pulmonary or cardiac complications are present. The general condition of the patient is at first but little affected, and there may be no fever for long periods. As the disease progresses, lassitude, anorexia and some wasting slowly develop, while bouts of fever occur, due to retained secretions or to some complication.

Physical signs vary with the extent and degree of dilatation, and also with the amount of secretion present. In the early stages there is at most slight dullness at one base, with diminished air entry, peculiar sticky, "leathery" râles, and diminished vocal resonance. When bronchiectasis is well developed the signs are almost characteristic. The patient may appear well nourished and of good colour, although on cold days, especially in children, duskiness or cyanosis is often noticeable. There is well-marked clubbing of the fingers, generally of drum-stick character, and pulmonary osteo-arthropathy, involving many joints, sometimes develops. There may be localised flattening or retraction of the chest wall over the affected area, with diminished movement, and the heart is drawn over to this side. The remaining signs vary with the state of the cavity. If this is full, there is diminished vocal fremitus, dullness and weak or absent breath sounds and voice sounds. If the cavity is empty or partly empty, the vocal fremitus

is increased, the percussion note is boxy or dull, while the breath sounds are bronchial or cavernous. Adventitious sounds are then generally audible, the most characteristic being sharp metallic or "leathery" râles. Bronchophony and pectoriloquy are marked, and not infrequently the "veiled puff" of Skoda can be heard. Signs of bronchitis are often apparent in the adjacent lung tissues; compensatory emphysema may be demonstrable in the unaffected parts of the lung, and on the opposite side. X-ray examination serves to define the extent of the disease, the degree of fibrosis, and the presence of the cavities.

Complications and Sequelæ.—The chief pulmonary complications are septic broncho-pneumonia, gangrene and abscess. The pleura may become involved, giving rise to dry pleurisy, which sometimes progresses to empyema and rarely to pyo-pneumothorax, while in other cases pleural adhesion and contraction result. Septic pericarditis may develop and prove fatal. Septicæmia and pyæmia sometimes occur as terminal results. Cerebral abscess constitutes a serious and somewhat common complication, and may be found in the frontal, parietal or temporal regions, the cerebellum or cord. Occasionally multiple abscesses form. Lardaceous disease sometimes develops, especially in the liver, kidneys and intestines.

Course.—This is progressive, but is often slow unless fever or complications develop, though the morbid process may eventually involve the other lung. The sputum at first may be simply purulent, then becomes unpleasant and finally foetid. The disease may start in childhood and not lead to death until well on in adult life. The course is slower in cases due to bronchitis and fibroid lung conditions than in those due to foreign bodies, new-growths or aneurysm.

Diagnosis.—In well-developed basic cases this is, as a rule, easy. The history of cough, influenced by posture and associated with copious sputum, is suggestive, especially when variable physical signs are observed. The development of the characteristic sputum with these signs renders the diagnosis almost certain, and the X-rays usually serve to confirm. Radiological investigation after the intra-tracheal injection of 20 c.c. of lipiodol, through the crico-thyroid membrane or between two rings of the trachea, under local anæsthesia, or with care directly between the vocal cords, has greatly facilitated the diagnosis of bronchiectasis. An attempt should be made to direct the lipiodol towards the affected side by turning the patient towards that side. The injection should be carried out in the X-ray room and the patient instructed to restrain cough if possible until the films have been taken. The pictures obtained are strikingly characteristic and of great value. In cases with less characteristic symptoms and signs the distinction has to be made from chronic bronchitis, especially the foetid variety, pulmonary tuberculosis, gangrene or abscess of the lung, and foetid empyema. The distinction from chronic bronchitis may be difficult, especially in the early stages when the sputum is not foetid, but the paroxysmal cough, the copious expectoration with signs including bronchial breathing and sticky râles at a base, may be strongly suggestive. In foetid bronchitis the foetid sputum is not constant, and the cough and sputum may occur only during exacerbations of the bronchitis. Pulmonary tuberculosis may give rise to difficulty, particularly in cases of apical bronchiectasis. Repeated examinations for tubercle bacilli and also for elastic tissue in the sputum should be made. The history, the mode of spread, and X-ray examination may all

assist. It should be remembered that the two conditions may coexist, and this may be suspected in some cases of fibroid tuberculosis with basic excavation. Abscess and gangrene of the lung have a more acute onset and course, but the chronic cavities left by these conditions may give rise to difficulty. In such cases the history may be an important aid in diagnosis. In fœtid empyema rupturing through the lung, particularly when of interlobar origin, the patient is generally acutely ill, there may be a history of pleurisy at the onset and possibly some evidence of mediastinal pressure or cardiac displacement.

Prognosis.—This varies with the cause. If due to aneurysm or growth, the duration is determined by these conditions. Bronchiectasis induced by a foreign body is generally permanent, even when the latter is removed, but it is not progressive. If the foreign body is not removed, complications generally supervene, and the course may be rapid. In bronchiectasis due to bronchial or pulmonary disease the course may extend into years, particularly if treatment is followed strictly, but sooner or later toxæmia and general or local complications supervene, with the result that the duration of life is inevitably considerably shortened.

Treatment.—Prophylactic treatment in cases of chronic bronchitis, delayed resolution in pneumonia and other conditions tending to fibrosis should be carried out. This comprises respiratory exercises, climatic treatment, inhalations and vaccines.

The medical treatment of bronchiectasis consists in measures to promote the general health and well-being of the patient, to secure efficient emptying of the cavity, and to lessen or control the putrefactive processes occurring in it. The first of these involves a careful mode of life, adequate rest and change, a good and digestible diet, and medicine such as cod-liver oil, iron, quinine, strychnine or arsenic. The evacuation of the cavity may be promoted by postural methods, such as bending over the edge of the bed or stooping forwards. Expectorants, especially of antiseptic character, may be given, such as creosote, terebene, tar preparations, balsam of tolu or Peru, compound tincture of benzoin or the benzoates. If the sputum is tenacious, or if much bronchitis coexists, iodides and alkalis may be given in an ordinary expectorant mixture. To lessen the fœtor, creosote is most frequently given in perles of 3 to 5 minims three times a day after food, or in an emulsion with cod-liver oil. Guaiacol carbonate and other creosote derivatives may also be tried. Syrupus alii, in 1-drachm doses, is sometimes given, and is of value; but it is not always well tolerated by patients on account of its taste and tendency to repeat. Although these drugs are helpful, the amount of antiseptic reaching the cavity by the blood must necessarily be small. Attempts to secure more direct application by intratracheal injection and by inhalation have been made. For the former 1 drachm of a mixture of olive oil 88 parts, guaiacol 2 parts, and menthol 10 parts is injected down the trachea by a special syringe, the nozzle of which is slightly inclined towards the affected side. Care must be taken to do this with the aid of a laryngeal mirror to ensure that none of the solution touches the larynx. Another solution used is 1 part each of creosote, menthol and thymol in 10 parts of olive oil.

For inhalation purposes, solutions of volatile antiseptics are employed on a Burney-Yeo mask, such as creosote, terebene, menthol or eucalyptol in

1060 DISEASES OF THE RESPIRATORY SYSTEM

spirits of chloroform. The mask may be worn almost continuously or at intervals during the day. The creosote vapour bath is, however, the most satisfactory form of inhalation treatment, and is of great value. This should be given in a concrete-floored room without furniture. The patient is covered with a smock, the eyes are protected by closely-fitting goggles, and the nostrils by cotton wool plugs. A small quantity of creosote is heated in a metal dish, on a tripod over a spirit lamp. When the patient inhales the vapour, which quickly fills the room, violent cough is excited and the cavity is emptied. The ensuing deep inspirations carry down creosote-laden air into the air passages. The baths should be at first given on alternate days and last from 10 to 15 minutes. When the patient becomes accustomed to them, they may be given daily for half an hour or longer. The results are often strikingly beneficial. Vaccines made from the predominant organisms found in the sputum have been given with benefit in some cases. Surgical treatment is now more often employed than formerly, but at present it should be considered only in cases where medical measures fail. The actual drainage of the bronchiectasis surgically is only practicable if the cavity is a single one, and it involves the risks of a permanent fistula and of cerebral abscess. Other procedures which are now sometimes employed are the induction of artificial pneumothorax, although this is often impracticable, owing to adhesions, except in early cases, in which it may be brilliantly successful. Thoracoplasty may also give excellent results in cases in which collapse by artificial pneumothorax is not practicable. It is, however, only to be considered in strictly unilateral cases. This is usually carried out in two stages, with an interval between them. A sufficient amount of a number of ribs is removed to allow the chest-wall to fall in and permit the lung to collapse and fibrose, thus allowing the bronchiectatic cavities to empty and contract. Ligation of the branch of the pulmonary artery going to the lower lobe has been performed in some cases. Phrenicotomy or exsiccation (evulsion) of the phrenic nerve has also proved useful. Lobectomy or removal of the affected lobe has also been recommended, but the mortality of this operation is at present considerable.

INJURY

External trauma applied to the chest-wall may cause rupture of a main bronchus. This is especially liable to occur after severe crushing accidents. One or other of the main bronchi may be completely severed from the trachea. The chief clinical feature presented in such a case is emphysema of the neck and upper portion of the chest wall. Death usually ensues in 2 to 3 days.

R. A. YOUNG.

G. E. BEAUMONT.

DISEASES OF THE LUNGS

HYPERÆMIA AND OEDEMA

Hyperæmia of the lungs may be either active or passive. In the former there is an increased supply of arterial blood through the pulmonary and

bronchial arterioles. In passive hyperæmia there is engorgement of the pulmonary venous radicles and capillaries. With both forms there is frequently œdema, due to the exudation of serous fluid into the lung alveoli. The term "congestion" is sometimes employed as an alternative to hyperæmia, but owing to its erroneous popular use it is best avoided.

(a) ACTIVE HYPERÆMIA

Ætiology.—This may occur in association with any acute inflammatory process affecting the bronchi, lungs or pleura. It sometimes results from the inhalation of pulmonary or bronchial irritants, such as poisonous gases or heated air. Severe muscular exertion and exposure to extreme cold are described as causes, but the former at least is doubtful. An important variety is that known as *collateral* or *fluxionary hyperæmia*, which occurs when there is obstruction to the circulation in the whole or part of one lung, from conditions such as a large or rapidly developing pleural effusion, an extensive and spreading pneumonia, or in association with pneumothorax. This may develop in the sound lung, or in the unaffected parts of that diseased. A primary form of acute hyperæmia, the "maladie de Woillez" has been recognised by French authors, but this is generally regarded as a mild or abortive pneumonia.

The clinical manifestations of acute hyperæmia are merged in those of the processes with which it is associated, and therefore do not need separate description.

(b) PASSIVE HYPERÆMIA

Ætiology.—Passive hyperæmia may be produced by (1) conditions impeding the venous return from the lungs; (2) those leading to increased resistance to the passage of blood through the pulmonary capillaries, and (3) failure of the driving power of the right ventricle. The commonest causes of impeded return are left-sided heart lesions causing overfilling of, and increased pressure in the left auricle. In mitral stenosis it may occur early and sometimes almost acutely, but aortic and myocardial lesions also lead to it, when the left ventricle fails and the mitral valve yields. Direct obstruction of the pulmonary veins sometimes results from external pressure by aneurysm, mediastinal tumour or enlarged bronchial glands, or from obstruction of the lumen by thrombosis. The passage of blood through the pulmonary capillaries may be impeded by emphysema, chronic bronchitis, pulmonary tuberculosis and fibrosis of the lungs. Failure of the right ventricle occurs in the late stages of right-sided heart lesions, such as tricuspid regurgitation, and as a late sequel of left-sided failure.

Passive hyperæmia is obviously in the main dependent on mechanical factors; it is not surprising, therefore, that gravity seems to play a part in the localisation of its effects, which are usually most marked in the bases or most dependent parts of the lungs. In bedridden, enfeebled or old patients, particularly if myocardial weakness or degeneration coexists, this factor becomes of great importance. Not infrequently some degree of œdema of the bases develops, and the condition is then called hypostatic congestion. If such an area becomes infected the resulting process is known as hypostatic pneumonia. Basal hyperæmia and œdema of the hypostatic type also result

from toxæmia due to diseases such as enteric fever, from poisoning by drugs such as morphine, and as a terminal event in many cerebral lesions causing increased intracranial pressure.

Pathology.—The pulmonary veins and capillaries are engorged, with the result that the lung is darker in colour and heavier, while the alveolar walls and septa are swollen. If the condition persists for some time, pigment derived from the hæmoglobin of red corpuscles escaping by diapedesis is deposited in the epithelium of the alveoli and in the fibroblasts in the inter-alveolar septa. In long-standing cases the lung is firmer than normal and brownish-red in colour, a condition described as *brown induration*. If any degree of œdema is present, serous fluid is found in the alveoli on post-mortem examination, and on section of the lung frothy serous fluid exudes, which may contain some of the pigmented alveolar cells, constituting what are called “cardiac cells.” Although congested and œdematous lung is heavier than normal, it usually floats in water.

Symptoms.—In slight degrees of hyperæmia these may be absent or negligible. In more advanced cases, they are those resulting from the impeded circulation through the lungs and the deficient aeration which this entails. Dyspnoea is the most prominent symptom, and it is generally a measure of the degree of hyperæmia. It is markedly increased by exertion of any kind, and in extreme degrees it is distressing and eventually alarming. It may be inspiratory or expiratory in type, and in the latter case it is sometimes described as *cardiac asthma*. In severe cases there is usually orthopnoea. Cough is almost invariably present, and there is usually some expectoration of frothy fluid, which may be blood-stained. The pigmented cells referred to above as “cardiac cells” may be found in it. Cyanosis is common and indicates the degree of deficient aeration. This may be associated with distension of the jugular veins, and there is often obvious distress. As in other forms of cyanosis there is usually some increase in the number of red corpuscles. The vocal fremitus at the bases may be diminished, the percussion note impaired, the breath-sounds weak and accompanied by rhonchi, crepitations or bubbling râles, although these signs are for the most part due to the associated œdema. In addition, the signs of the primary condition in the lungs or heart will be apparent.

Complications.—Pulmonary œdema and infarction are the chief complications.

Course.—If the venous engorgement cannot be removed, it usually tends to become progressively worse, whereas when it results from temporary cardiac embarrassment, recovery is usually complete as soon as the heart function is restored.

Diagnosis.—This condition has to be distinguished from (1) chronic bronchitis, in which case there may be some rise of temperature and the physical signs are more variable and more disseminated; (2) infarction, in which pain and hæmoptysis of sudden onset are the rule.

Prognosis.—This is so entirely dependent upon the nature and degree of the condition responsible for the engorgement that no general rule can be formulated.

Treatment.—In elderly patients, or those likely to be confined to bed for long periods, attention should be directed to the decubitus. This should be changed frequently, and if possible the patient should be permitted to sit

up or to get into a chair, and encouraged to take a few deep breaths several times during the day. If the hyperæmia is associated with cyanosis and engorgement of the right heart, bleeding to the extent of 8 to 12 ounces may be helpful. If this is not practicable, the application of 6 leeches over the liver, or dry cupping of the bases of the lungs may be tried. Free purgation and the administration of diuretics may also help indirectly to relieve the engorgement. In cases associated with cardiac failure, the administration of cardiac tonics, such as digitalis, strophanthus or squills, the injection of strychnine, or camphor in oil may all be of assistance. Moderate hæmoptysis should not be checked, and cough, if effective, may be promoted by suitable expectorants. In cardiac cases a "régime lactée" or strict milk diet is advocated by some French physicians.

(c) ACUTE OR HYPERACUTE PULMONARY ŒDEMA

In this condition flooding of the alveoli with the serous exudate from the pulmonary capillaries occurs with great rapidity.

Ætiology.—It is more commonly met with after the age of 40 than before, although cases have been recorded in children. It is considerably more frequent in the female than in the male sex. Arterial disease and hypertension are the most common antecedents, but acute or chronic renal disease and pregnancy may all act as predisposing factors. It sometimes occurs in diabetes. The actual exciting cause is often obscure, and probably varies in different cases. A heavy meal, an epileptic fit, or the administration of an anæsthetic may be the immediate cause in those predisposed. In other cases it may be a manifestation of angio-neurotic œdema. Sometimes paracentesis of a pleural effusion is quickly followed by œdema, no doubt as a result of a collateral hyperæmia. In diabetes the lipæmic condition which sometimes occurs has been suggested as the determining factor, possibly causing multiple fat embolism. In some cases dissociation of the action of the two ventricles has been supposed to be the cause, the right contracting forcibly while the left is in an enfeebled or asystolic condition. In support of this contention may be adduced the fact that acute pulmonary œdema has been observed after rupture of the chordæ tendinæ of the mitral valve.

Pathology.—The alveoli are found to be flooded with a thin serous exudate. The lungs are heavier than normal, sodden, and on squeezing exude large quantities of greyish-yellow or pinkish fluid. Frothy fluid of similar character is found in the bronchi and even in the trachea and nasopharynx in hyperacute cases.

Symptoms.—The onset is sudden, and generally occurs when the patient is lying down, hence being most frequently observed at night. The patient awakes with intense dyspnœa, and a sense of suffocation, then frequently rolls or rushes about in the endeavour to breathe, even clutching at the throat. Cyanosis is present, and the aspect is one of anxiety and alarm. Frothy fluid may soon stream from mouth and nose, or be brought up in great gulps. The chest movements are hurried, and the accessory respiratory muscles are in violent action. Vocal fremitus is diminished over the lower lobes. The percussion note soon becomes impaired over the lungs, commencing at the bases. The breath-sounds are at first vesicular or harsh with

prolonged expiration, then become faint and may be obscured by bubbling râles or crepitations, audible all over the chest. Voice conduction is diminished.

Complications and Sequelæ.—Owing to its acute and rapid course, complications do not occur. Bronchitis may result as a sequela.

Course.—The malady usually lasts only minutes or hours. Unless it remits, or treatment affords relief, the patient rapidly becomes unconscious and death follows, the heart continuing to beat after respirations have ceased.

Diagnosis.—The affection is usually so characteristic that the diagnosis is obvious. In the more protracted cases the dyspnœa and the physical signs are not unlike those of acute suppurative bronchitis or suffocative catarrh and broncho-pneumonia; but in both of these there is some degree of fever and the expectoration is less copious, and when it occurs is usually of purulent or muco-purulent character. The nocturnal onset of œdema may suggest asthma; but the physical signs and the late and scanty expectoration in the latter suffice to distinguish it.

Prognosis.—The prognosis is always very grave; but prompt treatment has saved some cases. Death may occur in less than 10 minutes, or be delayed for 24 or 48 hours. In the angio-neurotic type repeated attacks may occur.

Treatment.—The most successful treatment is the immediate subcutaneous injection of gr. $\frac{1}{4}$ morphine. Good results have also followed the injection of gr. $\frac{1}{100}$ atropine sulphate hypodermically. These are often given together. Oxygen inhalation will probably not be tolerated owing to the restlessness, and is of doubtful utility. Prompt venesection has been recommended, and should be tried if possible; but its value has not been established.

(d) CHRONIC PULMONARY ŒDEMA

This is usually the sequel of chronic passive hyperæmia, and the causes and symptoms are those of that condition. It may also occur in chronic renal disease. In marked degrees of œdema, however, the signs may closely simulate those of pleural effusion, save for the displacement of the cardiac impulse. It is important to remember that some degree of hydrothorax may occur as a complication, and increase the difficulty in diagnosis.

INFARCTION OF THE LUNGS

Infarction of the lungs or "pulmonary apoplexy" results when a branch of the pulmonary artery becomes occluded by embolism or thrombosis.

Ætiology.—*Embolic forms.*—The obstructing plug may originate in any part of the systemic venous system, in the right side of the heart or on its valves or in the pulmonary artery itself. The commonest peripheral cause of embolism is detachment of a thrombus in cases of thrombo-phlebitis. This may occur in the veins of the lower extremity, or in those of the uterus after childbirth. Thrombosis with embolic detachment may also develop in prolonged or wasting diseases, such as enteric fever, tuberculosis and cancer; in acute processes, such as influenza, septicæmia and pyæmia; and in localised septic lesions, such as otitis. Pulmonary embolism is not infrequently

observed after abdominal or pelvic operations, and after the radical cure of hernia or hæmorrhoids.

Intracardiac thrombi from the right auricle or ventricle, becoming detached, lead to embolism, and this occurs especially in cases of right-sided heart failure secondary to left-sided valve lesions. Vegetations forming on the tricuspid or pulmonary valves in infective endocarditis on detachment produce pulmonary infarction. Rarer causes are fat embolism after injury to bone or to a fatty liver, the entry of pieces of new growth or hydatid daughter-cysts into systemic veins, and even air embolism.

The exciting cause of embolism is not infrequently sudden movement or strain leading to detachment of a thrombus or vegetations.

Thrombotic forms.—Thrombosis occurs as a secondary process around pulmonary emboli; but it is probable that some cases of infarction are due to a primary thrombosis. This condition may be produced by some acute or chronic pulmonary disease, such as gangrene, tuberculosis and fibrosis, and by atheroma of the pulmonary artery. Any process leading to chronic venous hyperæmia may also cause it.

Pathology.—Although the pulmonary arteries are not strictly speaking end arteries, since there is some degree of anastomosis between them and the bronchial arterioles, yet the result of their obstruction is to produce infarcts comparable with those in other organs. The origin of the blood in the obstructed area has been much discussed. Cohnheim regarded it as the result of regurgitation from the veins, a view subsequently disproved, since the infarct is hæmorrhagic even when the veins are also obstructed. It is now regarded as due to influx from the anastomosing bronchial capillaries into the pulmonary capillaries, and the escape of this blood from the latter owing to their altered nutrition. It is generally accepted that embolism is much more common than thrombosis. It has been suggested that some infarcts are not obstructive, but are the result of hæmorrhage *per rhexin* in cases of extreme passive hyperæmia, and that the shape is due to the alveolar distribution of the bronchial area affected. If a large embolus has caused sudden death, it will be found arrested at the bifurcation of a large branch of the pulmonary artery, or even in one of the main divisions of that vessel. In such cases there has not been time for pulmonary changes to occur, and the chief post-mortem condition found is engorgement of the right side of the heart.

In post-mortem examination of cases where smaller emboli have led to infarction, the infarcts are usually found in the lower lobes, more commonly in the right lung. They extend to the surface in the majority of cases, and can be seen before section as slightly raised, dark red areas, with the overlying pleura a little roughened from inflammatory exudate. They feel hard and firm, and on section are typically wedge-shaped, with the base on the surface and the apex centrally placed. In the rare deep-seated infarcts a spheroidal form is the rule. When recent, an infarct is dark red in colour, and suggests hæmorrhage with clot formation, hence the term "pulmonary apoplexy." In some cases infarcts have a purplish hue, and are said to resemble the colour of damson cheese; later they change to brownish-red. Infarcted areas sink in water. There may be a single large infarct almost occupying one lobe, sometimes only a small one, or several of varying size and age scattered throughout the lungs. In some cases a fortunate section

may reveal the embolus with its ensheathing thrombus, but sometimes a thrombus only is found. Microscopically, the alveoli and finer bronchioles are filled with red blood corpuscles, and there is a sharp delimitation from the healthy lung. If the embolus is infective, suppuration occurs, and abscess or empyema ensues.

Symptoms.—If a large embolus blocks one of the main divisions of the pulmonary artery, there is sudden intense dyspnoea, pain in the chest, distress, cyanosis, and rapid unconsciousness, death resulting in a few minutes from asphyxia. In other cases the patient gives a short cry, and falls unconscious, death occurring almost immediately from syncope. In some cases unconsciousness develops so rapidly, and the respiratory symptoms are so little apparent, that a cerebral vascular lesion may be suspected. On the other hand, life may be maintained for several minutes or even hours, the patient being unconscious or in acute distress and anxiety with urgent dyspnoea, lividity and cyanosis. Respiration is deep and laboured, but fails to give relief to the sense of suffocation. In such cases also, death may result eventually from asphyxia or syncope, or the patient may slowly recover. In less severe forms, such as occur in cardiac and in some post-operative cases, there is sudden pain with difficulty in breathing, followed in a few hours or in a day or two by cough with hæmoptysis or by the expectoration of deeply blood-stained mucus persisting for some days, and slowly clearing up. If the embolus is infective, fever, often of hectic type, results, sometimes delayed for a day or more.

In the severe cases there is cyanosis, distension of the veins of the neck, acute anxiety with exophthalmos and cold, clammy skin. The only physical signs apparent are the deep, laboured breathing, the harsh breath sounds, and the evidence of cardiac embarrassment with feeble, failing pulse.

In less severe cases the signs are also not characteristic. There are evidences of cyanosis and distress of less urgent character, possibly some limitation of movement on the affected side, increase of vocal fremitus, localised dullness, with weak or absent breath-sounds, and sometimes a pleural rub. In some cases definite bronchial or tubular breath-sounds may be audible. A few fine râles are sometimes present in the adjacent lung areas.

Complications and Sequelæ.—Localised dry pleurisy is almost invariably present. With infective emboli, abscess or gangrene, and later empyema may result. In organisation an infarct leads to a localised area of fibrosis.

Course.—As already described, death may occur from asphyxia or syncope in the course of a few minutes or hours, although recovery occurs in some very severe cases. In the less severe forms, after the initial urgent symptoms have passed off, recovery is often rapid and uneventful, save for pain, cough and bloodstained expectoration.

Diagnosis.—The dramatic onset, the history and the associated lesions of the veins or heart render diagnosis easy as a rule; but it may be necessary to eliminate other causes of hæmoptysis, notably pulmonary tuberculosis and chronic venous hyperæmia.

Prognosis.—This depends largely upon the initial shock. The prognosis is very grave when the patient rapidly becomes unconscious. As there is less likelihood of sepsis in cases due to cardiac lesions than in those due to localised venous thrombosis, the prognosis is rather better in the former; but, on the other hand, organisation of a clot in a vein may completely remove

the source of the emboli, while the source often persists when they are derived from the heart.

Treatment.—The coagulability of the blood may be lowered by the administration of 30 grains of sodium citrate three times daily. This is a wise prophylactic measure in prolonged illness, especially when a milk régime is being enforced. When thrombosis has occurred in a peripheral vein, such as in the leg, the affected limb should be immobilised until organisation of the clot has taken place. Morphine is useful in quieting a patient if there is much mental distress when a pulmonary infarct forms; but usually the patient is collapsed and stimulant measures are indicated. An injection of morphine gr. $\frac{1}{6}$, atropine gr. $\frac{1}{60}$, and strychnine gr. $\frac{1}{30}$ is found of value in some cases. If there is dyspnoea oxygen should be administered. Venesection to the extent of 10 or 12 ounces may be tried in cases where there is marked lividity with a forcibly acting heart. Hæmoptysis, when it occurs, should not be checked. Pain may be relieved by leeches, cupping or by application of iodine. In cases with heart failure the appropriate treatment by cardiac tonics should be administered.

COLLAPSE OF THE LUNGS

In collapse of the lungs the alveoli are completely or partly devoid of air. The condition may be congenital, and due to non-expansion of the lung, when it is referred to as *atelectasis*. On the other hand, collapse may be the result of removal of the air from lung tissue previously expanded, when it is called *apneumatosi*s or *acquired collapse*. The three terms collapse, *atelectasis* and *apneumatosi*s are, however, used as synonyms by many writers.

ATELECTASIS OR CONGENITAL COLLAPSE

Ætiology.—This condition occurs in still-born and in premature infants, and probably persists to some degree for weeks or even months in weakly children. It may result from immaturity or from weakness of the inspiratory muscles, and from obstruction of the air passages by mucus and meconium. It may be a consequence of disease, such as congenital syphilis or lesions and developmental defects of the nervous system.

Pathology.—*Atelectasis* is due to failure of the respiratory mechanism to draw air into the alveoli and expand them, as occurs normally with the first few inspiratory efforts of the new-born infant.

Atelectatic lungs are solid, airless and small. They are usually described as presenting appearances similar to those of adult liver as regards colour and consistence. In partial *atelectasis* the lung appears mottled, and small expanded areas of pinkish colour may project from the surface. The condition is chiefly of medico-legal and pathological interest.

APNEUMATOSIS OR ACQUIRED COLLAPSE

Collapse of previously expanded lung may be active or passive, the former being due to active shrinking of the lung owing to defects in the inspiratory musculature, the latter to conditions disturbing the pressure relations within the thorax.

1. ACTIVE PULMONARY COLLAPSE.

Synonyms.—Active Lobar Collapse ; Massive Collapse.

Ætiology.—This condition was first described by William Pasteur in 1890 in cases of diphtheria associated with paralysis of the diaphragm. In 1908 he pointed out that it occurred also as a sequel of operations, especially of those upon the abdominal organs, less frequently of those upon the neck and pelvis. It is highly probable that many post-operative lung conditions formerly recorded as pneumonia were in reality due to active lung collapse. It may also follow after injuries, such as those resulting from falls from a bicycle or a horse. During the Great War, when chest wounds were collected in special hospitals, it was found that massive collapse was not infrequently an important complication of penetrating and non-penetrating wounds of the chest. It was also noticed in some cases after severe wounds of the buttocks and pelvis.

Pathology.—The mechanism by which deflation results is obscure, and is the subject of controversy. Pasteur regards the condition in the diphtheritic cases as due to paralysis of the diaphragm through the phrenic nerves or their nuclei, and in the post-operative and traumatic cases as a consequence of reflex inhibition of this muscle. Briscoe, on experimental, pathological and clinical evidence discards Pasteur's explanation. He maintains that the deflation is caused by an exaggeration of the normal phenomena of breathing in the supine position, in which he states that the crural portion of the diaphragm alone contracts, the costal portion being in abeyance. In the supine position, with quiet breathing, deflation of the lower lobes occurs, and this is promoted by conditions of debility, toxæmia or operation. The clinical manifestations described by Pasteur are regarded by Briscoe as the result of superadded pleurisy, or of inflammation of the crura of the diaphragm.

Recently Boland and Sheret have put forward the suggestion that massive collapse is due to obstruction of the bronchi, followed by removal of the air in the corresponding lung areas by absorption into the blood stream. The obstruction is supposed to be due to increased secretion and the inhibition of the cough reflex.

Post mortem, the lower lobe of one lung is usually found to be deflated and retracted towards the spine. Sometimes the whole of one lung may be affected, or both lower lobes. The collapsed area is bluish-red, firm, does not crepitate and sinks in water. Pleurisy or pneumonic changes may be seen, and these are regarded by Pasteur as secondary to infection of the deflated lung, the resistance of which is lowered, and by Briscoe as the essential factor in the production of the symptoms. In massive collapse the heart and mediastinum are displaced towards the affected side, and the sound lung is often bulky and distended.

Symptoms.—The symptoms commonly commence within 24 or 48 hours of the injury or operation, although they may rarely be delayed for 5 to 7 days. The onset is generally sudden, with pain in the lower part of the thorax or behind the sternum. Severe dyspnoea quickly follows, and the patient appears dusky, cyanosed and alarmingly ill. Cough, with viscid mucoid expectoration, generally develops in a few hours. The latter may become copious and muco-purulent if pneumonic changes ensue. The pulse and respirations are markedly increased in rate, and the temperature not infrequently rises to 103° F. Occasionally the onset is more gradual with pain

and cough, and in some cases of wounds it may give rise to few symptoms and be discovered only on routine examination.

Examination of the chest shows diminished movement on the affected side, and often absence or reversal of epigastric excursion with respiration, whereas the movement on the other side may be exaggerated. In other respects the signs usually simulate those of lobar pneumonia. Over the collapsed lung the vocal fremitus is increased, the percussion note is dull, the breath sounds are tubular, and bronchophony and whispering pectoriloquy are present; but as a rule there are no adventitious sounds, although occasionally rhonchi and a few fine râles may be heard. In some cases the breath sounds are very weak or almost absent, and voice conduction is diminished. Over the healthy lung, loud and harsh breathing is audible. The displacement of the cardiac impulse towards the collapsed lung is a point of cardinal importance. It is noteworthy that in certain cases of gunshot wounds of the chest the collapse affects the contra-lateral lung.

Complications and Sequelæ.—Bronchitis, lobar pneumonia, or pleurisy may occur as complications. There are usually no sequelæ, except that pleural adhesions may occur.

Course.—The course of the affection is rapid. After periods extending from 2 to 5 days the temperature falls to normal, the symptoms disappear, the lung quickly re-expands, the heart returns to its normal position, and there is complete recovery.

Diagnosis.—The most important conditions from which this malady has to be distinguished are lobar pneumonia, pulmonary embolism, pneumothorax and pleural effusion. The position of the cardiac impulse is often the deciding factor: in collapse it is displaced towards the lung involved, in pleural effusion and pneumothorax it moves away from the affected side, whereas in lobar pneumonia there is usually no cardiac displacement, although there may be dilatation. Labial herpes and blood-stained expectoration are frequently seen in pneumonia, but not in collapse. When in right-sided collapse there is marked distension of the left lung with obliteration of the normal cardiac dullness, the signs superficially resemble those of a left-sided pneumothorax; but with careful examination no such error should be made. The distinction from pulmonary embolism may be difficult at first, but the localisation of the signs, and the blood-stained expectoration, may give useful indications.

Treatment.—**Prophylaxis.**—The administration of morphine and atropine before the anæsthetic, propping up of the patient in bed as soon as possible after it, and the insistence upon periodic deep breaths are useful measures in preventing the onset of lobar collapse. When the "collapse attack" develops oxygen should be administered and pain relieved by local applications, such as leeches or poultices, or by an injection of morphine, atropine and strychnine. Expectorants may be given if the cough is ineffective, and cardiac tonics, such as digitalis, strophanthus and caffeine if there is much cardiac embarrassment. Injections of strychnine or camphor in oil are useful if the patient is collapsed at the onset.

2. PASSIVE PULMONARY COLLAPSE.—This form of collapse may affect the whole of one lung, or be confined to one lobe or to groups of lobules.

Ætiology.—Total collapse is generally the result of pleural effusion, empyema, pneumothorax or obstruction of a main bronchus. In a large

effusion and in **pneumothorax** collapse is complete, unless the shrinkage is prevented by adhesions. In a smaller effusion, the process may be limited to the lower parts of the lung. Other causes of lobar or partial lobar collapse are conditions leading to complete obstruction of a main bronchial division, particularly **new growth**, **aneurysm** or foreign body. It also occurs in aged or bedridden patients, or in those with enfeebled inspiratory muscles, when prolonged fever has enforced a dorsal decubitus. Abdominal distension from **tympanites** or **ascites** can also cause collapse of the bases of the lungs.

Lobular collapse results from any condition impeding the air entry to the smaller bronchi or bronchioles, such as **bronchitis**, **broncho-pneumonia**, **pulmonary tuberculosis**, **whooping-cough** and **diphtheria**. Obstruction of the **naso-pharynx** by enlarged tonsils and adenoids may cause partial collapse, especially in the upper lobes.

Pathology.—The deflation of the lung area may be produced in three ways—(1) By complete obstruction to the air from blocking of a bronchus or bronchiole, the residual air being absorbed; (2) by enfeeblement of the inspiratory mechanism similar to the process in active collapse; and (3) by disturbance of the intrapleural pressure by fluid or air, the lung at first contracting in virtue of its elasticity until the intrapleural pressure becomes equal to that of the atmosphere, when any further accumulation of fluid or air causes positive pressure and compression of the collapsed lung. It is said that a plug of mucus in a bronchus may act as a ball valve, allowing the escape of air during expiration, and preventing its entry during inspiration. This view has now few adherents.

Post mortem, in complete or lobar collapse the appearances are similar to those in active collapse. In lobular collapse the deflated areas are contracted and depressed below the level of the healthy lung. They are dark red or slaty in colour, while the adjacent areas are pinkish and often emphysematous. The collapsed areas do not crepitate.

Symptoms.—Total collapse of the lung or of a lobe being usually a secondary process, the symptoms and signs are masked by those of the primary condition, such as **pleural effusion**, **pneumothorax**, **growth** or **aneurysm**. It can, however, usually be demonstrated by X-ray examination, the collapsed lung being apparent as a fairly dense shadow lying alongside the vertebral bodies. Not infrequently, however, in **pleural effusion** definite tubular breath sounds, with **bronchophony** and **pectoriloquy**, may be audible in the relatively dull area above the level of the fluid posteriorly, and these signs are due to the collapsed lung. In **aortic aneurysm**, or less commonly in **mediastinal**, **pulmonary** and **bronchial neoplasms**, distinctive signs due to the local collapse may be apparent. These consist of slightly **diminished movement** of the corresponding part of the chest wall, with **diminution of vocal fremitus** and impairment of percussion note or actual **dullness**. Breath sounds are weak, as a rule, but may be bronchial or tubular. **Voice conduction** is increased, and in incomplete collapse crepitations are often audible. The cardiac impulse may be displaced towards the affected side, but this is less apparent than in active collapse, and it is not infrequently displaced to the opposite side by the primary condition. **Lobular collapse** gives rise to no symptoms which can be differentiated from those of the condition inducing it.

Course and Complications.—The lung usually re-expands wholly or in part when the condition causing collapse has been removed. Thus a lung that has been maintained continuously collapsed by artificial pneumothorax, with repeated refills for as long as 2 years or more, will re-expand when the gas in the pleural cavity is allowed to be absorbed. In chronic effusion, or in large or neglected empyemata, re-expansion may be incomplete, and some falling in of the chest wall results. Fibroid changes may occur in lung tissue which has been long collapsed.

Diagnosis.—This is frequently a matter of inference, owing to the nature of the primary disease. Valuable help may be afforded by X-ray examination.

Treatment.—No special treatment apart from that of the condition causing the collapse is required. If a pleural effusion is slow to absorb, the necessity for paracentesis, to avoid too long collapse, may have to be considered.

HÆMOPTYSIS

It should be recognised that hæmoptysis is a symptom, not a disease. It is here considered separately because the accurate diagnosis of its origin is essential to its treatment, which differs widely in different conditions.

Definition.—The term hæmoptysis is arbitrarily restricted to the expectoration of blood, entering the air passages from structures below the larynx or from the larynx itself. When the blood is derived from the naso-pharynx or mouth it is sometimes described as spurious hæmoptysis.

Ætiology.—1. Pulmonary tuberculosis is the commonest cause, the blood being derived from an aneurysm in a pulmonary cavity, or from ulceration of a small vessel, or congestive processes around the early lesions.

2. Chronic venous congestion, particularly in mitral stenosis. These two conditions account for the majority of cases.

3. Inflammatory and destructive diseases of the lungs, air passages or pleura, such as pneumonia, broncho-pneumonia, especially the influenzal variety, abscess, gangrene and bronchiectasis with ulceration of the walls. Pneumoköniosis, streptotrichosis and ulceration of the larynx, trachea or bronchi from tuberculosis, gumma or new-growth may also be associated with hæmoptysis. Breaking down of a caseous or calcareous bronchial gland is a rare cause, as also is rupture of an empyema through a bronchus.

4. Infarction of the lung.

5. New-growths of the lung, bronchi or mediastinal glands.

6. An aortic aneurysm may cause hæmoptysis by "weeping" through an eroded bronchus, or by direct rupture, the latter being of course immediately fatal.

7. Traumatic causes.—Injury may cause hæmoptysis, by fractured ribs wounding the lung, by contusion and by breaking down of healed tuberculous lesions. Hæmoptysis occurs frequently in wounds of the chest, both penetrating and non-penetrating.

8. Certain abnormal blood conditions, chiefly leukæmia, purpura, hæmophilia, scurvy, and occasionally pernicious anæmia. Hæmoptysis occasionally occurs in the malignant specific fevers, especially small-pox and measles.

9. Parasitic causes, such as pulmonary distomatosis and spirochaetosis, are common in Asia but rare in Europe. Hydatid disease of the lung may cause slight hæmorrhages.

10. Vicarious menstruation.—Some cases in women have been regarded as vicarious menstruation, and this view dates back to Hippocrates. It is probable, however, that most cases are to be explained as due to leakage from obscure pulmonary lesions.

11. Hæmoptysis occasionally occurs in apparently healthy persons. In some, with high systemic arterial tension, it is probable that the pulmonary arterial pressure is also raised, and the condition may be regarded as analogous to the epistaxis which occurs more commonly in such patients. Sometimes the hæmoptysis is due to leaking from an old arrested tuberculous lesion.

12. Rupture of an hepatic abscess or hydatid cyst through the diaphragm into a bronchus is an occasional cause.

Spurious hæmoptysis is usually due to staining of the saliva or the pharyngeal secretion with blood, generally derived from the gums, which are spongy and congested, often from early pyorrhœa. The condition is common in anæmic girls, and is, as a rule, observed in the morning. Hæmorrhage from an enlarged pharyngeal vein is often suggested as a cause, but is rarely seen. Hæmorrhage after tooth extraction, and staining of the mucus expectorated after epistaxis, are other causes of spurious hæmoptysis.

Pathology.—From the list of causes it might be inferred that the origin of the blood differs in different cases. It may come from the pulmonary or bronchial vessels in pulmonary tuberculosis and other lung or bronchial conditions, and also in chronic venous congestion or infarction. It may come from the thoracic aorta direct, or from some of its branches, in aneurysm and mediastinal new-growth, and from the hepatic vessels in abscess of the liver. In cases due to disease of the trachea and larynx it comes direct from the vessels supplying them.

On examination, the larynx, trachea and bronchi may contain clots, or blood-stained froth and mucus, and their walls may be stained in places. Dark reddish areas of lobular distribution, due to inhaled blood, may be seen in various parts of the lungs, particularly at the bases. Sometimes this may induce bronchitic changes, described as hæmoptoic bronchitis. Careful search in cases of profuse hæmoptysis will usually reveal the source of the hæmorrhage, and in pulmonary tuberculosis this is generally a ruptured aneurysmal dilatation in a cavity. The aneurysm may be small and escape notice unless many cuts are made into the lung.

Symptoms.—In hæmoptysis, the patient often experiences a tickling in the throat, followed by a gush into the mouth with a salt taste, and on expectoration notices blood. The alarm and anxiety this occasions lead to restlessness and rapid action of the heart. If the bleeding is profuse, cough is frequent, and large clots, together with liquid alkaline blood, may be expectorated to the extent of 20 or 30 ounces in a few hours. The bleeding may cease temporarily to recur at intervals for several days, until the patient becomes blanched, weak and syncopal, with rapid, weak pulse. In any profuse hæmoptysis, death may occur in a few minutes, either from asphyxia or syncope. In the former case, the blood, at first bright and arterial, is soon dark and frothed, while the patient becomes cyanosed and livid. In

slighter degrees of hæmoptysis there may be only streaks, small clots or liquid blood mixed with ordinary sputum. After the actual bleeding has ceased, the sputum may be blood-stained for some days, owing to the expectoration of blood inhaled into other parts of the lungs. This can be recognised by its colour, which varies from dark red to brown, owing to the changes undergone by the pigment.

Diagnosis.—This involves two problems—first the differentiation from hæmatemesis and spurious hæmoptysis, and secondly the recognition of the cause of the hæmorrhage. If the patient is seen at the time of the bleeding the first of these is easy. The nature of the blood, and its association with cough and possibly with pulmonary or cardiac signs, are conclusive. When the diagnosis has to be made upon the history given by the patient or by friends it may be difficult, especially in the absence of physical signs.

In hæmatemesis there is frequently gastric pain and faintness before the vomiting, the blood is acid in reaction, dark in colour, even brown from acid-hæmatin, and is sometimes mixed with food. The fact that in hæmoptysis blood may be swallowed and subsequently vomited increases the difficulty. Patients often give very dubious answers to questions as to whether the blood was coughed or vomited up. They should then be questioned as to whether sputum was brought up on the following day, and if so whether it was blood-stained. In cases of doubt the investigation of the pulmonary and abdominal physical signs, when the patient's condition permits, may decide the diagnosis.

Great caution should be exercised to exclude tuberculosis before making a diagnosis of "spurious hæmoptysis." Only when there are no pulmonary symptoms or signs, and when some obvious cause, such as anæmia or pyorrhœa, is found, is it safe to do so.

While distinguishing between the various causes of hæmoptysis it is well to regard and to treat it as due to pulmonary tuberculosis until some other cause is conclusively established. The sputum should be examined for tubercle bacilli on several occasions, the temperature recorded, and the physical signs most carefully watched.

The presence of a valvular lesion, especially mitral stenosis with signs of pulmonary engorgement, may render the cause of hæmoptysis clear. When tuberculosis and cardiac disease can be excluded, a careful study of the history, the symptoms and signs, may throw light on the diagnosis or suggest some investigation which will serve to establish it, e.g. examination of the sputum for parasites and hydatid hooklets, the cytological examination of the blood and an X-ray examination.

In other cases, as in bronchiectasis, abscess or gangrene, the history, the physical signs and the nature of the sputum are often characteristic.

Prognosis.—Apart from hæmoptysis, which is rapidly fatal, due to aneurysm or pulmonary tuberculosis, the immediate prognosis in cases of pulmonary hæmorrhage is not unfavourable, even when it continues for days. The ultimate prognosis depends upon the cause.

Treatment.—This is so entirely dependent upon the cause and origin of the bleeding that reference should be made to the corresponding diseases.

EMPHYSEMA OF THE LUNGS

Emphysema of the lungs, or alveolar-ectasis, is a condition of distension of the alveoli; it is usually progressive and is associated with definite changes in the inter-alveolar walls. The following varieties are generally recognised — (1) Large-lunged or hypertrophic; (2) small-lunged or atrophic; (3) compensatory; (4) acute vesicular; and (5) acute interstitial emphysema. The last-named condition has no relation to true emphysema except in name, but will be described in this group for convenience.

1. LARGE-LUNGED OR HYPERTROPHIC EMPHYSEMA (SUBSTANTIVE OR IDIOPATHIC EMPHYSEMA)

This is a chronic affection and is usually bilateral.

Ætiology.—*Predisposing causes.*—It may occur at any age, even in childhood, but is most frequently seen in middle and late adult life. It is commoner in men than in women, probably because they are more exposed to the conditions inducing it. Although not strictly hereditary, it often shows a familial incidence. Certain occupations are credited with being concerned in its production, notably those involving violent or prolonged muscular effort with closed or partially closed glottis, such as blowing wind instruments and lifting heavy weights. Dusty occupations also favour its onset by leading to bronchitis and cough.

The common exciting cause seems to be the strain of prolonged and repeated cough, induced by chronic bronchitis, bronchiectasis, asthma, whooping-cough, cigarette smoke inhaling, and other causes of irritation of the upper air passages.

Pathology.—The pathogenesis of emphysema has been much debated and various explanations have been offered. (1) Primary degeneration theory. Villemin suggested that the essential lesion was a fatty degeneration of the alveolar walls, while Cohnheim believed that there was a congenital defect of the elastic tissue of the lung. (2) The inspiratory theory, first suggested by Laennec and developed by Gairdner, postulates the force of inspiration as the distending agent. (3) The expiratory theory, first enunciated by Mendelssohn, was independently brought forward and established by Jenner. The distension of the alveoli is regarded as due to the effect of forced expiration and cough. Jenner pointed out the special and early involvement of the apices, the anterior and lower margins of the lungs; in other words, the parts least supported by the thoracic cage. (4) Freund regarded the changes in the lungs as secondary to calcification of the costal cartilages, the chest becoming fixed in the inspiratory position and the lung permanently expanded in consequence. The expiratory explanation is now generally accepted, and emphysema is regarded as the result of increased intra-alveolar tension, due to violent expiratory efforts, acting on walls weakened by congenital defects, by inflammatory processes or by toxic agents, such as alcohol (Nothnagel).

The characteristic conformation of the chest is usually apparent (see Symptoms), the costal cartilages are often calcified, and on opening the thorax post mortem, the lungs bulge instead of retracting, so that the peri-

cardium may be almost completely obscured. They are pale in colour, even in town-dwellers, a condition called albinism of the lung by Virchow. They are soft and pit on pressure, and, as described by Laennec, give the sensation of a down pillow. The surface of the lung under the pleura shows a finely vesicular appearance, due to the distension of the alveoli, the vesicles often being nearly as large as pins' heads. Not infrequently large bullæ or blister-like protuberances, varying in size from a pea to a Spanish olive, may be seen projecting from the surface, particularly at the apices and margins. These bullæ when incised show fine fibrous bands crossing them, the remains of inter-alveolar walls and of atrophied blood vessels. It was formerly customary to refer to such cases as bullous or marginal emphysema and to describe those in which the dilatation is less obvious but more widely diffused as general emphysema; but the conditions are so commonly associated together in varying degrees that little is gained by so doing. On section the lungs are anæmic and dry, except at the bases, where there is frequently some œdema in advanced cases. The bronchi may show some general dilatation, although less commonly than might be expected from the close similarity of the causal factors of emphysema and bronchiectasis. Where bronchitis coexists, muco-pus can be squeezed from the cross-sections of these tubes. As pointed out by Fowler, pleural adhesion is relatively uncommon. The infundibula and alveoli are dilated, and the inter-alveolar walls are thin and atrophic, even disappearing wholly or in part. The distension and coalescence of adjacent alveoli result in the formation of bullæ. The calibre of the pulmonary capillaries is diminished by stretching of the alveolar walls, and where atrophy of the inter-alveolar septa occurs the capillaries are destroyed. These two processes result in a considerable diminution in the total aerating surface, and cause the dyspnœa and cyanosis characteristic of the disease. Moreover, the normal anastomoses between the terminal bronchial and pulmonary capillaries increase considerably, and some of the blood in the latter may therefore fail to reach the alveoli and so escape aeration. Atrophic changes in the elastic tissue have been described. In order to maintain the circulation through the diminished capillary area, the right ventricle hypertrophies and the resultant high blood-pressure sometimes induces atheroma of the pulmonary artery. Emphysema being a progressive lesion, and the defective aeration of the blood perhaps interfering with the nutrition of the heart muscle, cardiac failure eventually ensues, causing tricuspid regurgitation, engorgement of the right auricle, and the visceral effects of venous engorgement, such as "nutmeg" liver.

Symptoms.—Dyspnœa of varying degree is the most characteristic symptom. In uncomplicated cases of moderate extent it is only present on exertion, unless bronchitis coexists. In advanced emphysema, dyspnœa is marked and becomes extreme in the bronchitic or "asthmatic" attacks and in foggy weather. Cyanosis is common, and is to some extent a measure of the degree of emphysema. The patient may walk about with a more extreme degree of cyanosis than in any other condition except congenital heart disease. Clubbing of the fingers of moderate degree is common. Cough is usually due to the associated bronchitis, and is worse in the winter and in foggy weather. It is frequent, noisy and often hacking and paroxysmal. Expectoration is also the result of the bronchial catarrh, and varies from a few grey mucoid pellets to copious muco-pus.

The chest is enlarged, particularly in the antero-posterior diameter, the upper thoracic spine is rounded and kyphotic, the sternum protrudes forward, and the angle of Louis (*angulus Ludovici*) is prominent, the general effect being the so-called barrel-shaped chest. The ribs run forward less obliquely and the intercostal spaces are wider than normal, the chest being as a whole in the inspiratory position. The respiratory movements are much restricted, the patient elevating the rigid thorax with little expansion on taking a deep breath, so that the inspiratory increase at the level of the nipples may be only half to 1 inch, instead of the normal $2\frac{1}{2}$ to 3 for an adult. There is often filling and even bulging of the supra-clavicular hollow, while the neck appears short, the sternomastoids stand out, and the jugular veins are full. A zone of dilated venules, the "emphysematous girdle," is often visible along the line of the costal attachment of the diaphragm, but is not pathognomonic. The cardiac impulse is not visible as a rule, and may only be felt with difficulty, but epigastric pulsation is usually apparent. Vocal fremitus is diminished, and the percussion note is hyper-resonant. The superficial cardiac dullness is greatly diminished or even absent, and the lower limit of pulmonary resonance may extend to the costal margin, back and front, the hepatic dullness being encroached on.

It is said that in bullous emphysema the breath-sounds are harsh over the outer part of the upper lobes in front, and weak at the bases. In general emphysema the breath-sounds are weak everywhere, inspiration is short, and expiration is greatly prolonged. A loud rumbling, from contraction of the thoracic muscles, may entirely obscure the breath-sounds. A few fine bubbling râles may be heard at the bases or at the sternal margins. If bronchitis is present, scattered rhonchi may be audible. Vocal resonance is generally slightly diminished. The heart-sounds are weak and distant, and in late stages a tricuspid systolic murmur may develop. The "vital capacity" of the lungs, measured by a spirometer, is often reduced even to one-half; for example, to 1800 c.c., instead of the normal 3600 c.c. Examination by the X-rays shows increased extent, and undue translucency of the lung tissue. The liver is sometimes palpable, possibly from downward displacement by the bulky lung, but more often from enlargement due to passive hyperæmia. The spleen may also be depressed and enlarged.

Complications.—Bronchitis is the commonest, and often constitutes a vicious circle. Asthmatic attacks, so-called "bronchial asthma," are common in later stages; on the other hand, spasmodic asthma may be the cause of the emphysema. Pneumothorax and interstitial emphysema may occur from rupture of the bullæ, although these accidents are surprisingly rare. Pulmonary tuberculosis is an occasional complication of emphysema, which, contrary to popular opinion, is not antagonistic to it, although it may mask and obscure the early stages. Right-sided cardiac failure, with its train of consecutive changes, is a late and often terminal complication.

Course.—Emphysema is progressive, unless the cause is removed or the effects of the disease are mitigated by residence in a warm, dry climate, especially in the winter. Conversely, residence in unsuitable districts, persistence in detrimental employment, and repeated attacks of bronchitis accelerate its course.

Diagnosis.—This is never difficult in advanced cases. The slighter degrees may be more difficult, and the diagnosis is then largely a matter of

inference from the association of chronic cough and dyspnœa, with physical signs of hyper-resonance and prolonged expiration.

Confusion may occasionally arise in regard to pneumothorax, thoracic aneurysm and pulmonary tuberculosis. Careful record of the symptoms and signs and the investigation of the sputum generally suffice to distinguish these conditions. In doubtful cases the X-rays may assist.

Prognosis.—This depends upon the degree of emphysema and the circumstances of the patient. If progressive, it exerts an increasingly crippling effect, and it certainly shortens life under urban conditions. A "vital capacity" of less than 50 per cent. of the normal is of serious import. The advent of severe bronchitis or of cardiac complications may affect the prognosis gravely.

Treatment.—Emphysema may be arrested but cannot be cured. Attention must be directed to prevention of the causes of chronic cough and increased intra-alveolar tension. In any person with hereditary tendency to emphysema or to winter cough, the questions of occupation and place of residence should be carefully considered. When the disease is established, the patient, if in a position to afford it, should spend the winter in a warm, dry climate, either abroad or at the south-west coast of England.

Various attempts have been made to increase the respiratory ventilation of the lungs, *e.g.*, by compression of the chest during expiration, by expiring into rarefied air, or by breathing compressed air. Of these the compressed air bath seems to have given the best results. The patient enters a special iron chamber fitted with a window, and the air pressure is raised during the course of half an hour to $1\frac{1}{2}$ atmospheres. He remains at this pressure for an hour, and is then decompressed to normal during the next half-hour. These baths may be given every other day and gradually increased in duration and frequency. This treatment is often efficacious in cases of emphysema associated with bronchial spasm or with bronchitis. It is possible that the increased pressure overcomes the obstruction caused by catarrhal inflammation or by spasm of the finer bronchi, and allows the alveolar air, pent up under pressure, to escape. Cases with marked arterial disease or with much rigidity of the chest-wall are unsuitable for this form of treatment.

The diet should be simple and easily digestible, especially in the later stages. If there is spasmodic dyspnœa or asthma, no late meal should be permitted. Cod-liver oil in the winter seems to help some patients. Clothing should be warm, but the excess of under-garments, often worn in fear of chill, is harmful.

In other respects treatment is largely symptomatic. In acute bronchitic attacks the measures to be adopted are in no way different from those in bronchitis uncomplicated by emphysema. In the more chronic bronchitis so commonly present in the winter, iodides with alkalis and balsamic expectorants seem beneficial. Terebene (M x) in emulsion or in capsule has been recommended. Counter-irritation to the chest by liniments, such as the *lin. terebinthinæ aceticum*, is often grateful to the patient, when cough is troublesome. When asthma or paroxysmal dyspnœa occurs, antispasmodic drugs and measures similar to those used in spasmodic asthma may be employed. When cardiac failure supervenes, the appropriate treatment must be vigorously applied. If there is marked cyanosis and venous engorge-

ment, venesection, leeching, purgative and diuretic drugs may be employed, and digitalis and other cardiac tonics administered.

2. SMALL-LUNGED EMPHYSEMA (ATROPHIC OR SENILE EMPHYSEMA)

Ætiology.—This condition occurs in old age and forms part of the general atrophy of the tissues.

Pathology.—The alveolar walls become thinned and disappear, so that adjacent alveoli coalesce. The condition is primarily atrophic, and therefore differs from true emphysema, although the result is to produce a diminished area for aeration. Post mortem the lungs are small and do not bulge or obscure the pericardium. They are often deeply pigmented, and are more spongy than normal, but although bullæ occur they are small. On section the lung tissue is bloodless and friable. The bronchi may be slightly dilated and show catarrhal changes.

Symptoms.—These are slight and are masked by the enfeeblement due to the general atrophy and debility. There is shortness of breath only on exertion, or on exacerbation of the chronic bronchitis which is frequently present. The chest is small, flat and thinly covered, the movements are poor and there is elevation of the chest as a whole, with poor expansion. There is little cyanosis, and no clubbing. The vocal fremitus is unaltered or slightly diminished. The percussion note is hyper-resonant, but there is no encroachment on the cardiac and hepatic areas of dullness. Breath-sounds are weak, and there is but little prolongation of expiration. Rhonchi and râles may be heard, especially if bronchitis is present, or if the heart is failing.

Diagnosis.—The condition is generally so obvious that no difficulty arises.

Treatment.—This is chiefly a matter of careful regimen and diet, with treatment of coexisting bronchitis or cardiac failure.

3. COMPENSATORY EMPHYSEMA (LOCALISED OR SECONDARY EMPHYSEMA)

Ætiology.—Localised emphysema is a sequel to some process inducing collapse, contraction or destruction of areas of lung tissue. It may be lobular in distribution in bronchitis, broncho-pneumonia, tuberculosis and diphtheria. It may affect one or more lobes, or the whole of one lung, especially in cases of fibrosis following tuberculosis, pneumonia, chronic pleural effusion and empyema.

Pathology.—It is generally conceded that the inspiratory theory of Laennec and Gairdner satisfactorily explains the genesis of this condition. When shrinkage of an area of lung occurs, the chest wall may fall in, if there is pleural adhesion, but otherwise inspiration tends to expand the normal parts of the lungs so as to contain the normal intake of air or the major part of it, owing to the difference it induces between the intrapulmonary and intrapleural pressures. None the less, it must be admitted that the expiratory strain of cough may assist in its production.

Although it may be compensatory and physiological at its inception, it is doubtful whether a true hypertrophy takes place after adolescence. In any case it soon leads to atrophy of the alveolar walls, as in true emphysema,

and thus becomes pathological and harmful. Post mortem the condition may be found in an upper lobe around contracted scarred lung tissue, or in a lower lobe when the upper lobe is contracted or disorganised. In cases where one lung is fibroid and contracted, compensatory emphysema may be found throughout the sound lung. The enlargements and contractions of the lung may produce some striking displacements, the lower lobe extending upwards nearly to the clavicle, or the anterior margin of the sound lung crossing the mid line. The general appearances are closely similar to those of ordinary emphysema, except that bullæ do not occur, at any rate until the process is advanced and definitely pathological.

Symptoms.—This condition does not produce symptoms that can be differentiated from those of the primary disease. When it affects a lobe or the whole of one lung, there is hyper-resonance over the area involved, which often contrasts strikingly with the dullness due to the primary lesion. The hyper-resonance may extend across the sternum and even for an inch or more beyond it. The heart is displaced towards the side where fibrosis is in progress. Vocal fremitus and vocal resonance are little altered, but may be increased at first and subsequently diminished. In the early stages, when there is alveolar dilatation without degenerative mural changes, the breath-sounds are exaggerated, harsh or puerile, but when such processes develop, they become weak and there are indications of dyspnoea and cyanosis on exertion.

Diagnosis.—This is easy, owing to the difference between the diseased and "compensatory" areas, and to the indications of contraction and displacement.

Treatment.—No special treatment apart from that of the primary condition is required.

4. ACUTE VESICULAR EMPHYSEMA

Although tradition has included this condition with emphysema, it is in reality only a temporary acute distension of the alveoli resulting from any condition causing widespread obstruction of the smaller bronchi. It is sometimes observed after death in cases of acute bronchitis, whooping-cough or asphyxia, and its existence may be inferred in severe asthma. Post mortem the lungs are bulky and the alveoli distended.

The symptoms are dependent upon the primary condition, although dyspnoea is invariably present. The chest is found to be fully expanded, the vocal fremitus is diminished, the percussion note is hyper-resonant, and the breath sounds vary with the condition inducing it.

5. ACUTE INTERSTITIAL EMPHYSEMA

In acute interstitial emphysema air is present in the stroma of the lungs, and in the subpleural connective tissues. It may follow external trauma, such as fractured ribs, or wounds penetrating the lungs. The alveoli may rupture with violent expiratory efforts, as occur in whooping-cough or influenzal broncho-pneumonia. It may occur in diphtheria. The air sometimes tracks along the pulmonary roots to the mediastinum, and appearing in the neck or on the chest-wall gives rise to surgical emphysema.

Post mortem, subpleural bullæ may be seen containing air, and on section of the lung minute air vesicles may be found in the inter-alveolar connective

tissue. A diagnosis cannot be made unless the visible signs of surgical emphysema are present. The air is usually completely absorbed, and a perfect recovery takes place. No special treatment is required beyond keeping the patient at rest, and giving sedative drugs to allay cough.

ABSCESS OF THE LUNG

Definition.—Abscess of the lung includes any circumscribed collection of pus formed in the lung tissue, but softened tuberculous areas and bronchiectatic accumulations are usually excluded.

Ætiology.—*Predisposing causes.*—These include any diseases producing general cachexia or malnutrition, notably diabetes and chronic alcoholism, also any conditions leading to diminished resistance locally in the lung, such as injury, disease or exposure.

Exciting causes.—These are pyogenic organisms, which reach the lung by inhalation, by extension from adjacent suppurative processes, or by the blood stream, either directly or in septic emboli. The common organisms found are streptococci, staphylococci, the pneumococcus, Friedländer's pneumo-bacillus, and the *Bacillus coli*—sometimes acting in conjunction with putrefactive bacteria. Pulmonary abscess may form under the following conditions:

(1) As a result of lobar or lobular pneumonia, especially after the deglutition and aspiration varieties of the latter. Such abscesses are sometimes called meta-pneumonic. (2) Secondary to an inhaled foreign body. (3) From infection of the lung tissue due to spread from adjacent disease. This may occur in bronchiectasis, in ulcerating new growths of the lung, bronchi, œsophagus or mediastinal glands, in caries of the vertebræ or ribs, and in suppurating mediastinal glands. Rupture of an empyema, of a subphrenic abscess, of a liver abscess, or of infected hydatid cysts of the lung or liver may also lead to pulmonary suppuration. (4) As a sequel of perforating chest wounds, or of fractured ribs piercing the lung. (5) In pyæmia, or following on septic pulmonary emboli due to right-sided infective endocarditis, or derived from distant septic processes such as otitis media, and infective thrombo-phlebitis. Amœbic abscess occurs occasionally after dysentery, and pulmonary abscess may be found as a rare complication of enteric fever.

Pathology.—Abscess of the lung is generally single and basic when consequent on pneumonia, whereas embolic abscesses are often small and multiple, and may be found in any part of the lung. Abscesses due to extension from adjacent disease, are generally solitary and are often large and irregular. The walls of acute abscesses are generally formed of congested and œdematous lung tissue or of a zone of unresolved pneumonia. Since acute abscesses commonly rupture quickly into a bronchus, a fibrous capsule is unusual, but in chronic abscess there is often considerable fibroid change in the neighbouring lung tissue. The pleura may become involved over superficial abscesses, leading to empyema, or to pyo-pneumothorax if rupture follows.

Symptoms.—These are usually an intensification of those due to the primary or antecedent condition. The patient invariably appears seriously ill, the fever becomes of septic type, remittent or intermittent in character, and of a high range. Rigors and sweating are common. The pulmonary

symptoms at first may be only slight cough with scanty muco-purulent expectoration. Dyspnoea may be present and pain of acute character develops if the pleura is involved. A considerable leucocytosis may be found, and occasionally the breath may be offensive, even before rupture into a bronchus occurs leading to the sudden expectoration of a large quantity of pus. The pus is sometimes unpleasant or offensive-smelling, but has not the extreme foetor of gangrene. Microscopical investigation will demonstrate the presence of pulmonary débris, especially elastic tissue, together with pus cells and micro-organisms. After the expectoration of the pus, the temperature usually falls and the general condition of the patient is much improved, though cough and expectoration persist. The physical signs in a deep-seated or small abscess are often inconspicuous and consist in slight dullness over a small area, weak breath-sounds and possibly a few râles in the surrounding infiltrated or œdematous lung tissue. With a large or a superficial abscess, the signs before rupture may be those of consolidated or collapsed lung. After evacuation occurs, the characteristic signs of excavation develop at once. In multiple embolic abscesses the signs are usually those of disseminated broncho-pneumonia.

Complications and Sequelæ.—The commonest complication is dry pleurisy. This may progress to empyema, or to pyo-pneumothorax if rupture into the pleura occurs. In some cases mediastinitis or pericarditis may develop. Gangrene is described, but is a rare sequel. Metastatic abscesses may be produced in other parts of the body, especially in the brain, and meningitis is a rare and serious complication. The most important sequelæ are fibrosis of the lung, pleural adhesion, and rarely indurative mediastinitis.

Diagnosis.—This is difficult before rupture, but abscess may be suspected from the gravity of the symptoms in relation to the history and signs, especially if leucocytosis and foetor of the breath are present. An X-ray examination may be helpful by demonstrating a localised shadow before rupture, and excavation afterwards, and also by establishing the situation of the abscess. The sudden expectoration of pus followed by retrogression of symptoms and signs of excavation is very suggestive of abscess. After rupture has occurred the differential diagnosis has to be considered from—

1. **Interlobar empyema.**—The signs are generally most marked in the region of an interlobar septum, there may be some cardiac displacement and the sputum, though purulent, does not contain elastic tissue.

2. **Bronchiectasis.**—The history, the characteristic cough and sputum, and the variation of the physical signs with the state of the cavity usually suffice to distinguish this condition.

3. **Gangrene of the lung.**—The distinction is not always easy in acute abscess, since the two processes are closely related. The extreme gravity of the patient's general condition and the horrible foetor of the breath and sputum are the most characteristic features of gangrene.

4. **Tuberculous excavation.**—The history, the distribution of the sign, and the characters of the sputum, including the presence of tubercle bacilli, are the distinguishing indications.

5. **Purulent bronchitis.**—The history, the widespread physical signs and the absence of elastic tissue from the sputum usually serve to establish the diagnosis.

In multiple or pyæmic abscesses, it is often impossible to recognise the

1082 DISEASES OF THE RESPIRATORY SYSTEM

condition, though it may be suspected from the severity of the symptoms and signs. In any doubtful case an X-ray examination should be carried out, if the condition of the patient permits.

Prognosis.—The prognosis, though grave in all cases, is better than might be anticipated. Many of those in which rupture into a bronchus occurs, recover. The chance of recovery is greatly increased by operation. Death is inevitable in the pyæmic cases.

Treatment.—Surgical treatment is indicated in cases of localised abscess before rupture, when the patient's general condition is good. The lung is exposed over the abscess by rib resection, adhesion of the pleura is produced by packing if its layers are not already adherent, and the abscess is subsequently opened along the course of an exploring needle. After rupture has occurred, the decision as to operation depends upon the drainage of the cavity. If it does not drain well and the temperature remains raised, operation should be advised. In the case of a large chronic abscess cavity, a more or less extensive thoracoplasty may be required to enable the lung to collapse.

Medical measures consist in attempts to evacuate the cavity by postural methods, the use of expectorant drugs and of antiseptics such as creosote, guaiacol carbonate and garlic if the sputum is offensive. Antiseptic inhalations may also be used on a Burney-Yeo mask, as for bronchiectasis. In like manner intratracheal injections of menthol, guaiacol and olive-oil have been used with benefit. Autogenous vaccines are sometimes valuable, but are contra-indicated if free drainage is not established.

GANGRENE OF THE LUNG

In this condition localised or diffuse areas of lung tissue undergo putrefactive necrosis.

Ætiology.—*Predisposing causes.*—These include old age, over-indulgence in alcohol, general debility, diabetes and insanity. In certain rare cases, especially after broncho-pneumonia complicating measles, gangrene of the lung is met with in children.

Exciting causes and associated conditions.—These are, in the main, identical with those of pulmonary abscess (see p. 1080). In addition, the pressure of aneurysm or of new-growth on branches of the pulmonary artery may lead to gangrene. The causal organisms are also very similar to those found in abscess of the lungs, and include staphylococci, streptococci, sarcinae, the *Micrococcus tetragenus*, the *Bacillus coli communis*, the *B. pyocyaneus*, the *B. fusiformis* with its associated spirochæte, and various anaerobes. In some instances acid-fast bacilli, classed as streptothriceæ, occur. Some of these organisms yield putrefactive products, with the liberation of phenol, indole and skatole compounds in the lung.

Pathology.—It is not quite clear what are the factors determining whether abscess or gangrene occurs in an infected area of lung. Doubtless the general resistance of the body, the degree of local vascular disturbance, and the virulence of the infecting organisms all play their part. Laennec first described the two varieties of gangrene, the circumscribed and the spreading or diffuse. Around the former there are indications of a line of demarcation, formed by congested lung tissue, which may present the appear-

ance of red hepatisation. The surrounding lung tissue is invariably somewhat oedematous. The gangrenous area is soft and pulpy, and its colour varies from reddish-brown to greenish-black. As the necrosis advances, putrefactive liquefaction occurs, with the formation of a horribly reeking fluid, containing shreds and masses of necrotic lung tissue. When this is discharged, excavation results, and isolated vessels may be seen running across the resulting cavity, the walls of which are rough and covered with foetid pus. The diffuse variety of gangrene is less common; there is no attempt at a zone of demarcation, and the whole of a lobe or of one lung may be affected. In both forms, the overlying pleura is intensely inflamed, and empyema or pyo-pneumothorax may be produced.

Symptoms.—These are similar to those occurring in abscess of the lung, but are more acute. The patient is desperately ill, rigors are more common and sweating is more profuse. The breath has a peculiar fœtor, which, on account of the presence of the skatole group of putrefactive products in the gangrenous lung, has an almost fœcal odour. The sputum is intensely offensive, and on standing separates into three layers, similar to those of the expectoration in cases of bronchiectasis. Elastic tissue is usually present, but it may undergo rapid disintegration. Hæmoptysis is not infrequent and may prove fatal. In rare cases gangrene is not accompanied by fœtid expectoration, especially when developing in the insane, in young children, and in diabetics, or after pulmonary embolism. The physical signs closely resemble those present in cases of pulmonary abscess, and are those of consolidation before liquefaction occurs, and of excavation afterwards. The signs of the antecedent condition such as bronchiectasis, aneurysm, or malignant disease may also be present.

Complications and Sequelæ.—These are similar to those met with in pulmonary abscess, but owing to the rapid course and greater fatality of gangrene, they are not so common. Cerebral abscess may occur.

Course.—The course is usually rapid, unless the disease is small and circumscribed. In rare cases of localised gangrene of small extent, absorption and subsequent fibrosis occur.

Diagnosis.—The differential diagnosis is as for pulmonary abscess, the distinguishing features being the extremely critical condition of the patient and the revolting fœtor of the breath and expectoration. X-ray examination may give great assistance if the patient's condition permits it to be made.

Prognosis.—This is invariably extremely grave, though a few cases of localised gangrene recover spontaneously. The prognosis is improved by early operation in suitable cases. The outlook is said to be worse if the condition is apical, and diffuse gangrene is invariably fatal.

Treatment.—Operation is indicated when the general condition of the patient permits, if the gangrenous area can be localised by physical signs or X-ray examination. Exploratory puncture should not be carried out unless the preparations for immediate operation are complete. The other operative procedures are similar to those for abscess of the lung. Operation is contra-indicated in cases of diffuse gangrene. The medical treatment is in all respects similar to that for pulmonary abscess. Injections of neoarsphenamin, in doses of 0·3 gramme, have given good results, especially in cases due to fuso spirochaetosis.

PULMONARY FIBROSIS

Synonyms.—Fibroid Disease of the Lung; Chronic Interstitial Pneumonia; Cirrhosis of the Lung.

Definition.—Pulmonary fibrosis is a late sequel of many acute and chronic inflammatory or irritative processes affecting the bronchi, lungs and pleuræ. It is therefore rather of pathological than of clinical interest, and in no sense constitutes a separate disease, although the end results are remarkably similar in different forms. It is described here partly in deference to tradition, and partly to point out the methods of diagnosis between the various causes producing such strikingly similar effects.

Ætiology.—(1) The commonest cause is pulmonary tuberculosis, particularly the fibroid and fibro-caseous varieties. (2) The group of pneumoconioses contributes a considerable number of cases, and possibly some varieties of gas poisoning may induce fibroid changes. (3) Bronchopneumonic processes, particularly the forms associated with measles and whooping-cough, may be followed by widespread fibrosis, especially in children. (4) Although fibroid induration is commonly described as a sequel of lobar pneumonia, this disease is one of the rarer causes. (5) Localised fibrosis may occur around any circumscribed pulmonary or bronchial lesion, such as that produced by syphilis, leprosy, glands or streptotrichosis. Similarly it occurs about infarcts, pulmonary abscesses and parasitic cysts. (6) Chronic venous congestion, if prolonged, leads to fibroid change, which is referred to as "brown induration." This is usually of moderate degree and does not affect the clinical manifestations. (7) Chronic pleural affections, particularly those leading to adhesions or causing pulmonary collapse, may induce fibroid changes within the lung, and these forms are described as "pleurogenous cirrhosis." (8) Any condition causing obstruction of a bronchus and leading either to collapse or to bronchiectasis may, if long continued, cause fibrosis of the corresponding lung area. Among such may be mentioned inhaled foreign body, new-growth, cicatricial contraction and thoracic aneurysm.

Pathology.—The fibroid overgrowth may be (1) Massive or lobar; (2) localised or insular; (3) peribronchial; and (4) reticular.

Any part of the connective tissue framework of the lungs and bronchi may contribute to the fibrosis. In the massive form, which generally affects the whole or the major part of a lobe or even of one lung, the appearances in cases due to tuberculosis differ from those due to other causes. In the tuberculous variety the primary distribution is apical, and evidence of other tuberculous processes may be apparent in the form of large or small dried-up cavities, inspissated caseous material or calcareous masses enclosed in fibrous strands. In non-tuberculous processes, the early localisation is commonly basal, and although the primary cause may be obvious in the form of bronchial obstruction or some pleural condition, this is not always the case. On the other hand, non-tuberculous processes may involve the upper lobe primarily and fibroid tuberculosis may fall with special stress upon the lower lobe. In both forms of fibrosis, bronchiectasis may result, although this is more common in the non-tuberculous cases. Apart from the special tuberculous lesions, the end results are very similar in both forms.

The affected area of the lung is shrunken and often devoid of air except for that in the bronchi and in the cavities. It is dark in colour, very firm and hard. On section it presents a mottled appearance owing to the strands of blue-grey fibrous tissue traversing it, contrasting with the pigmented, condensed, airless lung tissue. The fibroid area may be honeycombed by cavities or may present one large excavation due either to tuberculous cavitation or to bronchiectatic dilatation. There is nearly always thickening and adhesion of the pleura. The contraction of the abnormal fibrous tissue leads to marked displacement of the heart and mediastinum.

The localised form is commonly due to healed tuberculous processes at an apex. There may be simple puckering with or without pleural thickening and adhesion, or a dense mass enclosing dried-up caseous matter or calcareous spicules. In bronchitic or broncho-pneumonic processes a patchy fibrosis may occur, described as insular fibrosis by Fowler.

Peribronchial fibrosis is common and figures largely in X-ray reports on pulmonary cases. It is generally assumed that this is a sequel of tuberculous lesions acquired in early life. Although this is probably correct, it has not been incontrovertibly established.

Reticular fibrosis is a rare condition in which the fibrous tissue in the interlobular septa seems to become increased as well as that around the bronchi. It is at present only of pathological interest.

Symptoms.—The symptoms of pulmonary fibrosis are, in the main, expectoration and dyspnoea together with those of the primary affection. In the non-tuberculous cases, bronchiectasis is so frequently associated that the symptoms and signs found are practically those of this condition. Even in tuberculous cases, some degree of bronchial dilatation is the rule, although the sputum is rarely offensive. The cough is generally periodic and associated with change of posture. The expectoration is abundant, and if bronchiectasis is present, it has the usual characteristic features. The dyspnoea is proportional to the extent of lung involved. It may be extreme in the later stages, when the heart becomes embarrassed and begins to fail. Fever is usually absent, except when complications occur.

The patients are generally spare, although nutrition may sometimes be well maintained until late. They may show signs of deficient aeration in duskiness, cyanosis and congested cheeks. Polycythæmia of some degree is the rule. Clubbing of the fingers is almost constant. Evidence of contraction is generally forthcoming in the flattening and retraction of the affected side, with the dropped shoulder and compensatory spinal curvature. Movement is greatly restricted, contrasting with the increased expansion of the other side. The cardiac impulse is sometimes much displaced, especially in left-sided cases, when it may be in the left posterior axillary line or even under the angle of the scapula. In right-sided cases, it is drawn to the right of the sternum, even sometimes under or outside the right nipple. Vocal fremitus is usually diminished and percussion gives dullness of varying degree over the fibroid area, while the unaffected parts may be hyper-resonant from "compensatory" emphysema. The diaphragm may be drawn up, and the liver or stomach correspondingly displaced. The breath-sounds are often weak or inaudible unless there is bronchiectasis or cavitation, when the characteristic signs of these conditions can be

recognised. The vocal resonance is diminished if there is much pleural thickening, increased if cavities are present. Adventitious sounds may be entirely absent, and when present vary from rhonchi and bubbling râles to coarse metallic râles, according to the presence or absence of excavation. X-ray examination gives useful confirmation, showing displacement, excavation and pleural thickening.

Course.—The course is invariably chronic, and may extend to years, even ten or twenty.

Diagnosis.—The diagnosis is usually easy. The evidence of contraction and of mediastinal displacement towards the affected side, especially if signs of cavitation are also present, is highly suggestive. In the absence of the latter some difficulty may arise in regard to chronic pleural effusion or empyema. In the earlier stages the contra-lateral displacement of the cardiac impulse should prevent any mistake, but where partial absorption has occurred, this may be very slight or absent. In such cases an exploratory puncture or an X-ray examination may be helpful.

When the diagnosis of pulmonary fibrosis has been made, the differentiation of the cause is an essential to prognosis and treatment. If the condition is apical, there is a presumption in favour of tuberculosis; if basilar, some other cause is more probable. Repeated examinations of the sputum should be made for tubercle bacilli, and if these prove negative, X-ray examination may reveal some cause such as new-growth, aneurysm or even foreign body. In some cases a careful consideration of the history may afford a clue to the diagnosis.

Prognosis and Treatment.—These depend upon the primary condition, but in most cases the latter is mainly symptomatic.

PNEUMOKONIOSIS

Synonyms.—Pneumonokoniosis; Dust Disease of the Lung.

Definition.—Pneumokoniosis comprises all the pathological changes induced in the bronchi, lungs and pleura by the inhalation of dust particles.

Ætiology.—*Predisposing causes.*—Pneumokoniosis is one of the occupational diseases. It is practically limited to men, and usually develops between the ages of 25 and 40. Defective ventilation, bad hygienic conditions and alcoholism promote its incidence.

Exciting causes.—Various forms of dust, both inorganic and organic, serve to produce pneumokoniosis, and in general the harder and more gritty the particles, the more marked are the changes induced. Organic forms of dust lead especially to bronchitic changes, the inorganic forms to pulmonary fibrosis.

The following varieties are recognised:

1. *Anthracosis*, from coal dust (coal-miners' phthisis).
2. *Siderosis*, from the inhalation of fine metallic particles in tin, copper lead and iron-miners, and in grinders of steel goods (grinders' rot).
3. *Silicosis* or *chalicosis*, met with in workers in quartz, gannister and slate quarries, also in potters (quartz-miners' phthisis, and potters' asthma). Gold-miners' phthisis, the most serious form of pneumokoniosis, and especially prevalent in the South African gold mines, is due to the fine dust caused by the rock drills.

4. *Byssinosis*, a rare variety is met with in cotton workers, felt-hat makers, and the employees in shoddy mills.

5. *Asbestosis*.—A condition found occasionally in those working in the manufacture of asbestos articles.

Pathology.—The lungs of persons living under rural conditions are practically free from deposited pigment. A certain amount of carbon is invariably present in the lungs of town-dwellers, giving them a dark-grey mottled appearance, but producing no pulmonary fibrosis. In coal-miners this occurs to such an extent that the lungs are black (anthracosis), although even here little fibrosis occurs, except in miners of hard coal or anthracite. In siderosis and silicosis, fine sharp particles of metallic oxides or silica are deposited in the lung tissue. In asbestosis, iron-containing granules with discoid bodies, possibly asbestos fibres, are found in the lungs. There is also much fibrosis, and tuberculosis is liable to be a later development.

It is generally accepted that these particles are conveyed to the bronchi and alveoli by inhalation. It has been suggested by Calmette and others that they are swallowed and reach the lungs through the mesenteric and bronchial glands. It is admitted that particles can reach the lungs by this route under experimental conditions, but this factor is certainly of small importance in the genesis of pneumokoniosis. In normal breathing, most of the coarse particles are detained in the nose, and are discharged with the nasal mucus, whereas in mouth-breathers they readily gain access to the trachea and bronchi. Even then, the coarser particles may be discharged in the expectoration through the agency of the ciliated epithelium, but owing to the catarrhal processes induced by the irritation of the inhaled dust, this epithelium may be desquamated and the absorption of the particles is promoted. As a further consequence of this initial bronchitis, the finer particles may reach the alveoli, and passing between the epithelial cells, gain access to the tissue spaces, or in some cases they may be taken up into special "dust cells." Later, particles of dust become deposited in the connective tissue, and chronic peribronchial and perialveolar fibrosis develops. The bronchial glands also become enlarged and pigmented by the deposition of similar particles conveyed by the lymphatics. Other changes more or less constantly present are emphysema, pleural adhesion and bronchiectasis.

The relationship to tuberculosis has been much debated. It is now established that pneumokoniosis is non-tuberculous in origin, and that it may remain so throughout its course. On the other hand, certain forms undoubtedly favour the development of tuberculosis. In England and Wales coal-miners suffer less from tuberculosis than do all other males. On the other hand, gold-miners are extremely liable to it. It would appear that the determining factor is the presence of particles of silica. Silicates, as in clay, do not induce tuberculosis. Workers in freestone develop this disease, limestone workers do not. Slate quarriers do not acquire tuberculosis very readily, while metalliferous miners working in quartzite very frequently suffer from it. Mavrogordato describes three types of silicosis. (1) Silicosis, the damage found being due to dust alone. It is non-progressive if exposure ceases. (2) Tuberculo-silicosis, in which most of the damage is due to dust and tuberculosis is secondary. (3) Silico-tuberculosis, in which the chief lesions are due to the tubercle bacillus and the silicosis is

secondary or at any rate less marked. Haldane and Mavrogordato have demonstrated that particles of coal are absorbed by the "dust cells" whose movements are thereby stimulated, with the result that they appear in the black spit, which is therefore a healthy sign. The particles of silica are also absorbed by these "dust cells," but no stimulus to their movement is induced and they remain *in situ*.

Post mortem, the lungs are generally firm and pigmented, the colour varying with the cause, being black in anthracosis, reddish-brown in siderosis, and greyish-black in silicosis. The pleura is generally adherent, especially at the bases. On section the lungs are firm and often gritty. Small hard nodules may be felt with the finger. Fibroid changes are especially marked in silicosis. The bronchi are inflamed and sometimes dilated. Some degree of emphysema is usually apparent. If tuberculous lesions are also present, these vary from fibroid areas to miliary nodules. Destructive processes resulting in cavitation may also be seen. Microscopically, the alveolar walls are thickened, the connective tissue is everywhere found to be increased, the "dust cells" may be seen in the connective tissue or in the alveoli, and particles of pigment or silica are found widely deposited in the connective tissue cells.

Symptoms.—The onset is insidious, bronchial irritation and cough, especially in the morning, may be the first indications, but increasing shortness of breath and debility are frequently early symptoms. The expectoration, at first scanty and mucoid, becomes more abundant and may present characteristic features as in the "black spit" of anthracosis. Tinging of the sputum and later hæmoptysis occur, but these suggest the possibility of superadded tuberculosis. The patient may appear healthy and be but little troubled except by the shortness of breath, but later emaciation and an appearance of premature old age are not uncommon.

The physical signs are not characteristic; at first they are simply those of persistent bronchitis, then emphysematous changes may become apparent. Later, signs of fibrosis appear, very similar to those described in the preceding section. Even when tuberculosis develops the signs are often but little characteristic, and repeated sputum tests may be necessary to establish the diagnosis. Examination by X-rays may be helpful, showing mottling of the lung by sharply defined shadows.

Complications and Sequelæ.—The most important complication is tuberculosis, which forms the terminal stage of many cases of silicosis. This may be suspected when fever, night sweats, hæmoptysis or emaciation develop. Bronchiectasis of considerable degree sometimes results as a consequence of the fibrosis, and leads to the symptoms and signs characteristic of that condition.

Course.—This is progressive, unless the sufferer is removed from the exciting causes. Anthracosis runs a very chronic course, siderosis somewhat less so, while gold miners only live a few years (5 to 6—Oliver) after the onset of the disease.

Diagnosis.—The diagnosis can usually be made from the history of shortness of breath, cough and expectoration, developing in a worker in a dusty occupation. In the early stages, cigarette smoker's cough and bronchitis may give rise to difficulty. In the later stages, the possibility of a primary fibroid tuberculosis has to be considered.

Prognosis.—This is unfavourable except in anthracosis. If recognised early, and if the patient is taken from the dusty conditions, recovery may be anticipated. The development of tuberculosis affects the outlook very gravely.

Treatment.—*Prophylactic.*—Every means should be adopted to avoid the dusty conditions leading to the disease. Mines should be well ventilated, and respirators should be worn where practicable in dusty occupations. Factories and workshops should be provided with apparatus to draw away dust. Sprays or jets should be used with drills to moisten the dust produced.

Curative.—Directly the condition is diagnosed, the patient should be advised to change his occupation. Nutrition should be kept at a satisfactory level. Symptoms and associated conditions, such as bronchitis or tuberculosis, should be treated on general principles.

PULMONARY TUBERCULOSIS

Synonyms.—Phthisis ; Consumption ; Decline.

Pulmonary tuberculosis embraces all the abnormal conditions induced by infection of the lungs, pleuræ and bronchial glands with the tubercle bacillus.

Ætiology.—**PREDISPOSING CAUSES.**—**Age.**—The maximum age incidence is between the 15th and 45th years, although the disease may be encountered at any age.

Sex.—The disease is more frequent in males, but between the ages of 5 and 15 the female sex shows a preponderance.

Heredity.—Pulmonary tuberculosis certainly occurs with undue frequency in certain families. Since the direct transmission of the tubercle bacillus to the infant is extremely rare, two explanations seem possible—(1) Children born of tuberculous stock may inherit an increased susceptibility or diminished resistance, the tuberculous diathesis; or (2) they may contract tuberculosis on account of their exposure to massive infection in early life.

Race.—Differences in racial susceptibility probably depend upon the degree of inherited resistance acquired by the race from infection of previous generations. Native races suffer severely when first exposed. In Europe the Irish are particularly susceptible, whereas the Jews are relatively immune.

Climate.—Tuberculosis occurs in all climates. The prevalence of strong rainy winds and defective subsoil drainage may tend to increase its incidence.

Occupation.—The highest mortality from tuberculosis occurs in England amongst the workers in dusty occupations, thus Cornish tin miners head the list. On the other hand, coal miners are notably free from the disease. Any conditions leading to overwork or to underfeeding increase the liability to tuberculosis.

Environment.—Overcrowding, defective sanitation, dampness, dirt, lack of sunlight and insufficient ventilation are most potent factors in the spread of the disease, causing both lowering of the resistance and increased facilities for direct infection.

Trauma.—Trauma, involving the chest-wall, may be followed by active pulmonary tuberculosis. This is probably because the injury leads to activity of previously arrested disease, rather than to fresh infection at a spot of lowered resistance.

Gassing.—In certain cases the inhalation of poison gases causes rapid activity and spread in latent disease, or it may possibly prepare the ground for reinfection, but it is not a factor of great ætiological importance.

The influence of other diseases and conditions.—The following diseases predispose to the development of pulmonary tuberculosis: measles, especially when complicated by broncho-pneumonia, whooping-cough, influenza, pneumokoniosis, alcoholism, diabetes, syphilis, congenital heart disease and insanity. Tuberculosis may manifest itself for the first time during prolonged lactation or after repeated pregnancies; when previously existent it often remains quiescent during pregnancy, but it may spread rapidly after childbirth. Contrary to the usual belief, pulmonary tuberculosis not infrequently coexists with mitral stenosis. A partial antagonism between tuberculosis, asthma, emphysema and gout has been assumed. Cases apparently following pneumonia, pleurisy or bronchitis are usually tuberculous from the onset.

EXCITING CAUSES.—The causal organism is the *Bacillus tuberculosis*, discovered by Koch in 1882. It exists in four main forms, human, bovine, avian and reptilian; only the two former usually occur in man, but avian infection has been recorded. The human type is found in over 99 per cent. of pulmonary tuberculous lesions. In surgical tuberculosis, on the other hand, and in glandular tuberculosis up to the age of 5 years, nearly 80 per cent. of the bacilli isolated conform to the bovine variety.

The bacilli may gain access to the body by inhalation, by alimentary ingestion, through the tonsils, through the skin, or possibly, in rare instances, by hereditary transmission. It is probable that in the majority of cases of pulmonary tuberculosis in adults, the organisms are carried direct to the lungs in the inspired air, and Ghon showed that in children, who had died of tuberculosis of the lungs, a primary focus was present in the lungs in 92.4 per cent. As, however, extensive tuberculous lesions are frequently found in the bronchial glands in cases of pulmonary tuberculosis, it is believed by some that the glands are primarily affected, and that the bacilli pass from them to the lungs, either against the lymphatic flow or in the blood stream. Calmette and others have demonstrated that the bacilli may gain access to the bronchial glands from the alimentary tract through the lymphatic duct, or from the tonsils through the cervical and mediastinal glands. Cases have been recorded in which primary cutaneous infections have been followed later by active pulmonary tuberculosis. Direct transmission of the tubercle bacillus is believed to occur only when the mother is suffering from advanced tuberculosis, and even then is of great rarity.

The incubation period of tuberculosis is uncertain, owing to the difficulty in determining when infection takes place. It is now believed by many authorities that the majority of individuals are originally infected in infancy or early childhood, either from the ingestion of tuberculous milk, or by the inhalation of bacilli from dried sputum. Pulmonary tuberculosis is thus regarded as a late manifestation comparable with the tertiary stage of syphilis. On this hypothesis, active pulmonary disease in adult life may result either

from reinfection or from the activation of a dormant lesion in the body. As the organisms found in early life are frequently of the bovine type, whereas in pulmonary tuberculosis they are almost invariably of the human variety, it is probable that reinfection is the more common, since mutation of type has not so far been proved.

Provided that the proper precautions are taken, the risk of infection from person to person is not great, and only exists in "open" cases of tuberculosis, i.e., in cases with tubercle bacilli in the sputum. There is no increased incidence in workers in hospitals or sanatoria for consumptives, and the occurrence of conjugal disease can be as well explained by mating of those with hereditary diathesis, as by direct infection.

Pathology.—The earliest lesion in the lung is the formation of tubercles, whose structure is described in the general article on tuberculosis. They appear first near the apex. This may be due to the relative immobility of this portion of the lung, possibly as the result of calcification of the first costal cartilage (Freund), but in some cases the bacilli may spread from the cervical to the supraclavicular glands and thence to the adjacent lung. The initial deposit is usually in or around the small bronchioles of the third to fifth degree (Hirschfeld's bronchioles). The inflammatory swelling of the bronchioles obstructs their lumen, leading to collapse of the alveoli beyond and the formation of broncho-pneumonic areas. At the same time peri-bronchiolar inflammation develops.

SECONDARY CHANGES.—1. *Caseation.*—The tubercle is avascular, and owing to this, and possibly also to the action of tubercle toxins, coagulation necrosis and fatty degeneration frequently ensue. This combined process is known as caseation and results in the formation of a structureless, cheesy mass. Further changes may now occur, either softening, with the development of a "cold abscess" filled with tuberculous "pus," or calcification, with the subsequent formation of gritty masses known as "pneumoliths."

2. *Cavitation.*—Cavities result from the liquefaction of caseous areas, and the expectoration of the resulting debris. They may be no larger than a pea, or may occupy the whole of one or more lobes. A recent cavity has an irregular outline, with rough, shaggy walls and a vascular line of demarcation. It is often traversed by trabeculae, formed by bronchi and vessels which may be partly or completely obliterated, while sometimes the trabeculae consist of condensed lung tissue which originally separated adjacent cavities. In chronic cases, the cavity is surrounded by fibrosed lung tissue forming a pseudo-capsule, and its interior becomes lined by a thin, smooth, false membrane. Small aneurysms may be found, arising either from vessels running in the walls or in the trabeculae of the cavity, the former being the more common. In some cases, where hæmoptysis has occurred, rupture of such an aneurysm is the cause.

3. *Fibrosis.*—Reactive changes in the lung stroma lead to the formation of fibrous tissue. This may occur early or after caseation has taken place.

In the majority of deaths from all causes, old tuberculous lesions are found post mortem near the apex of one lung. These consist of small nodules of arrested disease, with thickening and dimpling of the adjacent pleura.

DISSEMINATION IN THE LUNGS.—The disease may spread from the primary peri-bronchial deposit—(a) By direct infiltration: (b) By the peri-bronchial

lymphatics and capillaries, leading to a racemose appearance or to peribronchial fibrosis; (c) By the subpleural and interstitial lymphatics, with localised miliary dissemination; (d) By inhalation into a bronchus of tuberculous material, which is then carried to other parts of the same or to the opposite lung—this not infrequently happens after hæmoptysis; (e) By the blood vessels, *e.g.* generalised miliary tuberculosis may result from erosion of a caseous tubercle into a vein.

The pathology of the clinically distinguishable forms of pulmonary tuberculosis will now be described.

1. ACUTE MILIARY TUBERCULOSIS.—A primary caseous focus may be discovered at the apex of one lung, in the bronchial glands, or at some distant spot in the body. Local erosion of a vein may be found, accounting for the dissemination of the disease. The lungs are usually studded with minute grey tubercles, the smaller ones requiring a hand lens for their recognition. In very acute cases death occurs before any secondary broncho-pneumonic changes take place. Miliary tuberculosis may develop as a terminal event in chronic fibro-caseous or fibroid tuberculosis. The tubercles are then found in large numbers around the old foci of disease, but to a less extent in the more remote portions of the lung.

2. ACUTE CASEOUS TUBERCULOSIS.—Large areas of consolidation form rapidly, which differ histologically from the common chronic tuberculous broncho-pneumonia in that the alveolar exudate is more definitely inflammatory and contains fibrin. In the rare lobar cases, the rapid caseation and the presence of tubercle bacilli show that the caseous pneumonia is a specific process. Firm yellowish patches, which may be confluent, are seen, usually scattered throughout both lungs. The affected areas are airless and sink in water. Softening is generally present in varying forms up to actual cavity formation, which may be extensive, involving even a whole lobe.

3. FIBRO-CASEOUS TUBERCULOSIS.—This is the commonest variety of the disease; the appearances of the lung vary with the relative preponderance of the caseous and fibrotic changes. The early lesions are miliary or broncho-pneumonic, but areas of caseation in varying stages are always present. The older lesions show considerable fibrosis, the strands of sclerotic tissue being pigmented and glistening. The earliest lesion is usually near the apex of the upper lobe at the back, more rarely a little lower and towards the front. The apex of the lower lobe is next affected, and the disease then spreads in the direction of the interlobar septum. The apex of the upper lobe of the opposite lung is next involved (Fowler's law of spread). Pleural adhesions are usually present over the oldest lesions, and in the interlobar fissures.

4. FIBROID TUBERCULOSIS.—Fibrosis may be localised around a small arrested lesion, or may spread throughout a lung in which caseation or excavation has occurred. One lobe or the whole lung is then contracted and firm. In the interstices of the fibrous tissue, which is usually pigmented, inspissated caseous material, calcareous patches, or cavities are seen. The shrinkage may lead to bronchiectasis, especially in the lower lobes. The overlying pleura is much thickened and adherent, and the mediastinum is drawn over towards the affected side. The opposite lung, or the sound portions of the fibrosed one, may show compensatory emphysema.

The bronchial glands.—The tracheo-bronchial glands are affected in all forms of pulmonary tuberculosis. They are enlarged, sometimes pigmented,

and may present miliary, caseous, calcareous or fibroid changes, in some cases primary, in others secondary to the lesions in the lungs.

The pleura.—This, too, is almost constantly affected. The commonest changes are an early dry pleurisy, and a later thickening with adhesions which may completely unite the visceral with the parietal layers. In acute disease or active spread, the pleura may be studded with miliary tubercles, leading to a large serous effusion.

The post-mortem appearances of the lesions situated in the other organs, found as complications of pulmonary tuberculosis, are described in the respective sections dealing with them, and include tuberculous meningitis, peritonitis, enteritis and genito-urinary tuberculosis. There is usually atrophy of the skeletal muscles, sometimes lardaceous and fatty degeneration of the liver, and hypoplasia with fatty degeneration of the heart.

Symptoms.—The symptoms fall into three groups (Pottenger)—(1) pulmonary, as catarrh, expectoration, hæmoptysis and pleurisy; (2) reflex, such as pain, cough and laryngeal irritability; (3) toxæmic, including malaise, tachycardia, pyrexia and loss of weight.

ONSET.—The mode of onset is very variable, but certain forms can be recognised.

(a) *Insidious.*—The early symptoms may be malaise, anæmia, amenorrhœa, cardiac irritability, progressive loss of weight, and slight rise of temperature, generally towards evening. Cough and expectoration often appear only when the signs in the chest are quite apparent. When there is intestinal stasis, the cutaneous pigmentation may suggest the diagnosis of Addison's disease.

(b) *Catarrhal.*—A series of febrile "colds" may usher in the disease, and such a sequence is always suspicious.

(c) *Phthisis ab hæmoptoe.*—Hæmoptysis may first draw attention to the lungs. It may be slight, and is then due to early congestion around the focus of infection. If it is more marked, it indicates breakdown of an old arrested lesion, or may afford dramatic evidence of extensive disease which had not been recognised previously.

(d) *Laryngeal.*—Hoarseness or aphonia may be the first symptom, but laryngeal tuberculosis is usually secondary to pulmonary disease, although the latter may have been unsuspected.

(e) *Gastro-intestinal.*—Anorexia and flatulence often occur early. When they are accompanied by slight loss of weight and pyrexia, the possibility of pulmonary tuberculosis should be suspected.

(f) *Pleural.*—Dry pleurisy is a frequent manifestation of latent pulmonary tuberculosis. When a serous effusion develops, its tuberculous character can be determined by laboratory investigations. Pneumothorax, developing in a previously healthy individual, is a rare but serious clinical mode of onset.

(g) *Pneumonic.*—"Galloping" consumption often begins with pneumonic manifestations, especially in the young.

(h) *Traumatic.*—Pulmonary tuberculosis may follow injury or "gassing," as described under ætiology.

(i) *Neurasthenic.*—Neurasthenia may occur as a complication of tuberculosis; but in some cases an initial neurasthenia dominates the picture, and the pulmonary lesion is only detected on careful examination.

(j) *Malarial.*—Regular attacks of sweating and fever may occur, especi-

ally in those who are or who have been residing in malarial climates, suggesting malaria, but in reality due to tuberculosis.

(k) *Associated with other diseases.*—Tuberculosis may follow immediately on an attack of measles, influenza or whooping-cough, especially if complicated by broncho-pneumonia. In some cases it develops at a later period after the acute disease.

THE CHIEF SYMPTOMS of pulmonary tuberculosis are—

Cough.—This varies considerably in different types of disease. It may be very slight or absent in generalised miliary tuberculosis, or in any form in the insane. It is sometimes dry, persistent and ineffective, especially in miliary extension in the lungs from an old focus of disease, in bronchial gland tuberculosis, or in pleurisy. When there is associated bronchitis or caseation, the cough is usually accompanied by expectoration, which, if very tenacious, may lead to retching or even to vomiting, particularly in the morning. In laryngeal tuberculosis the cough is husky and frequently painful.

Expectoration.—In early disease there is usually no sputum, and in some cases, more especially in the fibroid type, widespread lesions may be present with practically no expectoration. When caseation is in progress, or when there is secondary infection with bronchitis, the sputum may be abundant and amount to as much as 20 or more ounces in the 24 hours. It may be clear or mucoid, or thick tenacious muco-pus. If mucoid, it often contains small particles, the size of a pin's head or larger, of yellow caseous material. Nummular sputum may be met with in active caseous disease, especially with excavation. This consists of flat rounded masses of muco-pus, with a somewhat distant resemblance to coins. In tuberculosis the sputum is usually inoffensive, but may have the characteristic sickly odour which is also noticed to emanate from the patient himself (odor phthisicus). If bronchiectasis or gangrene occur as a complication, the expectoration becomes typically malodorous. Pulmonary calculi or pneumoliths, composed chiefly of calcium carbonate or phosphate, are sometimes expectorated. They vary in size from a pin's head to a pea, are irregular in outline and sometimes branched, being derived generally from the walls of a cavity. Although the occurrence of these does not necessarily indicate fresh activity in the lungs, yet such a possibility should always be suspected, and a careful watch maintained on the temperature during the next few days. In some cases larger pneumoliths, as big as a cherry, may be coughed up, and these are frequently derived from caseous tracheo-bronchial glands. They may give rise to alarming symptoms at once, and be the forerunner of fresh activity in the lungs.

The albumin reaction.—The significance of albumin in the sputum has been investigated by Ridge and Treadgold. It is found in nearly all cases of active pulmonary tuberculosis, and in the absence of tubercle bacilli, three consecutive negative albumin tests are strong evidence against the presence of active disease. Albumin, however, also occurs in the sputum in other destructive lesions of the lungs.

Microscopical examination.—The presence of tubercle bacilli in the sputum is the most decisive test of the existence of this disease. The small yellowish caseous particles should be selected from the sputum, and appropriately stained. If no tubercle bacilli are found, samples from the whole sputum of the 24 hours, concentrated by the antiformin method, can be ex-

aminated. The cells present are usually of the mononuclear type, either mononuclear leucocytes or altered alveolar epithelial cells. The presence of elastic tissue indicates that destructive pulmonary lesions are in progress. Secondary infecting organisms may be demonstrated by cultural methods.

Dyspnœa.—Slight dyspnœa occurring early in the disease may be due to diminished movement of the diaphragm on the affected side. In more advanced cases the degree of dyspnœa is proportional to the amount of lung tissue involved. In addition, cough and pyrexia play a part in its production. Complications such as pleurisy, pleural effusion, pneumothorax and cardiac failure increase the shortness of breath. It is rare to find orthopnœa even in acute and rapidly spreading disease. In arrested cases the dyspnœa is proportional to the extent of fibrosis.

Cyanosis.—This is not an early symptom of tuberculosis. It is dependent upon the amount of lung tissue involved, but is increased by the coexistence of emphysema or cardiac failure. The typical " hectic flush " of tuberculosis is a vasomotor effect caused by toxæmia.

Pain.—Not every sufferer from tuberculosis experiences pain, even in the acute stages of the disease. The commonest cause of pain is dry pleurisy. When the diaphragmatic layer of the pleura is affected, pain may be referred to the epigastrium or to the corresponding shoulder. In chronic fibroid phthisis there is frequently a dull, aching pain in the chest, which is more noticeable in damp weather. This is caused by the contraction of the condensing fibrous tissue. Cutaneous tenderness of the chest-wall is met with in some cases of advanced disease, and is probably due to a cachectic neuritis. A " cold abscess " forming along one of the ribs or costal cartilages is a rare cause of localised pain in the chest-wall. Cough may be painful, especially when paroxysmal or frequent, the pain being referred to the costal attachments of the diaphragm and upper abdominal muscles. The sudden occurrence of pneumothorax may cause such severe pain as to induce collapse; but when of more gradual onset no severe discomfort may be experienced. Tuberculous laryngitis may be the cause of very great suffering.

Night sweats.—Although not pathognomonic, night sweats occur more frequently in tuberculosis than in other diseases. They are met with in all stages of active lesions, and may be of great severity.

Loss of weight.—This is often an early symptom. It is most marked in acute disease and in the late stages of chronic fibro-caseous tuberculosis.

Fever.—Pyrexia is one of the most important indications of activity at any stage of pulmonary tuberculosis, although it does not follow that the disease is arrested when there is no fever. During treatment the temperature should be recorded at certain definite hours in the day. (a) On waking. The normal mouth temperature at 7 or 8 a.m. is 97° or 98° F. in the mouth, and 97°·2 to 99° F. in the rectum. This temperature should be taken in bed, before eating or drinking. (b) At 1 p.m., after the hour's recumbent rest. (c) At 6 p.m. (d) At 9 p.m., after retiring to bed. The maximum temperature is usually reached between 4 and 6 p.m., but may be delayed to 8 or 9 p.m. In most sanatoria the rectal temperature is taken, and a centigrade thermometer employed. The temperature is dependent upon the extent and the activity of the disease, and upon the amount of exercise taken.

(a) In acute miliary tuberculosis.—It may be continuous or remittent, and

the "typhus inversus" is not uncommon, the morning temperature being higher than the evening. This is generally regarded as a sign of grave prognosis.

(b) In acute caseous tuberculosis the high temperature at the onset is continuous, and the record resembles a pneumonic chart. When caseation occurs it becomes hectic or intermittent, with a daily swing of 4° or 5° F. This is probably due to the action of tubercle toxins, and not to the presence of a secondary infection.

(c) In chronic fibro-caseous tuberculosis there is no characteristic temperature record. There may be only a very slight rise occurring at intervals of a few days. On the other hand, the patient may be afebrile while resting, but febrile when ambulant (Stage 2. Inman's classification). Further an afebrile ambulant patient may over-exert himself, and by excessive auto-inoculation develop a sharp rise of temperature which subsides in a few days with rest. The temperature chart is thus a guide to prognosis and to treatment, and if acute miliary tuberculosis or caseation occurs, a typical temperature variation ensues.

(d) In fibroid tuberculosis the temperature is usually normal, unless excessive auto-inoculation results from exercise, or the disease advances. The occurrence of hæmoptysis may have a very definite effect upon the temperature. In some cases it is not followed by pyrexia, but if the inhaled blood leads to a hæmoptöic bronchitis, there may be a slight degree of fever lasting for a few days. When a definite and persistent pyrexia follows, it usually indicates activity around an old focus of disease, or fresh spread by inhalation of blood containing tubercle bacilli to a distant portion of the lung.

A premenstrual rise of temperature may occur; but as it is also met with in healthy women it is not pathognomonic.

Hæmoptysis.—Hæmoptysis occurs at some stage of pulmonary tuberculosis in about 50 per cent. of all cases. With early lesions the sputum is only streaked. This may result from the congestion of tuberculous bronchitis, or from a small area of collapse or broncho-pneumonia. In the pneumonic or broncho-pneumonic forms rusty sputum may be seen. Profuse hæmoptysis generally occurs in chronic disease; but it is occasionally met with in acute caseous forms. Recovery may take place after coughing up 2 or 3 pints, or death may ensue rapidly from suffocation before any considerable quantity of blood has been expectorated. After the cessation of bleeding the sputum may be coloured for several days. The source of profuse hæmoptysis is generally an aneurysm of a branch of the pulmonary artery lying in a cavity or in fibroid lung, although occasionally ulceration without previous aneurysm formation may occur. In the majority of cases hæmoptysis begins while the patient is lying down or resting, so that exercise or work are not frequent exciting causes.

The patient notices a salt taste, feels a warm gush in the mouth, and then expectorates the blood. He is usually greatly alarmed, flushed and sweating, with rapidly beating heart. The blood at first is as a rule bright and frothy, but some clots may be present; later it is mixed with muco-purulent expectoration, in the form of clots or streaks.

Circulatory system.—The heart may be small, but the right side often hypertrophies in chronic fibroid cases. Tachycardia may be due to nervousness, but when constant it generally indicates active disease or over-exertion on the part of the patient. The blood-pressure is usually low in the stages

of activity, and a steady rise during treatment is a favourable sign. If tuberculosis is coexistent with other diseases, such as atheroma, which raise the blood-pressure, higher readings are naturally obtained.

The blood.—The red cells are usually normal in number, but there may be a slight anæmia. On the other hand, when there is much cyanosis, or after sanatorium treatment, the red cells may be increased. The colour index is usually low. In the early stages the leucocytes may be slightly increased. A polymorpho-nuclear leucocytosis occurs in caseation and in early cavity formation, and at times with secondary infection of the lungs. A special differential count of the polymorpho-nuclear leucocytes themselves may be made by subdividing them into groups, according to the number of their nuclear lobes, as suggested by Arneth. An increase in number of immature cells with only one or two nuclear lobes constitutes a deviation to the left from the normal, and raises the Arneth index. This lævo-deviation is said to indicate toxæmia, and if it is not present, the disease will probably be chronic.

Alimentary system.—The tongue is usually clean and the appetite good even in cases with marked fever. When tuberculosis of the larynx is present, there is frequently severe dysphagia. Dyspepsia may be complained of, usually of a nervous type. Anorexia, flatulence, distension with nausea are the commonest symptoms, pain being rarely noticed. There may be marked intolerance of fat in the diet. The early hyperchlorhydria in tuberculosis, previously described, has not been confirmed by Mohler and Funk in America, using the fractional method of gastric analysis. Atonic dilatation of the stomach may occur in some cases towards the end of the disease. Constipation is common; on the other hand, diarrhœa may occur apart from intestinal ulceration or lardaceous disease.

Nervous system.—The classical “*spes phthisica*” is distinctly rare, but when present is very striking from its contrast with the realities of the disease. It is most commonly seen in acute caseous tuberculosis. More often the patient becomes emotional and self-centred, depression is common and hard to combat, and melancholia with delusions occasionally develops. Neurasthenia is frequent, and as mentioned above, may lead to errors in early diagnosis. Insomnia may be due to cough, pyrexia, night sweats or pain, especially in laryngitis. With marked cachexia, a definite peripheral neuritis may occur.

Genito-urinary system.—In the early stages there is often an increased sexual desire, and this may recur when arrest is taking place. This is probably in part due to the therapeutic régime, the rest, abundant food and lack of interesting occupation reacting upon the nervous system of young adults. In advanced disease, all sexual desire is lost. Menstruation often ceases early, and the patient may seek advice for amenorrhœa. Women remain fertile even in advanced disease. The urine is normal in the early stages, later a febrile albuminuria may occur, and casts or even sugar may be excreted without the occurrence of true nephritis or diabetes.

THE PHYSICAL SIGNS OF EARLY DISEASE.—The general appearance of the patient may be healthy, or may be that of malnutrition with the characteristics of the “*habitus phthisicus*,” the hair being lank and lustreless, the skin white, thin, dry and shiny, and the thorax of the alar or phthinoid type. Certain stigmata are described, which although useful, are not pathognomonic. The eyelashes may be long, dark and curling, the

back hairy and the thoracic cutaneous venules dilated. When present around the upper thoracic vertebral spines, they are sometimes known as "the varicose zone of alarm." Deficient movement may be observed below one clavicle, at the point of one shoulder, or at the lower costal margin. The corresponding shoulder may be slightly drooping, with flattening above or below the clavicle, and slight hollowing of the supra-spinous fossa with wasting of the trapezius muscle may be observed. Pottenger regards these shoulder signs, when not due to scoliosis or kypho-scoliosis, as reflex, and comparable with the fixation of a tuberculous joint and wasting of its adjacent muscles. In women it may be noticed that the breast on the affected side is smaller and hangs at a lower level, although a non-tuberculous mastitis is sometimes seen causing enlargement, especially in males.

Palpation confirms the diminished expansion, and reveals a slight increase of vocal fremitus over the affected area of the lung, usually at one apex. The normal increase in fremitus of the right apex over the left must be borne in mind, in order to prevent mistakes.

With light percussion slight dullness and a small increase in the sense of resistance can be detected. This is usually most apparent in the supra-spinous and upper interscapular regions. The extent of pulmonary resonance above the clavicle, known as "Krönig's isthmus," may be diminished by $\frac{1}{2}$ to 1 inch on the affected side.

Various types of breath-sounds may be heard over the affected portion of lung. They are—(a) weak inspiration, with expiration vesicular or inaudible; (b) cog-wheel inspiration, with expiration vesicular, prolonged or rarely jerky; (c) the "granular" breathing of Grancher, the breath-sounds being somewhat coarse and irregular, suggesting fine or distant râles, although none can be definitely detected; (d) harsh inspiration, with expiration vesicular or prolonged; (e) broncho-vesicular breathing; (f) definitely bronchial when early consolidation is in progress.

Often there are no adventitious sounds. Occasionally a few small rhonchi or fine crackling or bubbling râles may be heard with the first few deep breaths, or only with the inspiration immediately following coughing. If râles are constantly heard, it indicates that the lesion is already of some extent. Care must be taken to differentiate them from atelectatic râles, emphysematous râles audible along the sternal margin, and pleural friction or fascial creaks. There is usually a slight increase in the conduction of both the spoken and whispered voice, and the more definitely this extends away from the trachea in front, and from the vertebral spines behind, the more reliable is the sign as an indication of disease.

Mensuration is seldom practised in routine examination, but graphic records of the chest contour, which are of interest in following the progress of a case, can be obtained by cyrtometry.

THE PHYSICAL SIGNS OF CONSOLIDATION.—Limitation of movement and flattening over the affected part of the lung, usually the apex, is now more noticeable.

The diminution of movement is confirmed on palpation, and vocal fremitus is found to be definitely increased.

The pulmonary resonance is diminished to definite dullness and the sense of resistance is correspondingly increased.

The breath-sounds are bronchial, or in acute caseous disease may even approximate to tubular.

Adventitious sounds may be absent, but usually fine or medium crackling râles are heard with inspiration, especially after coughing. When active softening is in progress the râles frequently become coarse and sticky. The voice conduction is much increased, bronchophony and whispering pectoriloquy being audible.

Mensuration may confirm the presence of flattening.

THE PHYSICAL SIGNS OF EXCAVATION.—Flattening of the chest-wall and diminished movement over the cavity are now more marked; if the cavity is apical there is in addition notable dropping of the shoulder, and wasting of the shoulder-girdle muscles.

The diminution of movement is confirmed by palpation. Vocal fremitus is generally increased owing to the surrounding consolidation, but if the cavity is full or there is much pleural thickening, it is diminished.

The percussion note is dull when the cavity is small or filled with secretion. A peculiar hoxy or "cracked-pot" note, the "*bruit de pot fêlé*," is obtained over large superficial cavities, especially when communicating with an open bronchus. This is best heard on percussing with the mouth open, and Wintrich showed that the note may be altered in pitch over such cavities when percussing with the mouth open or closed, apart from the actual presence of the cracked-pot sound. Gerhardt's sign (alteration of note with the position of the body) is supposed to indicate a cavity of oval shape. It is rare, and of little value.

The breath-sounds are bronchial, broncho-cavernous, cavernous or amphoric, according to the size of the cavity, and to the amount of its contents. When it is full the breath-sounds may be distant, weak or even absent, and this is especially noticeable in basal bronchiectasis.

With a dry cavity there may be no adventitious sounds. Usually râles are audible; they may be medium or large, and bubbling or crackling in character. Over a large cavity a metallic tinkle and amphoric echo may be heard. With a very large cavity, extending through the whole of one lung, a typical *bruit d'airain* is at times obtainable. Voice conduction is increased, bronchophony and whispering pectoriloquy are present, and in some instances post-tussive suction is heard.

Mensuration affords a graphic representation of the flattening of the chest-wall.

THE PHYSICAL SIGNS OF FIBROSIS.—The chest is asymmetrical, the affected side being flattened and moving little, while compensatory scoliosis or kypho-scoliosis is often present. The cardiac impulse is seen to be displaced towards the affected lung and may be higher or lower than normal. It may be drawn over to the right axilla, or on the left side as far back as to the posterior axillary line, or even to the angle of the scapula. The intercostal spaces may be retracted, and dilated venules are sometimes seen over the front of the chest as the result of obstruction, caused by displacement of the mediastinum and traction on the deeper veins.

Diminution of movement is confirmed by palpation, and the cardiac impulse can be more accurately localised. Vocal fremitus may be increased or diminished; the former occurs when the lung is consolidated and the large bronchi patent, the latter when there is much pleural thickening.

1100 DISEASES OF THE RESPIRATORY SYSTEM

The percussion note over fibroid lung is dull and the sense of resistance increased, unless cavities are present. The opposite lung may be hyper-resonant, and its resonance extend across the mid-sternal line. The cardiac dullness is often continuous with that of the fibroid lung, and its area can only be determined by the cardiac pulsation.

The breath-sounds are weak and distant, unless modified by the presence of a cavity.

Often there are no adventitious sounds, although fine or medium râles of a sticky or metallic nature may be heard. The voice conduction is usually diminished, and there is no pectoriloquy unless excavation has occurred, when bronchophony and pectoriloquy are audible.

It must be borne in mind that in actual disease the lesions are not so clear cut and well-defined. In a case of some duration different stages of disease can be found in the same individual, thus infiltration, consolidation with softening, excavation and fibrosis, may be present in different lobes of the lungs, and so it is possible to determine the site of origin and path or spread of the disease.

Certain other signs are occasionally seen in pulmonary tuberculosis.

Myoidema is an undue irritability of the muscles to direct mechanical stimulation, revealing itself by a flickering fibrillary contraction on tapping with the finger, and may occur in tuberculosis at all stages. It is best seen over the pectoralis major on the affected side. It may be present quite early, but is not pathognomonic, as it may occur in any cachectic state.

Clubbing of the fingers is commonly seen in chronic cases, the nails are curved and present a parrot-beak appearance, the thumb, index and middle fingers being most affected. Drum-stick clubbing is only seen in fibroid lesions with bronchiectasis.

HILUM TUBERCULOSIS.—The existence of a special type of pulmonary tuberculosis commencing at the root of the lungs and spreading thence in a fan-shaped manner along the bronchi has been postulated by some in recent years, chiefly on X-ray evidence. According to Riviere the physical signs are always bilateral, and consist chiefly in alterations to percussion, the contraction of Krönig's apical isthmus of resonance, and the presence of parasternal and paravertebral bands of dullness when the tracheo-bronchial glands are also involved. The breath-sounds at the apex are often "granular" and adventitious sounds are frequently absent. When present, they consist usually of fine crackling râles, and may come to the surface at any point on the chest-wall over the lungs. Excavation occurs especially in the middle of the upper lobe, in the axilla, or at the base rather than at the apex. X-ray examination reveals signs of disease in the bronchial glands and extensions radiating from them throughout the lungs. It is doubtful whether this is common in adults, but in the relatively rare pulmonary tuberculosis of children, it is probably the usual type.

PULMONARY OSTEO-ARTHROPATHY.—In cases with bronchiectasis the joints also may be affected, swelling occurring especially in the wrist, ankles and knees, and rarely in the hips and shoulders. A serous effusion into the joints may be present. Pain is usually slight, but there is much deformity and functional impairment. X-ray examination reveals productive periosteal changes, which may also affect the long bones and the spine.

RADIOGRAPHY OF THE CHEST.—If possible, the chest should be examined

in every case with the fluorescent screen, and a photograph taken on a plate or film. Certain important points can only be determined by a screen examination. The chief of these are the respiratory movements of the diaphragm, lighting up of the apex of the lung with inspiration, and the cardiac pulsation. Unilateral restriction of diaphragmatic movement not infrequently occurs in early apical tuberculosis, but as it may be observed under other conditions, notably with pleural adhesions, it is not diagnostic. The plate will show the extent of the disease and in some cases it may suggest the existence of activity; thus areas of consolidation, caseation or excavation can be demonstrated, and thickening of the pleura, pleural effusion and pneumothorax give their characteristic appearances.

The significance of "root shadows" is still debatable. Although the presence of calcareous deposit in the glands at the roots of the lungs is usually obvious, the interpretation of shadows radiating out along the bronchi is a matter requiring great experience. They may be due to peribronchial thickening, caused by the formation of fibrous tissue, or may merely represent the shadows cast by the normal bronchial wall and vessels which in some are more apparent than in others. As the claims for the special type of hilum tuberculosis are largely dependent upon the X-ray evidence, this is clearly a point of great importance, and the physiological variations must always be remembered. Dilatation of the bronchi is more easily recognisable.

A plate is of less value in determining the presence of early disease, slight diminution of translucency of one apex may be due to an old arrested lesion, or, on the other hand, there may be definite physical signs of active disease, without abnormalities being found on X-ray examination. The heart shadow is often narrow and vertical in tuberculosis, and this form is said to be the typical one in hilum disease. Displacement of the heart due to pulmonary fibrosis or to affections of the pleura is clearly indicated. A good plate may also give valuable information as to the extent of lung involved and as to the presence of complications, such as effusion, pneumothorax or bronchiectasis. As the X-rays only cast shadows lacking in all pictorial details, tuberculous shadows cannot always be distinguished from those due to other pulmonary lesions, and, further, early disease may not obstruct the passage of the rays. It is thus clear that undue reliance must not be placed on the X-ray findings, which should always be interpreted in connection with the history, symptoms and physical signs of the case. The X-rays, although often of great help, do not afford a simple road to diagnosis or supply infallible evidence in determining the nature of an obscure case. On the other hand, they are absolutely essential in the determination of the suitability of a case for the artificial pneumothorax treatment and in controlling its application.

Complications and Sequelæ.—Compensatory emphysema is common in chronic fibroid disease, but bronchiectasis occurs less frequently. Gangrene of the lung is not often observed. Colds and catarrhal affections of the respiratory passages are frequent in sufferers from tuberculosis, and lobar pneumonia may develop as a complication. Bronchitis often occurs, due either to spread of the tuberculous process or to a secondary infection. In some instances asthma appears for the first time after tuberculosis has become manifest. A tuberculous abscess occasionally forms about a rib or costal cartilage

1102 DISEASES OF THE RESPIRATORY SYSTEM

Small areas of dry pleurisy are present at some stage in nearly every case ; a serous pleural effusion is common, and an empyema may develop as the result of a mixed infection, or from the tubercle bacillus alone. Pneumothorax may occur as an early complication, or late in the disease, generally from rupture of a caseous focus just under the pleura ; this frequently progresses to the formation of a pyo-pneumothorax. The deposition of tubercle bacilli from the expired air and sputum may lead to secondary foci in the larynx, trachea and epiglottis, or more rarely in the pharynx, tonsils, base of the tongue or nose. Swallowing of sputum containing tubercle bacilli gives rise to gastro-intestinal complications in many cases. The most common site for tuberculous ulcers is the terminal portion of the small intestine, but the appendix may be affected, and the connective tissue around the cæcum is sometimes matted and thickened to form a palpable mass (hypertrophic tuberculoma). Tuberculous peritonitis is not common in adults and is usually secondary to intestinal lesions. The stomach is very rarely ulcerated, but an atrophic gastritis may occur in advanced cases. Fistula-in-ano and ischio-rectal abscess are comparatively common complications.

Small vegetations may be found post mortem in the heart on the aortic and mitral valves, but these are usually due to some terminal infection. Fatty degeneration of the myocardium occurs as a result of toxæmia, and infection by direct spread along the lymphatics may lead to serous or purulent pericarditis. The peripheral circulation is not infrequently poor, chilblains are common, and cachectic purpura may be seen. Lardaceous degeneration as a consequence of chronic tuberculosis is not so common nowadays as formerly, but when present may affect the liver, spleen, intestines, lymph glands and kidneys.

The genito-urinary complications include lesions in the kidneys, bladder, epididymis and prostate. If the suprarenal body is affected Addison's disease will usually develop. Spinal caries is occasionally observed. A peripheral neuritis may form part of the lesions occurring with marked cachexia. Generalised dissemination of the tubercle bacilli by the blood stream is followed by tuberculous meningitis.

Course.—The course pursued by pulmonary tuberculosis is variable, depending upon the clinical type of the disease. In acute miliary tuberculosis, death may occur in from 1 to 3 weeks from toxæmia or generalisation of the lesions. In acute caseous tuberculosis, death usually results in from 1 to 6 months. In chronic fibro-caseous tuberculosis, the disease may be completely arrested, or after a temporary arrest may become active at intervals and again become arrested under suitable treatment ; in other instances it progresses steadily to a fatal termination. In fibroid tuberculosis, the disease may become completely arrested or smoulder quietly for many years.

Apart from the question of the expectation of life, various stages of tuberculosis are described based upon anatomical lesions, toxæmia and functional disabement. The most important of these are as follows :

1. **THE TURBAN-GERHARDT CLASSIFICATION.**—An anatomical classification based upon the extent of lung tissue involved. Three stages are described. *Stage 1.* Early cases in which physical signs, if unilateral, only extend from the apex to the second rib, and, if bilateral, are limited to the

supra-clavicular and supra-spinous regions. *Stage 2.* The signs, if unilateral, do not reach lower than the fourth rib, and, if bilateral, are situated above the second ribs. Excavation is not present in this stage. *Stage 3.* This includes more extensive lesions or localised ones in which excavation is present.

2. SIR ROBERT PHILIP'S CLASSIFICATION.—Both the extent of lung tissue involved and the degree of toxæmia present are taken into consideration. Twelve stages are described, which are indicated by the following signs:

L_1 , L_1s , L_1S , and 1_1S ; L_2 , L_2s , L_2S , and 1_2S ; L_3 , L_3s , L_3S , and 1_3S . L_1 , L_2 , and L_3 represent lung involvement to the extent of stages 1, 2 and 3 respectively, according to the Turban-Gerhardt scale. s applied to these letters indicates that there is only slight systemic disturbance, whereas S signifies marked systemic disturbance, and the signs 1_1S , 1_2S and 1_3S show that the systemic disturbance is excessive in relation to the lung involvement.

3. INMAN'S CLASSIFICATION.—This is based solely on the temperature in relation to exertion.

Stage 1. The patient is febrile when resting. *Stage 2.* The patient is resting afebrile, but ambulant febrile. *Stage 3.* The patient is ambulant afebrile. *Stage 4.* The patient is working afebrile.

The course taken by tuberculosis of the lung may lead to several terminations. These are—(1) permanent arrest, either by fibrosis prior to caseation, or, if the latter has occurred, by calcification and fibrosis; (2) incomplete arrest, as shown by the persistence of tubercle bacilli in the sputum, or by slight degrees of pyrexia on over-exertion; (3) rapid extension, here the disease spreads, and the toxæmia is out of all proportion to the extent of the lesions; (4) death, this may result from the pulmonary lesion or from complications. The former may prove fatal as the result of progressive asthenia or cardiac failure, from asphyxia due to acute miliary tuberculosis or hæmoptysis, or in a small proportion of cases directly from loss of blood in repeated hæmoptysis. The complications that most often prove fatal are meningitis, enteritis, laryngitis leading to dysphagia and starvation, or pneumothorax. Intercurrent diseases, such as pneumonia, influenza or diabetes, are occasionally the cause of death.

Diagnosis.—This is easy when definite signs are present in the lungs, and when tubercle bacilli are found in the sputum. On the other hand, the diagnosis of early cases may present one of the most difficult problems in clinical medicine. Tuberculosis may be suspected on account of symptoms, although the physical signs are indefinite. The conditions most frequently lead to doubt are dyspepsia, neurasthenia, debility, visceroprosis and intestinal stasis, oral sepsis, tachycardia associated with early Graves' disease or heart disorders, chlorosis, affections of the nose and throat, and in children enlargement of the bronchial glands or acidosis. The history and symptoms are of great importance in these cases, and a careful examination should be made of each system. A test meal, opaque meal, or blood examination may be required before the correct diagnosis is established.

On the other hand, there may be definite signs of disease in the lungs which have to be differentiated from those produced by other conditions simulating tuberculosis. The cases included in this group embrace the majority of pulmonary lesions, especially chronic bronchitis, fibrosis, bronchiectasis, asthma, emphysema, apical catarrhs and collapse, pleurisy, new-growths and cysts. Diagnosis depends upon the history and course

of the disease, together with a careful record of the physical signs in the chest, examination of the sputum for infecting organisms, and in some cases the determination of the Wassermann reaction or an X-ray examination.

When the diagnosis still remains doubtful the patient should be placed under observation, and a series of examinations carried out, the object of which is to determine whether or not active tuberculosis is present. The temperature should be observed with the patient in bed, a daily rise to 99° F. or a swing of 1.5° to 2° below normal being suspicious. The sputum should be examined repeatedly for tubercle bacilli by the ordinary method, and if not found the antiformin process should be carried out. The albumin test may also be employed.

Before applying any tuberculin tests the blood may be examined serologically. The determination of the opsonic index requires expert skill, and should be only carried out by a pathologist versed in its technique. The blood is examined before and after exercise, and figures below 0.8 and above 1.2 are believed to indicate an active lesion. The use of the Arneth blood count in diagnosis has been referred to on page 1097. The complement fixation test is still in the experimental stage, and does not yet afford reliable criteria of activity or quiescence.

The stability reaction of the blood, *i.e.* the rate of sedimentation of the erythrocytes in blood diluted with sodium citrate solution, is affected in this disease. In active cases the sedimentation rate is increased, but this reaction is not specific. It is also present in other conditions such as pregnancy, carcinoma, syphilis and acute infections. The test would be of value in pulmonary tuberculosis, if it should be established, as some observers claim, that a normal sedimentation rate is incompatible with active disease.

It has also been used as a guide to prognosis, since it is affirmed by some that arrest should not be considered as firmly established until the sedimentation rate has returned to normal. This may not occur until some time after the usually accepted clinical symptoms and signs of activity have disappeared.

THE TUBERCULIN TESTS.—1. *Cutaneous (the Pirquet reaction).*—Scarifications are made on the skin of the forearm through a drop of Koch's old tuberculin, human and bovine, and through a drop of saline as a control. A positive reaction is shown by the formation of a slightly raised, reddened papule at the site of the scarification through one or other varieties of tuberculin, whereas the control is not affected. Unfortunately, except in the first two years of life, this affords no indication of active disease, but only reveals the presence of previous infection with resulting tuberculin sensitiveness. A positive reaction is therefore given by the majority of adults. The graduated Pirquet is said to give an indication of the activity of the disease. In this process four scarifications are made through old tuberculin of strengths 1, 4, 16 and 64 per cent. respectively, and the resultant sizes of, and the differences in size between the papules, are measured and compared with a table.

2. *Calmette's ophthalmic reaction.*—A drop of 1 per cent. old tuberculin is instilled into one conjunctival sac. A positive result is shown by the development of conjunctivitis in from 3 to 12 hours. This test also affords no indication of the activity of the disease, and, as there is some risk of permanent damage to the eye, it is not usually carried out in this country.

3. *The subcutaneous test.*—The patient must be apyrexial, and must be

kept in bed— $\frac{1}{10}$ th mgrm. of old tuberculin is injected subcutaneously, and its effect determined. The reactions that may develop are—(a) local, an inflammatory swelling at the site of the injection; (b) focal, an increase of the signs observed at the seat of disease in the lungs, such as the temporary appearance of a few râles at one apex. This is the most important; (c) general, as judged by a rise of temperature and sense of malaise. The temperature should be charted 4-hourly after the injection, and a rise to over 99° F. indicates a positive reaction. If no reaction follows this initial dose, larger injections are given at intervals of 2 or 3 days, in this sequence: $\frac{1}{8}$ th, $\frac{1}{4}$ rd, 1, 5 and even 10 mgrms.

This test has the drawback of the two former tuberculin tests, that it does not indicate activity of disease, and it has the additional disadvantage that it may cause a quiescent pulmonary focus to light up and spread, and so cause irreparable damage. It is therefore wise to avoid it in cases of suspected lung disease.

Finally the X-rays may afford some assistance in the diagnosis of early cases with doubtful signs, and may also assist in the differential diagnosis of tuberculosis from other lung diseases with well-marked signs.

Prognosis.—A number of factors must be critically considered in the determination of the prognosis in pulmonary tuberculosis.

A marked family incidence generally suggests an unfavourable course, though this rule is not invariable.

Personal history.—Chronic alcoholism is serious, chiefly because the régime of treatment is then peculiarly irksome, while the digestion and powers of resistance are often impaired in alcoholics. Tuberculosis in syphilitics frequently assumes a fibrotic type, and its course may be beneficially influenced by anti-syphilitic treatment. The outlook is grave when tuberculosis is conjoined with diabetes. Congenital heart disease and pulmonary stenosis are unfavourable factors; but hypertrophy of the heart and mitral stenosis are said to be beneficial.

The prognosis is very grave in infants and young children; but slightly less serious up to the age of 20. Between 20 and 50 age has little influence; but in later years the outlook becomes progressively less favourable.

Apart from the effects of pregnancy and exposure, sex plays no important part.

Freedom from financial embarrassment improves the prognosis, inasmuch as advice can be sought early, and treatment carried out thoroughly.

Marriage often leads to a breakdown in arrested cases, and induces more rapid spread of active lesions.

Persistence in an unfavourable occupation, or return to it after completion of institutional treatment, affects the prognosis adversely.

Poor chest development and the "habitus phthisicus" are usually bad prognostic signs, although tuberculosis often runs a rapid course even in patients with good physique.

Patients with resolute and persistent personality are more likely to persevere with treatment and to recover, than those of weaker moral fibre.

The prognosis is greatly affected by the type of the disease—acute miliary tuberculosis is usually rapidly fatal, whereas in acute caseous tuberculosis, although the prognosis is very grave, recovery may occur. In fibro-caseous tuberculosis the prognosis is most uncertain and difficult

to forecast. Every factor must be carefully considered, and the response to treatment noted. The best outlook is in fibroid disease, which often undergoes complete and permanent arrest. The prognosis is usually fair in hilum tuberculosis, but acute and rapid spread sometimes occurs.

SYMPTOMS IN THEIR RELATION TO PROGNOSIS.—Persistent cough, by exhausting the patient and disturbing sleep, is often unfavourable.

The amount of sputum is usually dependent upon the type of disease and upon the presence of secondary infection, and may therefore be of value in prognosis.

The significance of tubercle bacilli in the sputum.—The figures obtained at the Midhurst Sanatorium, over a period of 8 years, in which the after-history of the patients was traced for the ensuing 6 years, show that the prognosis is best in “closed” cases; but that it is nearly as good in those cases in which the tubercle bacilli disappear from the sputum during the sanatorium treatment. Persistence of bacilli in the sputum is an unfavourable sign. The actual number of bacilli in the sputum and the presence of “beading” have no definite prognostic significance.

Cases commencing with hæmoptysis progress more satisfactorily than those with other modes of onset, chiefly because they are diagnosed earlier. Hæmoptysis occurring later may exert an unfavourable influence, either indirectly by spreading the disease into previously healthy portions of the lungs, or actually by the loss of blood.

If dyspnoea is not due to attacks of bronchial spasm, it has usually an unfavourable significance.

The temperature affords a clue to the type and activity of the disease, and is thus a valuable aid to prognosis. Profuse and persistent night sweats, or marked anorexia, especially when occurring early in the disease, are grave signs. Tachycardia due to toxæmia, and signs of cardiac failure, are of bad omen. The blood-pressure is thought by some to be a useful guide, systolic figures below 100 mm. Hg being unfavourable, whereas a rise of pressure may be associated with amelioration of the disease. In fibroid lesions the pressure may be raised throughout.

THE EXTENT OF PHYSICAL SIGNS.—The activity of disease rather than its extent is the important factor in determining prognosis. The development of compensatory emphysema is of value only as an indication of fibrosis in the tuberculous portion of lung, and therefore of chronicity.

THE INFLUENCE OF COMPLICATIONS ON PROGNOSIS.—Generally speaking, the presence of complications increases the gravity of the disease. Involvement of the larynx is a very serious complication, especially when accompanied by dysphagia; but complete recovery may take place if the pulmonary lesion is quiescent. In early cases spontaneous pneumothorax occasionally acts favourably; but when it develops in association with extensive tuberculosis, and especially if it progresses to pyo-pneumothorax, it is almost invariably fatal.

Pleural effusion often has a beneficial influence by diminishing the movements of a lung in which there is an early tuberculous focus.

Secondary catarrhal affections tend to increase the cough and expectoration, and may lead to further spread of the disease.

Meningitis is almost invariably fatal. Tuberculous peritonitis or enteritis is a very grave complication, but *fistula-in-ano* often occurs in chronic

cases, and exerts no marked deleterious effect. Involvement of the genito-urinary system increases the severity of the disease, especially if the kidneys or bladder are affected. If the epididymis alone is involved the prognosis is not materially affected, as the lesion can be dealt with surgically, although the administration of a general anæsthetic may cause spread of the pulmonary disease. For this reason when operations are urgently needed on these patients, gas and oxygen, local or spinal anæsthesia should be insisted on.

As shown by the figures obtained at the Midhurst Sanatorium, a fairly accurate guide to prognosis is afforded by observing the condition of the patient on admission to the sanatorium, and his response to treatment. Even in the most favourable cases, which are diagnosed in an early stage, and progress satisfactorily under treatment, the mortality rate is six times greater after discharge from sanatorium than it is for the remainder of the population of England and Wales for the same age periods; whereas in the cases of advanced disease the mortality rate is thirty-eight times greater than for the average population. As the most critical time is during the two or three years succeeding discharge from sanatorium, the prognosis is largely affected by the conditions of life during this period.

It seems probable that the rate of sedimentation of the erythrocytes (see p. 1104) may prove to be a valuable aid to prognosis. A persistently rapid rate is unfavourable.

Treatment.—*Prophylactic.*—The prophylaxis of tuberculosis involves a consideration of public health questions dealing with the purity of the milk supply, the infection of meat, sanitation and housing, the early diagnosis of tuberculosis, the examination of contacts, and the segregation of "open" cases. All these questions are considered in the general article on Tuberculosis.

Curative.—This varies with the type and stage of the disease. In all acute or febrile cases treatment should be commenced at home or in a nursing home or hospital, where the patient can be under careful observation in bed. The various forms of treatment which may be considered are—(1) sanatorium treatment; (2) home or institutional treatment; (3) dietetic treatment and personal hygiene; (4) climatic treatment; (5) graduated rest, exercise and labour; (6) medicinal treatment; (7) specific measures; (8) operative treatment; (9) symptomatic treatment.

1. **SANATORIUM TREATMENT.**—This constitutes the best mode of treatment for early and for certain types of chronic disease; but is totally unsuited for acute febrile or very active cases. The advantages obtained are—(a) the patient learns the most suitable mode of life, and the methods employed to check the spread of the disease; (b) the housing is specially designed and the climatic conditions are good; (c) the dietary is abundant and adapted to the patient's needs; (d) there is constant skilled medical supervision, and the daily routine is adapted to the actual physical condition of the patient.

On arrival a newcomer is kept in bed for a few days in order that his resting temperature may be observed, and the necessary examinations carried out. If there is pyrexia, rest in bed must be enforced until the temperature falls to normal. If the temperature rises above 99° F. when the patient is up, return to bed is usually necessary. The routine of sanatorium treatment varies in different institutions, the most important divergence

being whether or not a system of "graduated exercise" is employed. In nearly all an hour's recumbent rest is enforced before lunch and dinner.

After three months' stay it is usually possible to decide whether the patient is responding to treatment, and if so it should, if possible, be prolonged for at least another three months, or until the sputum is free from tubercle bacilli.

2. HOME AND INSTITUTIONAL TREATMENT.—Treatment at home, in nursing homes or in special hospitals is essential in early cases with fever, and in cases in which it is necessary to establish the diagnosis. Home treatment is also usually necessary on return from sanatorium or climatic treatment, if arrest is incomplete. An endeavour should always be made to carry out the principles inculcated at the sanatorium, and the patient should be under regular medical supervision. Advanced cases are best looked after in special institutions.

3. DIETETIC TREATMENT AND PERSONAL HYGIENE.—It is desirable to graduate the diet in each case so that the patient is restored to the previous maximum weight; but, in order to accomplish this, the food should be slowly increased and all ideas of enforced over-feeding discontinued. A total calorie value of 3000 to 3500 is usually ample; but, if the patient is performing heavy work, as much as 4000 may be necessary. Meat, fish, eggs and fats are usually well tolerated. It is not often necessary to give large quantities of milk when the patient is on a full dietary. If extra food is required, the protein may be increased by raw meat sandwiches, and additional carbohydrates may be taken.

In all cases in which there is expectoration the patient should be clean-shaven. Great care must be taken in the disposal of sputum to ensure that it does not become dry, and that flies do not have access to it. All patients who are up should carry special sputum flasks, while those who are in bed should have sputum cups suitably covered and containing disinfectant. The sputum should be burnt, or, if this is impossible, it should be emptied into the water-closet after disinfection with carbolic acid or other simple or cheap disinfectant.

Smoking is best avoided in cases of active disease or laryngeal tuberculosis, and in no instance should inhaling be allowed. Woolen under-garments should be worn; but all excess of clothing is harmful.

4. CLIMATIC TREATMENT.—This is undoubtedly of value in carefully selected cases. The climatic resorts fall into three groups—mountain, marine and inland.

The mountain resorts.—In Europe the most suitable places are found in Switzerland. Among these are St. Moritz (6090 feet), Arosa (6000 feet), Davos (5150 feet), Montana (5000 feet) and Leysin (4690 feet). In America the most celebrated resorts are in the Rocky Mountains at Colorado Springs (5000 feet) and Denver (5000 feet), or in the Andes or Adirondack Mountains. The advantages of high altitudes consist in the stillness, purity and rarefaction of the air, and the greater diathermancy of the atmosphere to the sun's rays. Metabolism and the general circulation are thereby increased.

High altitudes are suitable for early cases which are afebrile, or for quiescent cases of more advanced type. Contra-indications are recent hæmoptysis, active disease with fever, extensive fibrotic lesions and complications such as emphysema, asthma, cardio-vascular lesions or nephritis.

Marine and coast resorts.—Among the important coast resorts in the British Isles are Bournemouth, the Isle of Wight, Torquay, Falmouth, Llandudno, Penmaenmawr, Scarborough, Mundesley and the various seaside towns in Thanet. Farther afield are the French and Italian Riviera, Madeira, the Canary Isles, Morocco, Algiers and Egypt. The climate tends to be warm, moist and equable, and the amount of ozone is probably increased. These resorts are especially suitable for cases of more advanced and active disease, and for those complicated by hæmoptysis, bronchitis, emphysema and laryngitis.

Inland resorts.—These are to be found on the English and Scottish moorlands. The climate of California, the South African veldt, and parts of Australia and New Zealand are admirably suited to this disease, especially for arrested or early uncomplicated cases; but the laws against the admission of tuberculous patients are strictly enforced at all of them.

Sea voyages.—These are contra-indicated for all except completely arrested cases, owing to the lack of fresh air in cabins, the possibility of sea-sickness, and the difficulty of obtaining suitable treatment if the disease advances.

5. **GRADUATED REST AND EXERCISE.**—Treatment in bed is necessary so long as there is fever, and if the raised temperature is persistent, “absolute rest” should be enforced. This consists in keeping the patient recumbent in bed, sufficiently well covered to prevent any muscular contraction from chill, while feeding and washing are attended to by the nurse, and the use of the bed-pan and slipper for evacuations is insisted upon. When the temperature becomes normal the patient is allowed up for varying periods, commencing with 1 hour daily, and increasing slowly to 6 or 8. If still apyrexial, walking exercise of 1 or 2 miles or more daily can be allowed.

The system of “graduated exercise” which Paterson instituted at the Frimley Sanatorium has proved of great value. There are six grades, the first and lightest consisting of walking up a slope carrying a light weight such as a basket of earth, while the sixth and heaviest involves hard manual labour with a pickaxe or shovel for 6 hours daily. This system is based on the principle that muscular exercise leads to the discharge of tubercle toxins from the pulmonary focus, and by liberating these in gradually increasing doses, a condition of active immunity is induced. A careful watch must be kept during this controlled process of auto-inoculation to prevent excessive doses of toxin being discharged, which are early indicated by rise of temperature and of pulse-rate, headache, increased cough and expectoration, lassitude and malaise. If such occur, the patient should be put back to bed for a few days, and when the condition has subsided the graduated exercise may be resumed at the grade which induced the over-inoculation or that immediately below it.

6. **MEDICINAL TREATMENT.**—No specific drug has yet been discovered for the treatment of tuberculosis. Amongst the medicines in most general use are:

(a) *Cod-liver oil.*—This may be administered by the mouth in doses up to 2 ounces daily, or 0.5 to 2 c.c. of a 3 per cent. solution of sodium morrhuate may be injected subcutaneously once or twice a week (Rogers). The cod-liver oil may be of value either on account of its fat-soluble A vitamin content, or, as suggested by Rogers, it may assist by dissolving the capsules of the tubercle bacilli and so facilitating their disintegration.

(b) *Creosote*.—This may be given in doses of m ij to ijj three times a day after food, either in combination with cod-liver oil, or in capsules. It should be discontinued if gastric disturbance or hæmoptysis ensue.

(c) *Hypophosphites*.—These are not so generally used as formerly, and beyond their "tonic" effect upon the nervous system, have no demonstrable influence upon the pulmonary lesion.

(d) "*Nascent*" iodine.—With the idea of liberating free iodine in the tissues, potassium iodide grs. xxx is administered after breakfast in half a pint of water, and throughout the day 3 to 5 ounces of chlorine water are consumed with lemonade. This treatment is of value in certain chronic fibroid cases, but it often produces no appreciable results, and may cause dyspepsia.

(e) *Arsenic*.—Liquor arsenicalis m ij to ijj by mouth, or sodium cacodylate gr. $\frac{1}{2}$ to $\frac{1}{4}$ subcutaneously, are of value in some cases associated with anæmia. Salvarsan or novarsenobillon, administered intravenously, is useful in chronic cases complicated by syphilis.

(f) *Inhalations*.—Disinfectant drugs when inhaled often check cough, lessen expectoration and improve the general condition of the patient. *Leech's* inhalation, or some modification of it, is of value. It consists of creosote, parts 2; acid. carbol. 2; tinct. iodi mitis, 1; sp. ætheris, 1; and sp. chlorof. 2. About 6 drops an hour are placed upon a Burney-Yeo mask, which should be worn almost continuously throughout the day.

(g) Recently there has been a revival of interest in preparations of gold in the treatment of this disease, notably by Mollgaard, who uses sodium aurothiosulphate, to which the name of sanocrysin has been applied. In view of the toxic reactions, which are frequently obtained, a special anti-tuberculous serum is sometimes used at the same time, on the supposition that the toxic effects are due to the disintegration of tubercle bacilli in the lesions. This substance is now being employed in smaller doses than were originally used and seems likely to become established as a useful means of treatment in selected cases.

7. SPECIFIC MEASURES.—(a) *Active immunisation*.—Tuberculins.

The tuberculin treatment has not fulfilled the high hopes held out on its introduction by Koch. There are now numerous forms of tuberculin available, indicated by certain letters, and falling into three groups. (1) Those containing the exo-toxins only. These include Koch's old tuberculin T., O.T., and T.O.A., Denys' bouillon filtré (B.F.) and albumose-free tuberculin, T.A.F. (2) Those containing the endo-toxins chiefly, as Koch's "new" tuberculin, T.R. (3) Mixtures of endo- and exo-toxins, the most important of which are Koch's bacillary emulsion, B.E., the sensitised bacillary emulsion, S.B.E. and Béranek's tuberculin, T.Bk.

Tuberculins may be prepared from human or bovine bacilli; if from the latter the letter P. (*perlsucht*) placed before the letters indicating the variety of tuberculin, signifies its origin, e.g. P.T. In administration, some aim at producing reactions and establishing tuberculin tolerance by giving large doses at fairly frequent intervals; others believe in minute doses at longer periods, the chief object being to avoid the production of any reaction. The actual doses are either measured in milligrammes of dried tubercle bacilli, or in cubic centimetres or cubic millimetres of the fluid tuberculin. The usual method is to measure the doses in cubic centimetres or fractions

thereof, and to make the necessary dilutions in a series of bottles. Smaller initial doses should be used with a strong tuberculin such as the B.E. than with the weaker ones such as the T. or A.F. Thus, if adopting minute doses $\frac{1}{100,000}$ mgrm. of B.E. would be a suitable initial dose, then for T.R. $\frac{1}{100,000}$ mgrm. would be used and $\frac{1}{1000}$ mgrm. of T., B.F., or A.F. As the different tuberculins are supplied by the makers in varying strengths, 0·001 c.mm. of the original fluid is equivalent to the above doses.

Those who believe in minute doses commence with 0·001 c.mm. and work up to 0·1 c.c., whereas others commence with 0·5 to 1 c.mm. and increase to 1 c.c. The tuberculin should be injected subcutaneously, and a careful observation kept for local, focal and general reactions. Tuberculin if used injudiciously can be productive of harm. At Midhurst Sanatorium it was tried for some years, and no better ultimate results were obtained than in the "non-tuberculin" years. It seems wise, therefore, to use tuberculin only in very carefully selected cases, thus T.R. does at times appear beneficial in chronic tuberculosis, promoting the formation of fibrous tissue and leading to the disappearance of tubercle bacilli from the sputum.

Recently various attempts have been made to remove as far as possible the fatty and waxy constituents from the tubercle bacilli before preparing a vaccine from it. The best known of these is the *diaplyte* vaccine of Dreyer. Much and his collaborators have employed partial antigens or partigens derived from tubercle bacilli or in varying combinations. Some good results are on record from both of these methods, but on the whole their use has so far been disappointing.

(b) *Passive immunisation.*—The various serums such as those prepared by Marmorek and Maragliano have not proved successful, and this applies to the "contra-toxin" of Mehnarto and the "I.K." (immune bodies) of Spengler.

8. OPERATIVE TREATMENT.—(a) *Artificial pneumothorax.*—This mode of treatment is now becoming more generally adopted in selected cases. It is not indicated in early disease and in cases progressing favourably. In extensive bilateral disease it may be dangerous. If old and dense pleural adhesions are present, it is impracticable. If there is much emphysema or cardiac embarrassment, it involves risk. Only a relatively small group remains which comprises cases in which the disease is mainly unilateral, and those which remain febrile in spite of prolonged bed treatment. It is also of value in certain cases of repeated severe hæmoptysis. Tuberculous laryngitis or enteritis are not contra-indications, providing that other conditions are suitable. Nitrogen or sterile air is introduced into the pleural cavity, and the lung allowed to collapse. The method of induction of artificial pneumothorax is as follows: A preliminary subcutaneous injection of $\frac{1}{2}$ grain of omnopon is given half an hour before the start. The patient lies on the sound side with the head low and supported on a pillow. A second pillow is placed under the chest to expand the intercostal spaces. The skin and the tissues down to the pleura are anæsthetised with 2 per cent. novocain solution after the application of iodine. The site usually chosen is in the sixth intercostal space in the mid-axillary region. A special pneumothorax needle, attached by a rubber tube to the pneumothorax apparatus, which is carefully examined to see that it is in proper working order, is then pushed through the intercostal space until the pleural cavity

is reached. The apparatus is then adjusted so that the intrapleural pressure can be observed. No air should be introduced until the manometer shows a normal negative pressure range with inspiration, of 5 to 10 or more c.c. This is the test of entry into the pleural space, and when this is established 200 to 300 c.c. of sterile air may be allowed to enter the pleural cavity. The final pressures are then recorded and the needle is withdrawn. A refill is given next day and again after two more days, the quantities of air introduced being determined by the final pressures, which should be kept slightly negative. Subsequent refills are gradually spaced out to a week, then ten days and later to two, three and four weeks' intervals. The tendency now is to maintain the collapse for two or three years or even longer. If the condition of the patient is satisfactory, re-expansion may then be permitted cautiously. It should be remembered that after expansion pleural adhesion almost invariably occurs and the treatment by artificial pneumothorax cannot be repeated. In a few cases of bilateral disease, which is active but not very extensive in either lung, a cautious use of bilateral artificial pneumothorax has proved practicable and helpful, but very great care is necessary.

There are certain dangers in the procedure. These are now rare, and they can usually be prevented by careful attention to the technique. Death has occurred from pleural shock when the needle has reached the pleura and before any air has been introduced. Adequate anaesthesia of the pleura is the only known method of eliminating or minimising this risk. If the lung is adherent to the chest-wall, owing to pleural adhesions, or if the needle is pushed in too far, it may be inserted into the lung or into a pulmonary cavity; the manometer will then show a swing above and below the zero line instead of entirely below it. Under these circumstances, no air should be allowed to enter. The needle may be inserted into a blood vessel. In this case the manometer pressure will rise above zero and blood may appear in the glass section inserted in the rubber manometer lead from the needle. The needle should be withdrawn immediately, lest air should enter the vessel.

If the pleura is found to be adherent at the site of the first puncture, another attempt may be made elsewhere, e.g. just below the inferior angle of the scapula. This spot may be selected for the initial puncture in left-sided cases where there is marked cardiac displacement.

(b) *Thoracoplasty*.—If owing to adhesions it is impossible to collapse the lung temporarily by an artificial pneumothorax, permanent collapse may be considered. This can be effected in suitable cases by removal of a sufficient amount of the ribs from the first to the tenth to allow the chest-wall to fall in and so permit the lung to collapse. This may be done in one or two stages, and under local or general anaesthesia or both combined.

(c) *Evulsion (exairesis) of the phrenic nerve*.—This has also been performed in order to produce basal collapse. Division alone is not sufficient as a rule.

9. SYMPTOMATIC TREATMENT.—When cough is ineffective it may be relieved by a sedative lozenge or linctus containing heroin or codeine, or by the well-known liquorice lozenge. If there is difficulty in bringing up the sputum, a simple saline mixture is of value, such as sodii bicarb. grs. x, sodii chlorid. grs. iij, sp. chlorof. ℥ 10, and aq. anisi ad ℥i.

Pain in the chest is usually alleviated by local application of pigmentum iodi, liniments, mustard leaves or other counter-irritants.

Night sweats.—The windows should be widely opened at night. A pill containing zinc. oxid. grs. iij and ext. belladonn. sic. gr. $\frac{1}{4}$ is often of value. Picrotoxin, agaricin and strychnine have also been used.

Fever.—Rest in bed up to the extent of "absolute rest" is the best means of lowering the temperature. Antipyretic drugs have no effect upon the course of the disease, but may alleviate malaise. Amongst these may be mentioned aspirin, cryogenin and pyramidon.

Slight hæmoptysis, in which the sputum is only streaked, calls for no special treatment. Moderate hæmoptysis, with expectoration of 3 or 4 ounces of blood, requires more active measures. The patient should be put to bed, a saline aperient administered, and if there is anxiety or alarm a sedative drug should be given, such as heroin or morphine. In profuse or persistent hæmoptysis the patient should be confined strictly to bed, and if it is known from which side the bleeding has occurred, it is best to lie on this side. If the cough is troublesome, or if the patient is alarmed, morphine gr. $\frac{1}{4}$ to $\frac{1}{2}$, or heroin gr. $\frac{1}{8}$ to $\frac{1}{4}$ should be injected subcutaneously. The food is best given cold, and may be iced; no alcohol must be taken. A course of calcium lactate grs. x, t.d.s., may be commenced; but its action is somewhat uncertain, and should not be prolonged for more than 3 or 4 days. If the bleeding persists, various other remedies should be tried, these include the inhalation of amyl nitrite, or the injection of "coagulose," horse serum, or emetine hydrochloride subcutaneously. Ergot and adrenalin are both contra-indicated. If the hæmorrhage is still unchecked, or is frequently repeated, the advisability of establishing an artificial pneumothorax must be considered.

Gastro-intestinal symptoms.—Anorexia or dyspepsia can often be relieved by changes in diet, or by the administration of suitable drugs. Alkalis and gentian are especially valuable, and when hypochlorhydria is present, dilute hydrochloric acid in large doses (III x-xxx) should be given well diluted after meals. Digestive ferments, such as taka-diastase or papain, may be required at times. All tendency to constipation should be checked by laxatives, and if diarrhœa develops avoidance of diet leaving bulky or irritating residues should first be tried, before administering drugs containing lead, opium, bismuth or tannic acid.

Insomnia is often a troublesome symptom, and every endeavour should be made to obtain a good night's rest by administration of mild hypnotics, and by relieving distressing cough and pain.

The treatment of the complications of pulmonary tuberculosis is described under their respective headings. The after-care of patients discharged from sanatoria is an important subject, to which considerable attention is being devoted, and involves a consideration of the advisability of establishing training centres or colonies for consumptives.

THE PULMONARY MYCOSES (PNEUMONOMYCOSES)

A number of fungi produce pulmonary lesions. Considerable confusion exists in regard to their nomenclature, and at the present time it is difficult to give accurate accounts of them. The pulmonary mycoses have one feature in common, in that they produce chronic pulmonary lesions

practically indistinguishable clinically from those of the chronic forms of pulmonary tuberculosis.

Among the varieties of mycotic infection at present separated clinically may be mentioned — (1) Actinomycosis (Nocardiasis, Streptotrichosis); (2) Aspergillosis; (3) Blastomycosis; (4) Sporotrichosis; (5) Moniliasis; (6) Mucormycosis.

ACTINOMYCOSIS (NOCARDIASIS, STREPTOTRICHOSIS)

Ætiology.—The general characters of the streptothrix group of organisms are described in the section on Actinomycosis. It is now recognised that more than one of these may be pathogenic for man, and some authors give separate descriptions of the forms due to the various streptothrix organisms. At the present time there seems little advantage in so doing, since the important point in regard to treatment is to recognise that the morbid process is due to some form of streptothrix infection, the identification of the variety being a pathological refinement. The mode of access to the body is at present obscure. The organism is found especially in straw, barley and other grains. It is believed to enter the body by ingestion or by inhalation. A large proportion of cases show the first lesions in the head and neck regions, but primary pulmonary cases occur, and are probably more frequent than is generally recognised.

Pathology.—The streptothrix group of organisms produces an inflammatory reaction which leads to the formation of granulomatous tissue. This, like the granuloma of tubercle, is very liable to undergo secondary changes producing small areas of pus formation or leading to fibrosis. Unlike tuberculosis, however, streptotrichosis tends frequently to transgress anatomical limitations and spreads by contiguity. In the primary pulmonary cases the distribution of the lesions is at first very similar to that of tuberculosis, and the disease may extend in an identical manner. In the forms due to spread from other organs such as the liver, the base may be first involved, while in cases extending down from the neck the path of the infection is easily followed.

Owing to the tendency of the lesions to spread by contiguity, subcutaneous abscesses may form and simulate caries of the ribs. Pleural adhesion is the rule, but occasionally empyema results. When a subcutaneous abscess ruptures or is opened, the characteristic "sulphur granules" may be found, although this is not invariant. The skin around the sinuses which result is often puckered in a somewhat characteristic fashion.

Symptoms.—These are in general identical with those of the chronic forms of pulmonary tuberculosis, as cough, expectoration, which may be offensive, dyspnoea, fever and night sweats. The occurrence of local abscesses under the skin or the presence of the parasite elsewhere may give rise to special features; but these are late developments in primary pulmonary cases.

Complications and Sequelæ.—These are usually due to the other localisations of the parasite; but in addition empyema and bronchiectasis may be mentioned.

Course.—This is progressive, and leads eventually to asthenia, emaciation and death.

Diagnosis.—This can only be established by the discovery and identification of the parasite in the sputum and the discharge. The characteristic "sulphur grains" are not invariably present, and may escape notice unless looked for carefully. In any obscure case of pulmonary disease in which tubercle bacilli are not found after repeated search, the possibility of streptotrichosis should be considered, and direct films should be specially examined.

Prognosis.—This is serious, although some cases respond well to treatment.

Treatment.—Large doses of potassium iodide should be administered, commencing with 5 or 10 grains three times a day, and increasing until the dose reaches a drachm or even more thrice daily. If the parasite grows well in culture, a vaccine may be prepared and employed cautiously, especially if the iodides do not act satisfactorily. Surgical treatment of local abscesses or of empyema may be required.

PULMONARY ASPERGILLOSIS

Ætiology.—Infection of the bronchi and lungs sometimes occurs by the *Aspergillus fumigatus*, more rarely by the *A. nidulans*. The disease has been most frequently observed in France. It occurs among pigeon breeders and hair sorters and combers. The former acquire the disease from the process of artificial feeding, from grains in the mouth to the beak of the bird; the latter from the use of rye flour in cleaning the hair. Millers and farm labourers have also been the subjects of the disease.

Pathology.—The fungus induces nodular formations in the lung tissue somewhat resembling aggregated tubercles. Bronchitis, patchy lobular consolidation and fibrosis result. Emphysema, bronchiectasis and cavity formation may follow. A secondary aspergillosis may occur in chronic cases of bronchitis or lung disease, but is of little clinical importance.

Symptoms.—Primary aspergillosis produces symptoms similar to those of bronchitis, broncho-pneumonia or pulmonary tuberculosis, according to the localisation and degree of the lesions. The sputum may be blood-stained, or definite hæmoptysis may occur. There is generally wasting with irregular fever.

Course.—Acute broncho-pneumonic forms may be fatal in a few weeks or months. The chronic lesions may extend to years, and arrest with fibrosis is not uncommon.

Diagnosis.—The condition has to be differentiated from pulmonary tuberculosis, and from other varieties of pneumomycosis. This depends upon the recognition of the fungus by microscopical and cultural examination of the sputum.

Treatment.—This consists in avoiding further infection, and giving large doses of potassium iodide as in streptotrichosis. Open-air measures and general tonic treatment are also to be recommended.

OTHER MYCOTIC INFECTIONS

Fungi of the genera *Blastomyces* (*Oidium*, *Coccidioides*) and *Sporotrichum* are well known to produce cutaneous affections simulating chronic gummatous

or tuberculous lesions. They may also give rise to pulmonary disease producing symptoms like those of tuberculosis.

Castellani has described various broncho-pulmonary conditions due to species of the genus *Monilia*, including the "tea-tasters' cough" and "tea-factory cough." Another fungus, *Mucor mucedo*, has been found in the sputum, and is regarded as pathogenic to man.

All these moulds produce bronchitic symptoms and mild infections, while more severe forms simulate pulmonary tuberculosis. The diagnosis in each case depends upon the recognition of the fungus, and the treatment recommended is large doses of potassium iodide.

SYPHILIS OF THE LUNGS

Ætiology.—Clinically recognisable pulmonary syphilis is a rarity; but syphilitic lesions occur in the lungs in both the congenital and acquired forms of the disease.

Pathology.—Even post mortem it is often difficult to establish the syphilitic nature of the pulmonary lesions found in cases of syphilis, owing to the fact that they tend to the formation of scars presenting no characteristic features.

Congenital syphilis.—The essential changes are—(1) Round-celled infiltration with eventual fibrosis, starting round the bronchi and spreading to the inter-alveolar framework; (2) periarteritis of the smaller arteries; and (3) desquamation and degeneration of the epithelium of the alveoli and bronchi. Gummata may be present, but are rare. Spirochætae can be demonstrated in the lesions by Levaditi's method. The microscopic appearances comprise the "white pneumonia" of Virchow and an interstitial pneumonia, which is commoner, although both conditions are frequently associated. White pneumonia is found in premature or still-born infants, and in those dying soon after birth. The condition may be widespread or localised. The affected areas are firm, consolidated, smooth and greyish-white in colour. There are no interstitial changes, and the consolidation is due to the filling of the alveoli with desquamated, degenerating epithelial cells.

In the commoner interstitial form the lung is firmer, harder and darker grey in colour, and the connective tissue is mainly involved. To this condition the term "pancreatisation of the lung" has been applied by Rogers.

Acquired syphilis.—Syphilitic lesions of the bronchi have already been described in the section on diseases of the bronchi. Gummata may occur in or around the intra-pulmonary bronchi or in the lung tissue. They may be single or multiple, and vary in size from that of miliary granules to a hen's egg. They are said to be more common in the deeper parts of the lung near the roots and in the lower lobe. They undergo changes similar to those occurring in gummata elsewhere, but tend more to fibrosis and contraction than to softening. Owing to these secondary changes, the following conditions may result: broncho-pneumonic processes, widespread fibrosis and contraction with pleural adhesion, bronchiectasis and occasionally excavation.

Symptoms.—Small gummata may be latent and give rise to no symptoms or signs. When fibrosis occurs, they are similar to those of pul-

monary fibrosis from other causes. It is generally recognised that in rare cases a destructive process occurs, formally called "syphilitic phthisis," and almost exactly similar in its clinical manifestations to those of caseous or fibro-caseous tuberculosis.

Complications and Sequelæ.—Syphilitic lesions in the larynx, trachea or bronchi may complicate the course. Bronchiectasis has already been mentioned, and tuberculosis may occur as a complication.

Diagnosis.—This is often difficult and sometimes inconclusive. Obscure pulmonary signs in a syphilitic subject should arouse suspicion. The Wassermann reaction should be determined, and other indications of syphilis looked for in all fibrosing and destructive lung conditions when no tubercle bacilli are found in the sputum. The difficulty of diagnosis is increased by the association of syphilis and tuberculosis mentioned above.

Course and Prognosis.—Where the lesions are localised and can be recognised early, the course is favourable if anti-syphilitic treatment is applied. Where fibrotic changes occur, leading to bronchiectasis, the course is less favourable, and in the destructive form it is serious. An intercurrent tuberculous infection increases the gravity of pulmonary syphilis.

Treatment.—When a diagnosis of pulmonary syphilis has been established, vigorous anti-syphilitic treatment should be carried out. Its beneficial effect is undoubtedly promoted by open-air treatment. In cases where tuberculosis coexists with syphilis, anti-syphilitic treatment is strongly recommended, especially by French physicians.

NEW-GROWTHS OF THE LUNGS

Both simple and malignant tumours may occur in the lungs, the latter being the more common.

Ætiology.—Malignant tumours occur more frequently in the male sex: carcinoma is rare before the age of 40, but sarcoma may develop in earlier years. Simple tumours may arise at any age, but are found chiefly in adult life. The exciting cause is unknown. In some cases of malignant growth there is a history of thoracic trauma.

Pathology.—Simple tumours found in the lungs usually arise in the bronchial mucous glands or in the bronchi. They include adenoma, fibroma, lipoma and chondroma. Malignant tumours may be primary or secondary, the latter being much more common. The primary growths are carcinoma, sarcoma or endothelioma. Carcinoma arises either in the bronchi, as a columnar-celled growth, or in the alveoli as a spheroidal-celled carcinoma; but pleomorphism is often a marked feature of growths in the lung. Round-celled and spindle-celled sarcomata growing from the pulmonary connective tissue are met with, while endotheliomata are usually derived from the endothelium of blood vessels and lymphatics, or from the pleura. A primary carcinoma of the breast, œsophagus or mediastinum may directly invade the lungs. Secondary carcinoma may have its primary focus in the breast, stomach, intestines, liver, pancreas or prostate, whereas a secondary sarcoma most often results from metastasis of a primary bony growth. Chorion-epithelioma and hyper-nephroma also give rise to secondary deposits in the lungs.

Primary malignant tumours are usually unilateral; but secondary growths are often multiple and diffuse. Dissemination in the lungs may occur by spread along the bronchi or vessels, and a condition of miliary carcinomatosis is at times produced. The pleura is often affected by direct extension. Infiltration of, or pressure upon, the mediastinal structures frequently occurs.

Symptoms.—Simple tumours are pathological curiosities and, as a rule, only produce symptoms when they cause destruction of a bronchus or press on mediastinal structures.

The early symptoms of malignant growths are slight, and consist of malaise with, perhaps, cough and expectoration. Later, when the growth becomes more extensive and exerts pressure on, or involves the larger bronchi, mediastinum or pleura, they are more noticeable. Pain, dyspnoea and loss of weight with cachexia usually develop, and the cough and expectoration are more marked. The latter is often of the typical "currant jelly" or "prune juice" appearance due to altered blood. Microscopically, groups of large fatty cells, or irregular epithelial cells may be seen. There are usually no definite physical signs until the tumour causes pressure upon the bronchi, mediastinum or deep thoracic veins or nerves. The chest wall may bulge locally, owing to the presence of a growth near the surface, or it may be retracted if a main bronchus is obstructed. An actual subcutaneous swelling caused by the tumour eroding through the chest-wall may be visible. Enlarged veins often run across the chest, and one or other arm may be swollen or oedematous if there is mediastinal obstruction. Vocal fremitus is often unaffected; but is increased when the growth is near the surface, and diminished if pleural effusion has occurred. The percussion note over a moderate-sized tumour is impaired and may be extremely dull. The breath sounds vary with the size and position of the growth, and with the displacement or pressure effects produced. They may be weak, or loud and stridorous. Adventitious sounds depend upon the presence of complications such as bronchitis. Some degree of fever often occurs. The supra-clavicular and axillary glands are not infrequently enlarged, and evidence of malignant disease may be present in other parts of the body such as the abdomen.

Complications and Sequelæ.—Bronchitis is nearly always present in some degree. Pulmonary collapse, fibrosis, bronchiectasis, emphysema, gangrene, hæmoptysis and pleural effusion are sometimes observed. The latter is frequently bloodstained. In cases of primary malignant disease of the lungs, secondary deposits may occur in other parts of the body.

Course.—This is progressive, the patient gradually losing strength and dying from cachexia or some intercurrent affection.

Diagnosis.—This is difficult in early cases, and not easy in some advanced ones. Difficulties may arise in connection with pulmonary tuberculosis, fibrosis and gumma of lung, aneurysm, pericardial and pleural effusion and enlargement of the mediastinal glands due to Hodgkin's disease or tuberculosis. The whole body should be searched for evidence of malignant disease elsewhere. The sputum should be examined repeatedly for tubercle bacilli and for cellular elements, and an X-ray examination made of the chest. By the stereoscopic method excellent evidence of pulmonary neoplasms is often obtainable.

Prognosis.—Apart from those cases in which early recognition may in

suitable conditions render lobectomy, with removal of the growth, possible, this is hopeless, death occurring in a few weeks, or being delayed for two or three years.

Treatment.—In cases unsuitable for lobectomy, this can only be palliative and symptomatic. Useless cough should be checked by sedative lozenges or a linctus. Dyspnoea due to pleural effusion may be relieved by tapping; but the fluid often reaccumulates rapidly. Pain should be relieved by analgesic drugs, and in the later stages those containing opium or its alkaloids may be required. Deep X-ray treatment is sometimes used, and also radium.

PARAGONIMIASIS

Synonyms.—Pulmonary Distomatosis; Lung Fluke Disease; Endemic Hæmoptysis; Parasitic Hæmoptysis.

Ætiology.—(See p. 330.)

Pathology.—The flukes settle down in the lungs and form burrows. These burrows may coalesce and give rise to cystic swellings, varying from $\frac{1}{2}$ to $1\frac{1}{2}$ inches in diameter. These in turn develop fibrous sheaths and may give rise to abscess formation or pleurisy. The adult fluke is hermaphrodite, and lays numerous eggs which measure $100 \times 70 \mu$. These are coughed up in the sputum, and are easily recognisable owing to their large size. The adult parasites are also occasionally found in the brain, liver, lymph glands and peritoneal cavity.

Symptoms and Complications.—The onset of symptoms, after infection has taken place, is insidious, with cough and expectoration. The latter is very constantly blood-stained, and there may be profuse hæmoptysis. Secondary pleurisy occurs when the cysts reach the surface of the lungs, causing pain. Examination may reveal no abnormal signs, at most there are a few scattered râles, together with signs of dry pleurisy at one point. Later in the disease the characteristic signs of the various complications may appear.

For general, abdominal and cerebral symptoms and complications, see pp. 330, 331.

Course.—This is chronic: the disease often persists for years, without giving rise to any acute disturbance apart from periodic hæmoptysis.

Diagnosis.—Distinction from other forms of hæmoptysis is accomplished by discovering the ova in the sputum. To facilitate the examination a little 0.1 per cent. sulphuric acid should be added to it.

Prognosis.—The immediate prognosis is good, the ultimate unfavourable, as there is considerable difficulty in eliminating the parasites, and permanent damage is wrought in the lungs when they settle there.

Treatment.—Prophylaxis is important where the disease is endemic. No bathing should be allowed in infected rivers, and all water used for drinking or washing should be boiled or filtered. Crabs should not be eaten. When the disease has developed the patient should move from the infected area. Potassium iodide (grs. x-xx, t.d.s.) is recommended, but other treatment is symptomatic.

HYDATID DISEASE OF THE LUNG

Hydatid cysts may develop in the lung in patients infected by the ova of the *Tænia echinococcus*.

Ætiology.—Man is the intermediate host of this parasite, and becomes infected directly or indirectly from the dog. The modes of infection and the life history of the parasite are elsewhere considered. Males are more often affected, and the condition is commoner among the poor than the well-to-do. It is rarely seen in this country except in patients from abroad, especially from Australia.

Pathology.—Hydatid cysts have been described in the lungs in from 5·6 to 16·8 per cent. of cases of hydatid disease in different parts of the world. The right lung is more often the site of the disease than the left, and the cyst is usually basic, though it may occur in the upper parts of the lung. It is generally supposed that infection of the lung is usually secondary to the liver, the ova reaching the lung through the diaphragm; but the occurrence of primary lung hydatid suggests the possibility of the embryo gaining access to the general blood stream, and thus reaching the lung by the pulmonary artery. There is, as a rule, a single cyst in the lung, but multiple or multilocular cysts are occasionally observed. The cyst may become as large as a cricket ball, but usually ruptures before it reaches this size. It has the same structure as hydatid cysts of other organs, with ectocyst and endocyst. It may develop brood capsules and daughter cysts, but is often sterile in this situation.

The reactive changes in the lungs are at first irritative and congestive, but eventually some fibroid changes occur, producing a more or less definite fibroid capsule around the ectocyst. The overlying pleura may become inflamed, thickened and adherent when the cyst grows near the surface. Rupture may occur into a bronchus, into the pleura, pericardium or peritoneum, or occasionally into the pulmonary vein. Rarely the contents of a small cyst may become inspissated, thus producing spontaneous cure.

Symptoms.—Until the cyst becomes large enough to cause irritation, there may be no symptoms, but sooner or later cough and expectoration develop. The latter is generally mucoid, and frequently bloodstained. Dyspnoea becomes apparent and pain results if the pleura is involved. The signs may be: diminished vocal fremitus, localised dullness and weak or absent breath-sounds and voice-sounds over a limited area, generally in the lower lobe. A few râles may be audible round the dull area. Occasionally with a large cyst there may be some bulging on the affected side, and “hydatid fremitus” has been described. The heart may be displaced in rare cases. Examination by the X-rays generally shows a suggestive rounded shadow with very little change in the surrounding lung, except in chronic cases where some fibrosis may be observed.

Some degree of eosinophilia is common but not invariable. When rupture into a bronchus occurs, there is usually sudden copious expectoration of watery fluid containing hooklets. Daughter cysts and parts of the ectocyst may be coughed up and lead to dyspnoea and even suffocation from laryngeal obstruction.

After rupture, spontaneous cure may result if the ectocyst is expectorated.

More commonly the cavity becomes infected and the symptoms and signs become those of chronic abscess (see pp. 1080, 1081). Rupture into the pleural cavity produces great pain, dyspnoea, cyanosis and shock, similar to the condition induced by pneumothorax. Rupture into the pericardium or into a vein is usually quickly fatal. When rupture occurs into a serous cavity, urticaria and severe toxic symptoms sometimes develop.

Course.—This is generally progressive, though occasionally spontaneous cure occurs either before or after rupture. More commonly the cyst causes increasing pressure or irritative symptoms, and eventually rupture or suppuration produces acute manifestations.

Diagnosis.—The clinical features of pulmonary hydatid may be suggestive of pulmonary tuberculosis, pleural effusion or new-growth. Diagnosis may be difficult before rupture occurs; after this the discovery of hydatid hooklets or pieces of cyst-wall may establish the diagnosis. In suspicious cases the X-ray findings may be of great assistance, and confirmatory evidence may be obtained from cytological and serological examination. The former frequently shows eosinophilia, and the latter gives complement deviation when a suitable antigen, such as extract of hydatid cyst-wall, is used. A precipitin reaction may also be obtained with the fluid from another cyst.

Prognosis.—The prognosis is serious owing to the risks of rupture and suppuration. Spontaneous cure is rare, but can occur. After rupture into a bronchus, recovery may ensue, but more commonly abscess formation results. Rupture into a serous cavity is frequently fatal. Early surgical treatment either before or after rupture improves the outlook.

Treatment.—Aspiration of the cyst, either exploratory or therapeutic, is to be avoided. If the cyst can be diagnosed and localised before rupture, the lung should be exposed by thoracotomy, the pleura stitched together and the cyst incised, the endocyst removed, and the cavity drained. Suppuration of a pulmonary hydatid must be treated as a pulmonary abscess.

THE PNEUMONIAS

The term pneumonia has been somewhat loosely applied to any inflammatory condition of the lung producing consolidation. When the consolidation affects large areas of lung uniformly it is described as lobar pneumonia, and when it is patchy or lobular in distribution it is called lobular or broncho-pneumonia.

LOBAR PNEUMONIA

Synonyms.—Croupous or Pleuro-Pneumonia.

Definition.—This is an acute infectious disease characterised by an inflammatory lobar consolidation.

Ætiology.—*Predisposing causes.*—Pneumonia may occur at any age. It is common in children up to the sixth year, the incidence being about equal in the two sexes. It is commonest between the ages of 15 and 40, when there is a preponderance in the male sex of two or three to one. It is also a fre-

quent terminal malady in the aged of both sexes. It may be doubted whether race has much influence, although in America and in the Rand mines the incidence and mortality among the black races are both high. Pneumonia is met with all over the world, but it is more rife in localities with changeable climate and cold winds. Its seasonal incidence is well marked; it is uncommon in the summer and autumn, and is most prevalent from November to March in this country. Although pneumonia is as a rule endemic and sporadic in its incidence, it is generally admitted that localised epidemics occur. Recent studies of its bacteriology lend support to this view. Urban conditions, defective sanitation, overcrowding and insufficient ventilation all conduce to the incidence of pneumonia. A previous attack of pneumonia is an important predisposing condition, since this disease seems to confer an increased susceptibility, although this may be preceded by a brief period of relative immunity. It is not uncommon to obtain a history of several previous attacks. Although the disease often attacks those in normal robust health, there can be no doubt that debilitating conditions and diseases predispose to it, among them being chronic nephritis, diabetes, over-fatigue, exposure and alcoholic excess.

Exciting causes.—The exciting cause in most cases is the presence of the pneumococcus of Fränkel in one of its more virulent forms. It may be the only pathogenic organism found in the lung lesions and in the sputum, but not infrequently others, such as streptococci, staphylococci or Pfeiffer's bacillus are also present. Occasionally these organisms, and others, such as Friedländer's pneumo-bacillus, the *Bacillus typhosus*, the gonococcus and the *B. pertussis*, cause lobar consolidation; but these conditions should be regarded as varieties of secondary pneumonia, and differentiated from the acute primary condition now under consideration.

The pneumococcus.—The pathogenicity of the pneumococcus has been the subject of an interesting study at the Rockefeller Institute, New York, by Cole, Dochez, Avery and Gillespie. By serological reactions they have separated four types. The organisms of types I., II. and III. are clearly defined and account for about 75 per cent. of the cases of pneumonia investigated. They differ in virulence, type III. producing a more serious form of pneumonia with a high mortality, but fortunately it is the least common form. This organism has a somewhat characteristic morphology and distinctive cultural appearances. It is sometimes described as the *Pneumococcus mucosus*, and is probably identical with the *Streptococcus mucosus* of Schött-müller. Specific agglutinating serums exist for each of these three types. Type IV. is a heterogeneous group of organisms, mostly of low virulence, and no common agglutinating serum exists for them. It is now generally referred to as group IV. They are frequently present in the mouth and saliva of healthy persons, but may cause a mild form of pneumonia with a low mortality, and they are commonly found in pneumococcal lesions in other situations than the lungs. It is probable that other types exist, since F. S. Lister found that among the cases he investigated in South Africa types I and II. were common, but nearly one-third of the cases were associated with one and perhaps two types which were not described in the New York cases.

The American observers have shown that 40 per cent. of contacts with cases of pneumonia due to types I. and II. may harbour the corresponding

organism for an average period of 23 days, and that they may develop pneumonia from it. They have further demonstrated that a convalescent patient may carry pathogenic pneumococci in his mouth for as long as 90 days from the onset of the disease. They have also found pathogenic pneumococci in the dust of rooms in which patients suffering from pneumonia have been nursed, whereas in other rooms only the relatively non-virulent type IV. has been found. The significance of this work is obvious. It confirms the view that pneumonia is an infectious disease, capable of being spread by carriers, by the convalescent patient, and by the dust of rooms.

Although the pneumococcus is the specific exciting cause, its activities are often determined by some other factor, such as chill, exposure, over-exertion or injury. The presumption is that these conditions lower the general resistance of the individual, and thus impair the defensive mechanisms. Post-operative pneumonia may be a further instance of this, but doubtless some supposed cases are in reality due to lobar collapse.

Pathology.—The pneumococcus can be found in the blood, in the pulmonary lesions, and elsewhere when complications occur. Recent experimental investigations on animals indicate that the avenue of infection is to the lungs by way of the trachea and bronchi, the blood infection being secondary to the pulmonary lesion. This is in opposition to the view, current till recently, that infection occurred from the mouth or pharynx to the blood and thence to the lungs. Four stages are commonly described in the process by which the lung becomes consolidated and returns to normal, namely, engorgement, red hepatisation, grey hepatisation and resolution.

In the stage of engorgement the affected part of the lung is slightly enlarged, deep red in colour, and heavier than normal, although it still crepitates and floats in water. The pleura over it may be injected and lustreless and may even show early fibrinous exudate. On section, the hyperæmia is obvious and there may be some œdema. On squeezing, frothy, bloodstained fluid exudes. Microscopically, the engorgement of the capillaries, the swelling and partial desquamation of the alveolar epithelium are the chief changes to be noted. In the stage of red hepatisation the affected area becomes completely consolidated, the general aspect on section being remotely similar to liver, hence the name hepatisation. The pleura is now notably inflamed and may be obscured by yellow fibrinous exudate. The hepatised area of lung is larger and much heavier than normal and bears the impress of the ribs upon it. On section, it is seen to be red in colour, solid and completely airless. It does not crepitate and it sinks in water. The lung tissue is found to be more friable than normal. On scraping the cut surface, which has a granular appearance, a reddish fluid is collected, containing small fibrinous plugs, which are practically alveolar casts. Microscopically, the alveoli are occupied by a coagulated exudate rich in fibrin and red blood corpuscles, with scanty leucocytes and a few larger cells derived from the alveolar epithelium. In the stage of grey hepatisation the lung tissue, although still solid, airless and non-crepitant, is greyish in colour, softer in consistence and still more friable. The surface of the section is less granular, and on scraping, a pale yellowish, almost puriform fluid is obtained. Microscopically, the blood vessels are found to be relatively empty, the alveoli are now incompletely filled, the fibrin and red corpuscles have largely disappeared, and the alveoli are occupied by leucocytes and

desquamated alveolar cells. In the stage of resolution, the exudate becomes more liquid and its cellular constituents undergo fatty degeneration. The liquefied exudate is largely absorbed, although expectoration may possibly assist in its removal. The lung returns to its normal spongy state and the alveolar epithelium is replaced. Some pleural thickening or adhesion may, however, result. In very severe and fatal cases, the stage of resolution may be replaced by one of purulent infiltration, in which the lung becomes paler, softer and in places almost diffuent. The scrapings are practically purulent.

Although these four stages are described, it should be remembered that they are not sharply defined from one another, and that they only represent special appearances in a continuous process. Consequently, although the major part of the affected area of lung may be characteristic of any one of them, all four stages may be recognisable, especially in cases of a spreading type. The base is more often affected than other parts, and the right side more than the left, in the ratio of 3 to 2. The unaffected parts of the lung may show some catarrhal bronchitis, or some degree of collateral hyperemia or cedema. Pleurisy is an integral part of the affection, but it may proceed to serous or purulent effusion. Pericarditis and less frequently acute endocarditis may be found in fatal cases. Pneumococcal meningitis, arthritis and otitis are very occasionally observed. The liver and kidneys may show cloudy swelling, and the spleen is often slightly enlarged and soft. Jaundice may be observed, especially in right-sided cases. The right side of the heart may be engorged and dilated.

Symptoms.—The exact incubation period is not yet established, but it is short, being probably from 1 or 2 days up to a week. The onset is sudden and acute, with chill, shivering or rigor in the majority of cases. In children convulsions take the place of rigors. Vomiting at the onset is not infrequent, occurring in about one-third of the cases. Less commonly the onset is insidious, or is preceded by malaise and catarrhal symptoms. The temperature rises with the rigor, and as a rule a short, dry, irritating cough develops quickly, accompanied by a severe cutting pain on the affected side. The pain often becomes intense, and coughing may cause the patient great distress. The cough is frequently restrained as much as possible, and the breathing is rapid and shallow. By the second or third day the pain becomes less and the cough easier and more effective. Sputum, which at first is scanty, extremely viscid, tenacious and difficult to expectorate, now becomes more abundant, although remaining viscid. In typical cases it is characteristically rusty at this stage, containing mucus, altered red blood corpuscles, alveolar epithelium and large numbers of pneumococci. In a few instances a small but definite hæmoptysis occurs. Occasionally the sputum is thinner and of "prune juice" type.

Sleeplessness is often a distressing symptom, especially in the early and late stages. In some cases there are marked cerebral symptoms. Headache at the onset is common. Delirium is frequent, particularly in the asthenic type, in apical cases, and in alcoholics. In the latter it may be violent and is often like delirium tremens. The temperature is usually of high continuous type throughout, reaching 103°, 104° and even 105° F. or more on occasions, especially in the sthenic type. In the asthenic it is often of lower range. Defervescence is by crisis in about 60 per cent. of the cases. Crisis is commoner in the sthenic type, and occurs more often on the odd than on

the even-numbered days of the disease. The most common day for the crisis is the seventh. It is rare before the third or after the ninth day. At the crisis the temperature falls to normal or subnormal in about 12 hours. The patient often sleeps soundly at this time and may sweat profusely; respiration is slower and easier and the pulse-rate falls. On waking, a dramatic change in the condition is usually noticeable. Pain and distress are ameliorated, cough is loose and easy, and the patient feels better, although weak. Looseness of the bowels and free diuresis are not infrequent, constituting the "critical evacuations." The crisis is sometimes preceded by a pseudocrisis, in which a considerable fall of temperature occurs, with little or no improvement in the general condition. A slight post-critical rise of temperature of 1° or 2° F. is sometimes seen, but as a rule the temperature remains subnormal for a few days and slowly returns to normal. The pulse-rate may be slow for a time. Convalescence is generally rapid, although in cases which have had marked delirium, some mental confusion may be present for a day or two. Defervescence by lysis is more common in the asthenic type. The temperature remits and may take from 2 to 4 days to reach normal or subnormal levels.

The physical signs vary with the stage of the disease. At first there is some restlessness, but soon the patient assumes a dorsal decubitus, or lies more on the affected side. The cheeks are flushed, often markedly so on the side of the lesion. The eyes are bright, but the expression is one of pain or anxiety. A crop of herpes on the lips is very common. The tongue is thickly coated and white, becoming dry and cracked in bad cases at a later stage. The skin feels dry and pungently hot. The *alæ nasi* are in action, and in children a puff or grunt accompanies each expiration, while the pause follows inspiration, instead of expiration. The respiration and pulse-rate are increased, the former disproportionately, so that the pulse respiration ratio becomes 3 or even 2 to 1, instead of the normal 4 or 5 to 1.

In the early stage the pulmonary signs are slight. At the most there is lessened movement and diminished vocal fremitus over the affected area, with dubious impairment of note, weak air entry and possibly a few crepitations (indux), or pleural friction sounds, vocal resonance being unaltered. Of these, lessened air entry is probably the most common. Slight hyperresonance of the opposite lung, with harsh breathing, may lead to error in diagnosis as to the side affected.

The signs of consolidation (hepatisation) are generally apparent on the second or third day, except in cases where the disease starts deeply (central pneumonia). There is definite limitation of movement on the affected side, which is, however, slightly increased in size, as can be demonstrated by mensuration. Vocal fremitus is markedly accentuated over the affected area except in massive pneumonia, and friction fremitus may be palpable. The note on percussion is dull, but has not the resistant stony character of that over an effusion. The note above or below the consolidated area is sometimes skodaic. The breath-sounds are tubular, and a few crepitations may be heard, but frequently adventitious sounds are absent. In some cases a friction rub is audible. Bronchophony and pectoriloquy are usually very marked over the consolidated area. The breath-sounds in other parts may be vesicular or harsh, and a few rhonchi may be present. The heart is usually in its normal situation, but is sometimes slightly displaced away

from the affected side. In later stages the signs of dilatation of the right heart may become apparent.

During resolution, which begins after the crisis or during lysis, the tubular character of the breath-sounds disappears, and they become at first bronchial and later harsh or vesicular. Coarse moist sounds, known as *redux crepitations*, are heard both with inspiration and with expiration. The dullness gradually diminishes, and the voice-sounds return to normal. In basal cases, in which the diaphragmatic pleura is involved early, there may be pain, tenderness and abdominal rigidity simulating peritonitis, perforation or appendicitis. X-ray examination is usually not practicable, and in any case should only be employed where diagnosis is in doubt. It is rare for the spleen to be sufficiently enlarged to be palpable. The blood shows a leucocytosis up to 40,000 or 50,000 per c.mm. in sthenic infections. Blood culture may yield pneumococci, although this was successful in only 30 per cent. of cases at the Rockefeller Institute. The urine is diminished in quantity, and there is a great reduction in the sodium chloride excretion until the crisis. Albumin and albumose are frequently found in small quantities in the urine during the febrile stage, and a few granular casts may be present. The uric acid excretion is increased to two or three times the normal, commencing the day before the crisis and generally falling to normal during the ensuing week. This is probably due to disintegration of the exudate in the alveoli, and so forms a measure of resolution, although some authorities maintain that it runs parallel with leucocytosis and not with cell destruction. Palmer has recently shown that an organic acid of unknown nature is excreted in the urine in considerable quantities in many cases of pneumonia with severe intoxication, but estimation of the CO_2 in the plasma shows that the degree of acidosis produced is not great. Pneumococci can sometimes be obtained from the urine at the height of the disease. The blood-pressure usually falls during the course of pneumonia, and according to G. A. Gibson a sudden rise indicates the imminence of some complication, such as delirium, whereas a sudden fall suggests the onset of cardio-vascular paralysis.

The disease does not always follow the typical clinical course, and certain varieties are described:

Apical pneumonia.—The consolidation may be limited to the apex or upper lobe of one lung. This is more common in children, the aged and alcoholics, and is often associated with marked cerebral symptoms.

Creeping pneumonia (Migratory or wandering pneumonia).—The consolidation spreads irregularly in one or both lungs. Partial resolution occurs, but there is no true crisis, and as successive portions of the lungs become involved the temperature exacerbates, eventually falling by lysis in cases that recover.

Central pneumonia.—The symptoms and appearance of the patient may suggest lobar pneumonia, and yet no abnormal signs can be detected in the lungs. In some of these cases there may be a deep-seated consolidation, whose presence can be revealed by X-rays. A typical crisis may occur.

Massive pneumonia.—The bronchi, as well as the alveoli, may be filled with a fibrinous exudate. It is a rare condition and leads to difficulty in diagnosis, as the physical signs resemble those of pleurisy with effusion, vocal fremitus being diminished and breath-sounds weak or absent. The heart, however, is not displaced, or only slightly so.

Post-operative pneumonia.—It is probable that a large proportion of cases that were formerly described as post-operative pneumonia were in reality instances of massive lobar collapse (see p. 1068). At times a pneumococcal pneumonia follows the administration of a general anæsthetic, but it does not present any peculiar features.

Traumatic pneumonia.—The fact that an injury to the chest may be followed after a short interval by a pneumonic process in the lungs has long been recognised. The condition was called “contusional pneumonia” by Litten in 1881. Külbs showed later that the changes in the lungs in dogs following local trauma were mainly hæmorrhagic, and that the lung opposite to the side injured may be affected by “contre-coup.” In the recorded cases of traumatic pneumonia two types can be differentiated—(1) those with hæmorrhagic lesions only, and (2) those showing hæmorrhagic foci with a superimposed bacterial infection. The former recover rapidly, the latter often lead to a fatal issue.

Pneumonia in children.—This often presents certain characteristic features. There is rarely any sputum, the expectoration being swallowed. Convulsions at the onset are common. The lesion is often at the apex of the lung. Cerebral symptoms are frequent, and empyema or otitis media often occurs as a complication.

Pneumonia in the aged.—This occurs frequently as a terminal infection, often leading to a rapid and comparatively painless death. The onset may be insidious and the physical signs slight.

In *pneumonia in the insane*, lobar consolidation is often observed, without marked constitutional disturbance other than fever.

Secondary pneumonia.—Lobar pneumonia may develop during the course of certain acute specific fevers, notably enteric, typhus and plague. It is doubtful whether a true lobar pneumonia occurs in influenza, the condition to which the name influenzal pneumonia is applied being due to coalescing lobular pneumonia with hæmorrhagic extravasations.

Complications.—Delayed resolution not infrequently occurs, the signs of consolidation persisting for weeks instead of days. Frequent careful examinations should be made and possible errors in diagnosis considered, such as the presence of tuberculosis or empyema. Gangrene and abscess are rare but recognised complications.

Dry pleurisy is an invariable accompaniment when the consolidation reaches the surface, and in a considerable proportion of cases slight serous effusion occurs. This occasionally becomes frankly purulent and an empyema results. Bronchitis is common and may be due to a complicating secondary infection. Cardiac failure is a grave occurrence and can be recognised by increasing cyanosis, lividity and dyspnoea, with signs of enlargement of the right heart and with enfeeblement of the heart-sounds. Pericarditis is not very uncommon and is a serious complication. It may be dry or proceed to serous or purulent effusion. Acute endocarditis, sometimes of infective type, occurs. Abdominal complications are comparatively rare. They include pneumococcal peritonitis, colitis and nephritis. Acute dilatation of the stomach occurs in rare cases, and is usually rapidly fatal. Meteorism is more common and, although serious, is more amenable to treatment. Jaundice, due to catarrh of the bile-ducts, or to hæmolysis, is sometimes present.

Pneumococcal meningitis supervenes in rare cases, and is invariably

fatal. Delirium has already been referred to, and is especially serious when occurring in alcoholics. Peripheral neuritis has been described, but is very uncommon. Otitis media and arthritis, proceeding sometimes to suppuration, occur as complications, both being commoner in children. A parotitis sometimes going on to suppuration, is an occasional and serious complication, especially in old people. During convalescence, thrombosis of the veins of the legs may occur in rare instances.

Sequelæ of lobar pneumonia are uncommon. Perhaps the most remarkable is the liability to subsequent attacks. Some permanent pleural thickening or adhesion may occur, and after an empyema the usual sequelæ may result. Pulmonary fibrosis (chronic interstitial pneumonia) is rare, especially in comparison with its frequency after broncho-pneumonia; this may lead to bronchiectasis.

Course.—The course depends on the type and virulence of the infection and on the resistance of the patient. In a typical sthenic case, consolidation is well established by the second or third day, defervescence by crisis occurs usually on the seventh day, signs of resolution become apparent a day later, and all signs clear up within 14 days of the onset. In asthenic cases the course is less typical and often prolonged to 9 or 10 days, defervescence occurring by lysis. In fatal cases, death commonly occurs between the fourth and tenth days, although severe cases may prove fatal as early as the first or second day. After the tenth day a fatal result is generally due to complications. An abortive course is described, in which typical symptoms occur with slight or indefinite signs, the temperature falling by crisis within 36 hours, followed by rapid recovery. This group includes the "*maladie de Woillez*." It is difficult in many instances to establish the true causation of such cases.

Diagnosis.—When the disease is well established and the history is available, diagnosis is as a rule easy. To prove the pneumococcal origin, sputum examination, lung puncture, or blood or urine culture is necessary. It would seem probable that in the future the investigation of serum reactions will be necessary to establish the type of pneumococcus concerned as an essential to specific treatment.

At the onset, especially before the signs of consolidation develop, difficulties in diagnosis often occur. The initial rigor or convulsion with vomiting may suggest scarlet fever. In children, especially those with early apical pneumonia, headache, vomiting, convulsions, head retraction, squint and even slight Kernig's sign may lead to an erroneous diagnosis of meningitis. Pain in the side and cough, the altered pulse respiration ratio, and the presence even of slight abnormal physical signs in the chest, usually suffice in both instances to suggest the correct explanation.

Occasionally the onset of pneumonia may simulate an acute abdominal condition, such as appendicitis or perforation of a gastric ulcer, owing to referred abdominal pain, sometimes with rigidity. The diagnosis may be very difficult, and laparotomy has not infrequently been carried out in error. The history, the pulse respiration ratio, the absence of tenderness on rectal examination, and the presence of pulmonary signs usually enable a correct decision to be made.

Influenza may start acutely and simulate pneumonia, but the distribution of the signs and the examination of the sputum generally serve to dis-

tinguish between them. Typhoid fever less often gives rise to difficulty, but some cases of pneumonia pass quickly into a typhoid state, while some cases of typhoid fever develop consolidation in the first week.

When consolidation is well established, the chief conditions to be differentiated are—(1) Broncho-pneumonia. The slower onset, the more prolonged course, the bilateral patchy physical signs, and the marked predominance of the bronchitic manifestations usually suffice to differentiate this group of conditions. (2) Secondary pneumonias, such as those in plague, typhoid fever, and influenza, can be diagnosed only from the history, the associated symptoms and signs, and from the bacteriological examinations. (3) Friedländer's pneumonia is rare. Its course is short, its prognosis grave, and it can only be recognised by bacteriological investigation. (4) Massive collapse. The diagnosis of this condition and its differentiation from pneumonia are discussed on pp. 1068, 1069. (5) Acute pneumonic tuberculosis. The onset and early signs may be identical with those of pneumonia. The persistence of the fever, its tendency to become remittent or intermittent, and the occurrence of night sweats should suggest looking for tubercle bacilli in the sputum. (6) Pleural effusion and empyema. Differentiation is generally easy, except in cases of massive pneumonia. Investigation of the position of the cardiac impulse, and of vocal fremitus and resonance, affords the most valuable aid. Grocco's triangle may also assist. In some cases the diagnosis can only be established by the exploring needle. (7) Intarction of the lung in cardiac disease, causing pain, cough, blood-stained expectoration, and dyspnoea, may simulate pneumonia. The absence of fever, the presence of the cardiac condition and the localised physical signs are generally characteristic. (8) Acute oedema of the lung, especially in mitral stenosis, may suggest pneumonia. Fever is generally absent, the sputum is typical, and the primary cause may be apparent. An attack of paroxysmal tachycardia may give rise to difficulty, when it leads to dullness and crepitations at the bases, but careful examination should establish the very rapid action of the heart and the evidence of venous engorgement in other parts.

Prognosis.—Lobar pneumonia is a serious disease, with a high mortality rate. This is profoundly influenced by age. It is but little fatal in childhood, except in the first years of life. After the age of 60, it may show a mortality of 60 to 80 per cent. The New York investigations at the Rockefeller Institute have demonstrated the importance of the type of pneumococcus in prognosis; thus, it was found that the mortality of cases with types I. and II. was about 25 to 30 per cent., of those with type III. 50 per cent., and of those with type IV. only 12 per cent.

The previous habits and history of the patient influence prognosis considerably; chronic alcoholism doubles the risk of a fatal issue, and the outlook is grave in patients who are the subjects of diabetes, chronic cardio-vascular disease, nephritis, marked debility or obesity. Unfavourable indications during the course of the disease are profound toxæmia, a pulse-rate persistently 130 or more, a blood-pressure in millimetres of mercury lower than the pulse-rate, and a temperature remaining at 105° F. or over for several days. Absence of the usual leucocytosis is generally of sinister import. Dilatation of the right heart, with cyanosis progressing to lividity, is most grave. Modern statistics confirm the traditional view that labial herpes is a favourable prognostic sign.

Of complications, meningitis is invariably fatal, while infective endocarditis is extremely grave. Cases with abscess or gangrene, although serious, sometimes recover, especially if operative treatment is practicable. The prognosis of those with pericarditis is serious, but not uniformly unfavourable. Cases with bilateral empyemata show a high mortality. Late delirium is a very serious indication.

Treatment.—*Prophylactic.*—Prophylactic vaccination has been used with success by Lister in South Africa. He employed a triple vaccine, made from three types, and gave 6000 millions of each. Three injections were made at weekly intervals.

When a case has occurred, all contacts should have a throat examination, and if virulent pneumococci are found a suitable antiseptic mouth wash should be used. Quinine preparations have a high pneumococcicidal action. The best is optochin or ethyl-hydrocupreine hydrochloride, or else quinine bisulphate in a dilution of 1 in 10,000 with liquor thymolis diluted 1 in 10. The room in which the patient has developed the disease should be disinfected afterwards. If possible, no case of pneumonia should be nursed in a general ward of a hospital, and the doctor and nurse in attendance should wear gauze masks. All sputum should be disinfected. The patient should lie in a narrow bed away from a wall to facilitate nursing. The room should be well ventilated, and the temperature maintained at 60° to 65° F. Treatment in the open air is not advisable, except in very mild weather. Two important factors are rest and sleep. The patient should, therefore, be disturbed as little as possible by the examination of the physician and by the attentions of the nurse. He should not, however, be allowed to lie flat all the time, to avoid basal congestion. The diet should be restricted to fluids and semi-solids, eggs, milk, meat extracts and the various invalid foods being given up to 2 or 3 pints in the 24 hours. Too much milk should be avoided, as it is liable in adults to cause indigestion and flatulence. The irritating cough, which induces such intense pain, should be checked by a sedative linctus, or by lozenges, but it may be necessary to inject $\frac{1}{2}$ th grain heroin, or even $\frac{1}{4}$ th grain morphine to relieve pain and to induce sleep in the early stage. Local applications to the chest help to relieve pain. Usually hot linseed poultices to the back and side are employed, but anti-phlogistine applied on lint does not require such frequent changing and disturbs the patient less. A pneumonia jacket is preferred by some, by others the ice poultice or ice-bag is found very soothing. A dose of calomel should be given at the onset, and the bowels should be opened daily, either by a laxative or by a small soap enema.

Medicinal treatment has probably but little influence on the course of the disease, and should be in the main symptomatic. In the early stage, a simple saline diaphoretic mixture may give comfort by promoting the action of the skin and by rendering the sputum less viscid. For this purpose liq. ammon. acetat. \mathfrak{ss} , potass. citrat. grs. xx, syrup. aurantii \mathfrak{ss} and water to the ounce, may be given every 4 to 6 hours. The use of depressant drugs, such as tartar emetic, aconite, or pilocarpine, although formerly recommended, is now generally discarded. Expectorants such as ammonium carbonate or iodide of potassium in doses of 3 to 5 grains are often recommended after the second day, but are of doubtful utility. Potassium iodide in doses of 5 to 10 grains, with creosote 5 minims, in a mixture, had a recent vogue, but it

may be doubted whether its beneficial effects are commensurate with its unpleasantness and its bad influence on appetite and digestion.

Cardiac embarrassment and failure are the conditions requiring the most active treatment in this disease. A careful watch should be kept upon the colour of the patient, the condition of the pulse and the size of the heart. Digitalis, in doses of 5 to 15 minims of the tincture, may be added to the mixture, or given with brandy. Camphor grs. xx, in sterile olive oil $\mathfrak{z}\text{ij}$, may be given hypodermically every other day, or smaller doses may be given once or twice daily. If signs of acute heart failure occur, strophanthin gr. $\frac{1}{200}$ may be given intravenously, or digitalin gr. $\frac{1}{100}$ with strychnine sulphate or hydrochloride gr. $\frac{1}{60}$ to $\frac{1}{30}$ hypodermically. The latter may be repeated in from 4 to 6 hours if necessary. Strychnine may be given in doses of gr. $\frac{1}{60}$ every 4 hours, and is often very useful. Other cardiac tonics which may be employed hypodermically are pituitrin $\frac{1}{2}$ to 1 c.c., or adrenalin 5 to 10 minims of 1 in 1000 solution. Alcohol is often useful; it should not be given too early in the attack, but where there are indications of incipient cardiac weakness 4 to 6 ounces daily may be given, and this even to alcoholics.

Oxygen inhalations may be helpful in any case where there is distress or cyanosis. It should be warmed, and may be bubbled through alcohol or administered more economically through a nasal tube. Venesection to the extent of 10 or 12 ounces is of some value if there is lividity from right-sided engorgement, especially in sthenic cases. As a rule it is best not to interfere with the temperature by antipyretic drugs and measures unless it remains over 104° F., when sponging, either tepid or cold, should be tried.

Sleeplessness is a frequent and distressing symptom and requires treatment. In the early stages 10 grs. of Dover's powder or an injection of morphine or heroin are usually effective. In the later stages, morphine should only be given with care, and then in association with atropine gr. $\frac{1}{60}$ to $\frac{1}{100}$ and strychnine gr. $\frac{1}{60}$ to $\frac{1}{30}$. Paraldehyde $\mathfrak{z}\text{ij}$ with syrup of orange in 2 ounces of water, is safe and often effective. Chloralamide grs. xx to xxx, with bromides may be tried. In cases with delirium an ice-cap should be applied to the head, and the patient sponged with tepid water. Morphine may be necessary, and in severe cases hyoscine, gr. $\frac{1}{100}$, may be injected; but the latter is a dangerous drug and the patient's condition should be watched, and strychnine administered if necessary. Tympanites, when present, is distressing and exhausting, and should be treated by passing a rectal tube or by the administration of an enema of asafoetida or a turpentine wash-out.

Specific.—Various serums have been introduced and employed with varying success. The researches at the Rockefeller Institute afford the explanation of the discordant results, and promise to put this matter on a scientific and practical basis. So far an effective serum seems to have been obtained only for type I., although serum has been prepared for type II., but is less effective. At present antisera have not been obtained for type III. and group IV. Consequently, if it is proposed to employ serum treatment, it is necessary first to determine the type of pneumococcus concerned by serological tests. The patient's sensitiveness to the serum must then be determined by an intradermic injection of 0.02 c.c. of diluted serum (diluted $\frac{1}{10}$ with saline), and if he shows a reaction he must be desensitised by small injections to prevent anaphylaxis. The serum is then diluted with an equal volume of warm sterile saline and 10 to 15 c.c. injected intravenously.

at the rate of 1 c.c. a minute, followed by 90 c.c. more during the next quarter of an hour. This dose is repeated every 8 hours until improvement occurs.

Vaccine treatment is recommended by some, but the results are generally disappointing during the acute stage. A common method is to give 20 millions of a stock pneumococcus vaccine, and then to use an autogenous one as soon as it can be made. Sensitised and detoxicated vaccines have also been prepared. Vaccines seem to be more valuable in cases of delayed resolution.

BRONCHO-PNEUMONIA

Synonyms.—Lobular Pneumonia; Catarrhal Pneumonia; Capillary Bronchitis.

Pulmonary consolidation of lobular distribution occurs in a variety of conditions which have little else in common. A satisfactory classification is at present difficult. The term capillary bronchitis is misleading and should be regarded as obsolete, since any inflammatory condition affecting the finer bronchi is invariably associated with alveolar changes. For convenience the following varieties of broncho-pneumonia may be described: (1) Primary. (2) Secondary. (3) Aspiration or deglutition. (4) Tuberculous.

1. PRIMARY BRONCHO-PNEUMONIA

Ætiology.—This form almost invariably affects infants under 2 years of age, in whom a lobular pneumonia seems sometimes to occur under conditions which would induce lobar pneumonia in older children or adults. It occurs equally in the two sexes, and is commoner in the winter and the spring. Rickets, malnutrition and debility are predisposing conditions, but it sometimes develops in healthy robust infants after exposure or chill. The pneumococcus is the organism usually found, either alone or in association with others, such as streptococci, staphylococci, the *Micrococcus catarrhalis* or Friedländer's pneumo-bacillus.

Pathology.—Widely scattered patches of consolidation are found in one or both lungs. These may be small and separated by areas of collapse or emphysema. Occasionally they are almost confluent, and at first sight appear like lobar pneumonia, constituting the pseudo-lobar form; but careful observation shows that the distribution is lobular and that zones of incomplete consolidation or of normal lung tissue separate the solid areas. If the process reaches the surface some degree of pleurisy is present, although this is less than in lobar pneumonia.

Microscopically, the appearances approximate to those of the lobar form; the alveoli are found to be filled with exudate, in which leucocytes and desquamated epithelial cells are present, together with some fibrin and red blood corpuscles. Catarrhal changes are also present in the bronchi.

Symptoms.—The onset is acute, with vomiting and chill, or convulsion, as in lobar pneumonia. Cough, cyanosis and dyspnoea develop rapidly. There is no expectoration, since infants and young children swallow the sputum. Cerebral symptoms simulating meningitis are common. The

temperature rises quickly to 103°, 104° F., or higher, and the range is of the same character as in lobar pneumonia. Defervescence by crisis is the rule.

The physical signs are variable. In cases with widespread consolidation they are very similar to those of lobar pneumonia, with dullness, tubular breathing, increased voice-sounds and crepitations. In other cases, although the aspect of the infant appears characteristic of pneumonia, with rapid breathing, cyanosis, reversed rhythm of inspiration and expiration, sucking in of the lower ribs and dilatation of the *alæ nasi*, the signs are more scattered. Tubular breathing and increased voice-sounds may only be heard in localised patches, especially in the lower lobes. Crepitations are commonly present, and rhonchi may be audible over both lungs.

Complications and Sequelæ.—These are similar to those of lobar pneumonia.

Course.—This is usually short, the temperature falling by crisis in from 3 to 7 days, but it may be more prolonged and be suggestive of tuberculosis, or some other form of secondary bronchitis.

Diagnosis.—Primary broncho-pneumonia has to be distinguished from the lobar form, to which ætiologically and pathologically it is so closely related. The acute onset without previous respiratory symptoms will suggest its primary character, while the patchy distribution of the signs generally suffices to establish its lobular distribution. In pseudo-lobar forms, this differentiation may be almost impossible during life. The cerebral symptoms at the onset, and the early absence of pulmonary signs may give rise to difficulty, as in the first stage of lobar pneumonia.

Prognosis.—The prognosis of primary broncho-pneumonia is generally favourable, except in very young or debilitated infants.

Treatment.—This is practically identical with that of secondary broncho-pneumonia in children.

2. SECONDARY BRONCHO-PNEUMONIA

In this condition there is inflammation of the bronchi, spreading down to and involving the alveoli. It is generally a catarrhal process, but may go on to septic or suppurative manifestations.

Ætiology.—A secondary broncho-pneumonia may occur at any age, but is much more common in early and advanced life. It is equal in its incidence in the two sexes. It frequently occurs as a complication of measles, whooping-cough and influenza, less commonly in cases of diphtheria, scarlet fever, plague and the enteric group. A bronchitis starting in the larger tubes may spread downwards to the alveoli. Broncho-pneumonia may develop during the course of acute gastro-enteritis. A secondary broncho-pneumonia occurs as a terminal infection in many old and debilitated persons and in those with chronic wasting or cachectic diseases, and also in chronic cardiovascular conditions, chronic renal disease and in many progressive nerve degenerations. Any septic process may produce a metastatic broncho-pneumonia. This occurs in association with otitis media, suppurative processes about the appendix or Fallopian tubes, and cerebral abscess.

Bacteriology.—This is, as might be expected, very varied. Streptococci are frequently present, generally associated with other organisms, such as the pneumococcus, Pfeiffer's bacillus, staphylococci and those found in

catarrhal conditions of the upper air-passages. The *B. pertussis* may be found in cases associated with whooping-cough, the *B. pestis* in plague, and occasionally the *B. diphtheriæ* in diphtheritic broncho-pneumonia. The importance of Friedländer's *B. pneumoniae* was formerly over-estimated in this connection.

Pathology.—When, from any of the above-mentioned causes, an inflammatory process reaches the finer bronchi, the alveoli become affected in three different ways. Owing to the blocking of the bronchi by secretion or exudate, small areas of collapse of lobular distribution are produced. The inflammatory process extends into some or all of these, and areas of lobular consolidation result. Not infrequently the adjacent groups of alveoli become distended and are thus in a condition of acute emphysema. The lungs are normal in size or slightly enlarged. The surface presents a somewhat uneven, mottled appearance. There are small projecting patches of firmer consistence and reddish-grey colour, due to the consolidated lobules. Adjacent areas may be depressed and slaty blue, from lobular collapse, while the intervening lung tissue is normal or pinkish and emphysematous. There may be dimness or slight roughening of the pleura where the consolidated areas reach the surface, but serous or purulent effusion is uncommon. On section, the lung is found to be congested and sometimes œdematous, especially at the bases, while the bronchi exude pus or muco-pus from their cut ends. The reddish-grey areas of consolidation are found to vary in size from a pin's head to a hazel nut. They are generally more abundant in the lower lobes, especially posteriorly. The consolidated and collapsed areas both sink in water, and do not crepitate. There is often some peribronchitis, and the bronchial glands are usually enlarged. Microscopically, the finer bronchi and the consolidated alveoli are found to be filled with an exudate containing large numbers of leucocytes and desquamated, proliferating epithelial cells, but in which few red blood corpuscles and little or no fibrin are found.

In the very acute condition to which the name capillary bronchitis was formerly applied, consolidation may not be apparent, but microscopical examination invariably demonstrates the involvement of the alveoli. In influenzal broncho-pneumonia the pathological changes probably commence as an exudative bronchiolitis, associated with capillary hæmorrhages. Secondary infections are probably responsible for the consecutive broncho-pneumonic process, which results in flooding of the alveoli with an exudate containing red cells, but little or no fibrin.

Symptoms.—In the cases ensuing on bronchitis in infants or old people (formerly called capillary bronchitis), initial symptoms may be slight, and simply those of ordinary bronchitis, namely, malaise, slight fever and cough, with or without expectoration. The implication of the finer tubes and alveoli is usually marked by a rapid rise of temperature, great prostration, quick breathing and an irritating, persistent and often ineffective cough. In children, the *alæ nasi* work, the lower ribs are sucked in, and the pneumonic type of breathing develops. The patient becomes cyanosed, the pulse is rapid, 120 or more, and the respirations 50 or 60 per minute. The physical signs are in general indistinguishable from those of primary broncho-pneumonia, but breath sounds are often harsh and puerile, while tubular breathing is not heard, or only in very localised areas. In old people, cyanosis, rest-

lessness and delirium may occur, and later the cough may become less frequent, the patient being drowsy and tending to sink down in the bed, whereas previously there was orthopnoea. These symptoms are ominous and indicate failure of the respiratory centre.

The physical signs are often those of bronchitis, harsh or weak inspiration and prolonged expiration, sibilant and sonorous rhonchi and crepitations or crepitant râles especially at the bases. Patches of tubular breathing with increased voice sounds may develop but are not always present.

In other forms of secondary broncho-pneumonia similar symptoms and signs develop more insidiously in the course of the primary disease. Broncho-pneumonia should be suspected when cough, expectoration and dyspnoea, together with a remittent type of temperature, develop in the course of an acute specific fever or other severe illness. In all forms, anorexia is common, the mouth and tongue become dry, and thirst is complained of. The urine presents the usual high-coloured, concentrated character of febrile conditions. It is often diminished in quantity, may contain a small quantity of albumin, and not infrequently deposits urates.

Complications and Sequelæ.—These are relatively infrequent. Pleurisy may proceed to effusion, and when this occurs it is often purulent. Abscess and gangrene are rare, but develop rather more frequently than after lobar pneumonia. Other complications, such as pericarditis, endocarditis, meningitis and nephritis, are probably due to blood-borne metastases.

The most important sequel is pulmonary fibrosis, which is often the origin of bronchiectasis later in life. Pulmonary tuberculosis is frequently described as a sequel, especially after measles, and may be due to inflammatory changes in the bronchial glands activating a quiescent tuberculous deposit there. In many cases of tuberculosis described as following on broncho-pneumonia, it is more probable that the original lung affection was tuberculous.

Course.—Secondary broncho-pneumonia generally has a longer course than either the primary form or the lobar variety of pneumonia. The fever often persists in remittent type for two or three weeks, and sometimes even for two or three months, although in this case tuberculosis should be suspected. The decline is almost always by lysis. Convalescence is often slow, the patient being left thin, weak, anæmic and debilitated.

Diagnosis.—The development of pulmonary symptoms, and of more or less characteristic physical signs in the course of measles, whooping-cough or one of the other diseases mentioned above, usually renders the diagnosis easy. Difficulty may arise in regard to tuberculosis, which in one form produces lobular pneumonic lesions with symptoms and signs indistinguishable from other varieties of secondary broncho-pneumonia. In any case where the fever lasts more than three weeks, or where the signs show no tendency to resolve or are chiefly apical, tuberculosis should be suspected. Unfortunately in children sputum is rarely available. An attempt is sometimes made to obtain it on gauze held in forceps, after exciting cough by touching the fauces. The mucus in the fauces may also be examined for tubercle bacilli. The diagnosis may, however, remain doubtful, until signs of softening become established.

Bronchitis rarely gives rise to difficulty. The fever is usually less high, and of shorter duration, while the physical signs are different, signs of consolidation being entirely absent. Hypostatic pneumonia may have to be

considered. There is usually some obvious cause for this, such as cardiac disease and failure, or prolonged confinement to bed. The temperature is generally lower and the distribution is lobar.

Pleural effusion and empyema can generally be differentiated by the alteration of vocal fremitus and the displacement of the cardiac impulse. In case of difficulty the exploring syringe enables a distinction to be made.

Prognosis.—The prognosis in secondary pneumonia is serious. Many deaths occur from this complication in the acute specific fevers, particularly with measles and influenza. Even the form following on severe bronchitis is frequently fatal, especially in old people and in wrongly fed or debilitated infants. The development of delirium, of a pulse-rate over 150, of marked cyanosis and dyspnoea are unfavourable. In old people, drowsiness, sinking down in the bed, and cessation of cough are very grave indications.

Treatment.—The treatment is very similar to that of lobar pneumonia, except that stimulant and expectorant drugs may be necessary from the first. At the present time there is practically no difference in the methods of treatment applicable to the primary and secondary forms, although, as the means of specific treatment become more developed, there is hope for the discovery of specialised methods.

The patient must be in bed, and the position should often be changed so as to prevent hypostatic congestion. The room should be well ventilated, but without draughts, and the temperature kept at 65° F. both night and day. In the early stages the air may be moistened by a steam kettle, but the use of a tent is generally to be avoided. Poultices are now less generally employed than formerly, especially for children, and a light pneumonia jacket of Gamgee tissue is usually preferred. The diet should be restricted to fluids and semi-solids, as in pneumonia. Stimulants may be given early if the pulse becomes weak, in doses of 10 drops of brandy every 2 hours to infants, and quantities up to 4 or 6 ounces in the 24 hours to old people. The dry, distressing cough at the onset may be loosened by giving a simple alkaline febrifuge mixture, such as liq. ammon. acetat. ℥ij, pot. citrat. grs. x, sod. bicarb. grs. x, with flavouring agents, such as a syrup of tolu and chloroform water. Later, ammon. carb. and vin. ipecac. may be given, but large doses of expectorants are to be avoided because of their irritant effect on the stomach. Opiates should not be administered except as tinct. camph. co. or possibly Dover's powder in the early stages. In infants they should not be given at all.

When in infants or children, the bronchi are becoming blocked by the secretion within them, as evidenced by increasing dyspnoea, an emetic should be given. For this purpose vin. ipec. or ammon. carb. in emetic doses is the most effective. In old people, ammon. carb. may be given in milk in doses of grs. x two or three times a day, and energetic counter-irritation applied to the bases by means of turpentine stupes, dry cupping or strong liniments.

Strychnine either by the mouth or hypodermically is strongly recommended in cases in which the respiratory centre shows signs of failure. It may be pushed, if necessary, to the point of producing slight muscular twitchings. Camphor injections and cardiac tonics may be given under the same conditions as in lobar pneumonia. The administration of warmed oxygen may give relief to dyspnoea and distress.

In cases in which resolution is delayed the question of vaccine therapy may be considered. It seems sometimes to be of distinct value.

3. INHALATION, ASPIRATION AND DEGLUTITION BRONCHO-PNEUMONIA

Acute broncho-pneumonic processes may be caused by the inhalation or aspiration of fluid or solid particles, derived from the upper air-passages or from other parts of the lung. To this form the name of aspiration, or inhalation pneumonia is applied. When from any cause food particles are drawn in to the bronchi and broncho-pneumonia results, the condition is referred to as deglutition pneumonia. The resultant processes are similar, and are in effect analogous to those caused by other septic or infected foreign bodies inhaled into the bronchi.

Ætiology.—These conditions may occur at any age, but are more common in adult life. They result from septic processes in the mouth, naso-pharynx, larynx or trachea, and from any morbid state leading to anesthesia of the pharynx, or to difficulty in deglutition. They occur in association with ulcerating growths of the mouth, tongue, tonsil, pharynx or larynx, and after operations for these conditions or upon the nose and throat, including tracheotomy. Carcinoma of the œsophagus eroding the trachea may be a cause. Diphtheritic or other forms of paralysis, coma from any cause, especially cerebral vascular lesions and uræmia, may lead to the passage of food particles into the air-passages. Other cerebral lesions, such as abscess or tumour and bulbar paralysis, can also produce the same condition. Infected material may be aspirated from diseased to healthy parts of the lung, as in hæmoptysis, abscess, gangrene and bronchiectasis, or after rupture of an empyema into a bronchus.

Pathology.—Any material reaching the air-passages in this manner is certain to be laden with infective micro-organisms, which may induce bronchitis and broncho-pneumonia. Since pyogenic organisms are often present, suppuration is frequent and multiple abscesses result, or even gangrene. If the pleura becomes involved, empyema may develop.

Symptoms.—These are in general similar to those of secondary broncho-pneumonia and are superadded to those of the primary condition. There is generally high temperature, sometimes with rigors, cough and expectoration which is occasionally offensive. It may be mixed with food material and with blood. The physical signs are those of bronchitis and widespread broncho-pneumonia.

Complications and Sequelæ.—These are somewhat similar to those of other inhaled foreign bodies, and comprise abscess, gangrene and empyema.

Course.—The course is generally short, owing to the severity of the process and the gravity of the primary cause. In the comparatively rare cases that recover the course may be severe and protracted.

Prognosis.—From the nature of the primary condition and the intensity of the resulting broncho-pneumonia, this is usually grave.

Treatment.—*Prophylactic.*—The utmost care should be paid to the toilet of the mouth and pharynx in disease of, or operations upon, these parts. In paralysed or unconscious patients it may be necessary to resort to nasal feeding. In hæmoptysis or bronchiectasis the patient should lie rather on the affected side.

The treatment of the developed condition can be only palliative or symptomatic in many cases. In most instances the general treatment is similar to that of secondary broncho-pneumonia.

4. TUBERCULOUS BRONCHO-PNEUMONIA

This constitutes one form of pulmonary tuberculosis (see Acute Caseous Tuberculosis, p. 1092).

G. E. BEAUMONT.

DISEASES OF THE PLEURA

PLEURISY

Pleurisy or pleuritis is an inflammation of the pleural membrane covering the lung, or of its parietal reflexions.

An ætiological classification, based on the bacteriological findings, would be the most satisfactory one, but is at present impracticable, chiefly owing to the difficulty of establishing the bacteria concerned in many cases. The classification usually adopted depends upon the effects produced. If the process leads only to fibrinous deposit it is described as *dry pleurisy*. If, in addition, much serous fluid is poured out, the condition of *pleurisy with effusion* results, while if pus-formation occurs, the affection is described as *purulent pleurisy* or *empyema*.

It is, however, important to recognise that, although such a classification is convenient from a clinical standpoint, the three conditions are in reality only stages or degrees in the pleural response to irritative or noxious agents. The form occurring in any given case depends upon the nature of the cause, the extent of the infection and the degree of resistance possessed by the individual affected. Further, pleural inflammations may be primary or secondary to local disease or to blood infection, and they may be acute or chronic in course.

A.—ACUTE DRY PLEURISY. (ACUTE FIBRINOUS OR PLASTIC PLEURISY)

Ætiology.—This affection may be primary or secondary, the latter being much more common. Even in many cases of so-called idiopathic or primary pleurisy, the condition is in reality secondary to latent or unrecognised disease of the lung or adjacent structures.

Primary dry pleurisy.—Predisposing causes include occupation and climate. Exposure to sudden changes of weather or cold winds, and the necessity of remaining in wet or damp clothing, favour its onset. It is commoner in men, particularly in those of poor physique. It may occur at any age, but is most frequently seen between the ages of 20 and 40 years. Chill seems to be common as a determining cause. Formerly this variety was often described as "*pleuritis a frigore*." It is now certain that the great majority of cases

are due to the tubercle bacillus, and that chill or injury is simply concerned in lowering resistance and thus promoting activity of the bacillus. It is possible that some cases may be due to acute rheumatism.

Secondary dry pleurisy.—Dry pleurisy is a frequent complication or concomitant of many diseases of the lungs, notably of pulmonary tuberculosis in any form. It is almost invariably present in lobar pneumonia. It occurs in association with pulmonary collapse, interstitial pulmonary fibrosis, bronchiectasis, abscess, gangrene, infarcts and new growths of the lung. Injuries of the chest-wall, disease of the ribs, chronic nephritis, septicaemia or pyaemia may all be complicated by acute dry pleurisy.

Pathology.—The inflamed area is often localised, but the process may be widespread or even involve the whole pleural surface. Either the visceral or parietal layer may be first affected, but as a rule both become involved. There is at first hyperaemia with exudation of serum into the subpleural connective tissue. The pleura then appears slightly dull or matt, instead of shiny. Further exudation leads to the deposit of fibrin on the roughened pleural surfaces in the form of a thin false membrane, which often presents a rough or even shaggy appearance. This membrane consists of fibrin entangling leucocytes, a few red blood corpuscles and desquamated epithelial cells.

During the process of resolution, localised adhesions commonly form, but this is not invariable, and a patch of thickening without adhesion may be the ultimate result.

Symptoms.—The onset is usually sudden with acute pain in the side, often described by the patient as a “stitch.” Occasionally a sense of malaise may precede the development of the pain by a few hours or even days, but this is not the rule. The pain is aggravated by deep inspiration, by coughing or even by movement. Cough is generally an early symptom, and it is characteristically short, dry, ineffective and distressing. The temperature is usually raised, but, as a rule, only to 100° or 101° F., and some cases are practically apyrexial. In secondary pleurisy these symptoms are added to those of the primary condition.

The decubitus is variable. The patient may lie on the affected side, but in some cases this aggravates the pain, and it is more comfortable to lie on the back or slightly turned towards the sound side. There is diminished movement on the affected side, and breathing may be rapid, although not dyspnoeic. On palpation, vocal fremitus is unaffected, but local tenderness is sometimes elicited, and occasionally a friction fremitus may be felt. The breath-sounds are generally unaltered, but they may be short or jerky in the neighbourhood of the lesion. The characteristic sign of dry pleurisy is the friction rub. This is typically a creaking, rubbing or leathery sound heard towards the end of inspiration and sometimes at the beginning of expiration. In the early stages there may be fine crepitant friction sounds only at the end of inspiration. These are very similar in character to intrapulmonary crepitations and can only be distinguished by their association with local pain, and by being unaltered by cough. Pleural friction sounds may be localised to a small area, and may not be present with every respiration. They may sometimes be brought out again after disappearance by moving the arm, or by taking a deep breath. The voice-sounds are not altered.

Complications and Sequelæ.—Dry pleurisy may proceed to effusion, or may lead to pleural adhesion, and this in turn may result in interstitial pulmonary fibrosis. The most common sequel is pulmonary tuberculosis, sometimes after an interval of years, the explanation being that the original pleurisy is frequently tuberculous. Aching pain in the side with some dyspnoea may be a temporary sequel of dry pleurisy.

Course.—The temperature usually subsides in 2 or 3 days, the pain in the side and cough disappear, and convalescence is rapid, unless effusion occurs.

Diagnosis.—The differentiation of dry pleurisy from the other causes of pain produced in, or referred to, the chest-wall is not always easy and requires careful observation of the case. The distinction is important, since an erroneous diagnosis of pleurisy may arouse a suspicion of tuberculosis in subsequent febrile diseases. In the conditions comprised in the term *pleurodynia*, which include fibrositis of the intercostal muscles and membranes, the pain is increased by deep inspiration, by other muscular movements, and by local pressure, but there is no rise of temperature and **pleural friction** is not present. In *intercostal neuralgia*, the pain follows the course of the nerve and is often periodic in character. It may be influenced by movement, but is less affected by respiration than that of pleurisy. There may be tenderness and hyperalgesia over the points of exit of the posterior primary, lateral or anterior cutaneous branches of the nerve affected. Similar manifestations may occur at the onset of acute posterior ganglionitis or herpes *zoster*. Other conditions inducing pain referred to the chest-wall are tumours or aneurysm pressing on the intercostal nerves, malignant disease of the spinal cord or of its membranes, and caries of the vertebræ. Where the pain lasts more than a few days, and no friction is heard, these conditions should be borne in mind.

Occasionally adventitious sounds of extra-pleural origin may give rise to some difficulty. Contraction of the muscles of the chest may cause a muscular "susurrus"; grating sounds may be produced in the shoulder-joint or in the fascial planes of the back muscles. The origin of these sounds can usually be determined by causing the patient to cease breathing while carrying out movements of the shoulder or back muscles. Occasionally true friction sounds may have a cardiac rhythm as well as a respiratory one, when the area of pleura involved is near the pericardium. It is then referred to as pleuro-pericardial friction.

Having established the evidence of dry pleurisy, a careful search should be made for some primary condition before regarding the case as one of simple primary dry pleurisy. Pulmonary tuberculosis, pneumonia, bronchiectasis and the other causes mentioned above should be considered and excluded.

Prognosis.—The immediate prognosis is good, but as has been mentioned already, the condition may be of tuberculous origin, and eventually be followed by active disease of the lung.

Treatment.—The patient should be kept in bed, no matter how mild the attack. The diet should be fluid or semi-fluid, especially if more than a moderate degree of fever occurs. The pain can often be relieved by strapping the affected side. Strips of adhesive plaster are applied from the sternum to the vertebræ, beginning from above and working downwards. Occasion-

ally this fails to afford relief and may even induce dyspnoea. As alternatives, a local application of tincture or ointment of iodine, a mustard leaf, capsicum ointment or small flying blisters may be employed. Leeches may also give relief in severe cases. Sometimes the pain is so intense that a small injection of heroin or morphine is necessary. A dose of Dover's powder is useful in the early stage to ensure a night's rest. The irritative cough is often relieved by strapping, but a sedative linctus or lozenge may be a comfort to the patient. An aperient is usually advisable. As a rule no other drugs are necessary, but in cases suspected to be due to rheumatism, salicylates and alkalis should be administered. Convalescence is usually rapid, but the patient should not be allowed to resume work until fully restored to health, and if a tuberculous origin is suspected prolonged treatment on sanatorium lines should be advised.

Certain localisations of dry pleurisy require separate notice. These are the diaphragmatic and interlobar forms.

DIAPHRAGMATIC ACUTE DRY PLEURISY

Ætiology.—This affection may occur primarily under conditions similar to those causing dry pleurisy in other parts; more commonly it is secondary to pathological changes in the abdomen. Thus hepatic cirrhosis, perihepatitis, perisplenitis, perinephric suppuration or peritonitis may lead to a spread of infection through the diaphragm to the adjacent pleura. It may also occur as a localised variety of secondary dry pleurisy, when the primary lesion is situated near the base of the lungs.

Symptoms.—Pain is usually very severe and may be referred to the shoulder or to the abdomen. The former is caused by nociceptive impulses ascending the phrenic nerve to its origin in the third to the fifth cervical segments of the spinal cord, leading to pain and hyperæsthesia in the cutaneous area of distribution of the fourth cervical root, at the summit of the shoulder. The abdominal pain is in the epigastric and hypochondriac regions, and in addition there is a localised tender spot, known as the "*bouton diaphragmatique*" of Guéneau de Mussy. This is situated in the subcostal plane, about 2 inches from the mid-line. The diaphragm is nearly motionless on the affected side, and there is often some rigidity of the corresponding upper abdominal muscles. Hiccough may be a noticeable and troublesome symptom. The diaphragm, being nearly fixed in the inspiratory position, may cause a slight downward displacement of the liver if the pleurisy is on the right side. A pleural friction rub is rarely heard, the only abnormal signs commonly present being diminution of air entry, and possibly slight dullness over the corresponding lower lobe of the lung.

Diagnosis.—This is often difficult, owing to the fact that the severity of the symptoms and their localisation frequently suggest the occurrence of some acute abdominal catastrophe such as perforation of a hollow viscus. The abdomen should be most carefully examined in every case. The history, the collapsed state of the patient and the evidence of free gas in the peritoneal cavity in perforation may assist in distinguishing between these conditions.

Treatment.—This is similar to that of simple dry pleurisy elsewhere, save that morphine should be withheld until the diagnosis is conclusively established.

INTERLOBAR DRY PLEURISY

Just as inflammation may be limited to the diaphragmatic portion of the pleura, so the membrane in the cleft between two lobes of the lung may be alone affected. This does not give rise to definite symptoms and signs by which it can be diagnosed during life, though its effects are not infrequently seen in X-ray films. It is frequently discovered on autopsy, but is generally secondary to pulmonary tuberculosis or pneumonia, and there is usually evidence of pleurisy elsewhere. It only assumes clinical importance when followed by effusion, and this condition is considered later.

B.—CHRONIC DRY PLEURISY

Under this heading a variety of conditions are included. Strictly it should be restricted to those rare cases, probably usually tuberculous in origin, in which the signs of dry pleurisy persist for long periods, or recur at frequent intervals. In such cases coarse dry friction may be heard over large areas of one lung, often with little or no accompanying pain.

Pleural adhesion and thickening are usually included in the group of chronic dry pleurisies. There may be no symptoms, or at most slight dyspnoea on exertion, with aching or pain on straining, or on lifting weights. Signs suggesting adhesion are local flattening and limitation of movement of the chest-wall. Litten's sign is also absent or diminished when the adhesion is basic, that is, the shadow cast by the movement of the diaphragm, best seen in the region of the seventh and eighth ribs in the anterior and mid-axillary lines, is not present or is much restricted. The vocal fremitus may be diminished and the percussion note impaired. The breath-sounds are often slightly weaker, and the voice-sounds may be diminished over the area where the thickening or adhesion exists.

Chronic diaphragmatic pleurisy or adhesion may give rise to a group of symptoms simulating chronic gastric ulcer. There is pain in the hypochondrium extending through to the back and aggravated by food. A radiogram may be of value in demonstrating limitation of movement of one cupola of the diaphragm, together with an angularity due to alteration of its normal contour. Investigation of the gastric functions may also prove of value in diagnosis.

The treatment of chronic dry pleurisy is mainly symptomatic.

C.—PLEURISY WITH EFFUSION

Many cases of pleurisy, possibly the majority, proceed to effusion. The effusion is usually serous in character, but may be hæmorrhagic. Inflammatory effusions must be distinguished from passive transudates, which will be considered separately under the heading of hydrothorax.

SERO-FIBRINOUS PLEURISY

Ætiology.—This is in the main identical with that of dry pleurisy, of which it is, in effect, a later stage. It has now been established that the

majority of cases of sero-fibrinous pleurisy are due to the tubercle bacillus. The evidence on which this conclusion has been arrived at is—(1) the subsequent history of the cases shows that a considerable proportion develop active lung signs within 5 years; (2) the cytological and bacteriological examination of the exudate; (3) post-mortem examination of fatal cases; (4) the results of tuberculin reactions.

Other conditions which may give rise to serous effusions are lobar and lobular pneumonia, pulmonary infarcts and new growth. It may also occur in the course of generalised infections such as the enteric group, acute rheumatism, and septicæmia due to streptococci or staphylococci. In most of these conditions the exudate often becomes purulent. Inflammatory serous effusion may also occur as a complication of severe anæmias, leukaemia, chronic nephritis, injury to the chest-wall and inflammatory conditions below the diaphragm or in the pericardium. It is also a common feature of polyrrhomenitis.

Pathology.—The affection commences with dry pleurisy spreading over the visceral and parietal pleura, the fibrinous exudate soon forming a thick rough layer on the surface. Further exudation of fluid occurs and accumulates in the pleural cavity, the lung collapsing *pari passu* to accommodate it. Owing to the hilar attachment of the lung, it retracts upwards and inwards, allowing the fluid to accumulate at the bases and in the axillary region, where it reaches its highest level, unless previously existing adhesions prevent it. The lung retracts in this way owing to its elasticity, until the pleural negative pressure is completely abolished. In like manner the mediastinal contents, including the heart, are displaced away from the affected side. If fluid continues to be effused after the lung has retracted to the full extent, and after the negative pressure has become abolished, a positive pressure is produced. The lung is now compressed, and the diaphragm with the liver and spleen are pushed down, while the mediastinal structures are now displaced further towards the sound side. In long-standing cases, the lung may undergo the change known as carnification, as the result of the compression apneumatosis. The lung appears dark red or slaty grey in colour, is firm, airless and heavier than water. If old adhesions are present, the effused fluid may be loculated and the collapse of the lung may be only partial.

If there is much positive pressure collateral hyperæmia of the sound lung may result and progress to œdema. The fluid in the pleural cavity is pale and clear; it often coagulates after withdrawal. Its characters are further described on page 1146. The quantity may amount to as much as 5 or 6 pints.

Symptoms.—The onset is usually similar to that of dry pleurisy, but the constitutional symptoms are often more marked. There may be an initial rigor, but as a rule pain and dry cough are the earliest symptoms. The fever is of moderate degree, although it may reach 103° F. or more. When effusion develops the pain is often relieved owing to the separation of the inflamed pleural surfaces. If a large quantity of fluid is poured out rapidly, distress of another kind becomes apparent, namely dyspnoea caused by the mechanical effects of the fluid, collapsing the lung and dislocating the mediastinum. In more slowly developing effusions there may be little or no dyspnoea, except on exertion. Expectoration is not common, unless there is co-existent pulmonary disease, or unless œdema of the sound lung develops.

The patient often lies on the affected side or may be propped up in bed. Cyanosis is not a marked feature even in large effusions, unless there is collateral hyperemia of the sound side. There is generally some prominence on the side of the effusion, but the intercostal spaces are rarely bulged. Movement is restricted or absent in the lower part of the chest on the affected side, although with a moderate effusion the apical region may still expand. The cardiac pulsations may be seen in an abnormal position, the impulse being displaced away from the side of the fluid. In left-sided effusions, the pulsation may be most marked in the fourth space on the right side as far out as the nipple line. On palpation, the position of the impulse should be verified, and then the amount of chest movement and the character of the vocal fremitus determined. The latter is diminished or completely absent over an effusion of moderate or large size, although it may be obtained over the area where the collapsed or relaxed lung is in contact with the chest-wall. The percussion note over the fluid is one of stony dullness, and the sense of resistance is greatly increased. The exact limits of this area of dullness should be determined with the patient sitting up and recumbent. With moderate effusions the upper level is usually found to assume a curved line, with the summit in the mid-axilla; this is known as the S-shaped curve of Ellis or Damoiseau's line. In the recumbent position, a change in the level of this line may be observed particularly in the front of the chest and in the axilla. This shifting dullness forms one of the pathognomonic signs of fluid, but it is not always easy to demonstrate. It is much more apparent in cases of pyo-pneumothorax. In large effusions, the dullness may extend up to the level of the clavicle and reach across the mid-line of the sternum; moreover, in left-sided effusions it blends with the cardiac dullness, and the area of gastric resonance, known as Traube's space, may be encroached on or obliterated. The relaxed lung above the effusion in front often yields a skodaic note, which becomes dull if the quantity of fluid increases. At the back there is a triangular area of relative or moderate dullness above the stony dull area of fluid. This is known as Garland's dull triangle. It also corresponds with the relaxed or collapsed lung. At the extreme base on the contralateral side there is often a small area of dullness known as Grocco's triangle. The apex is usually at the vertebral column, about the upper level of the effusion, the base extends outwards at the lower margin of the lung for 1 or 2 inches. This paravertebral dull area is believed to be due to mediastinal displacement by the effusion. Elsewhere over the sound lung the note may be slightly hyper-resonant. The area of deep cardiac dullness should be carefully marked out. In left-sided effusions it is displaced to the right and extends beyond the sternum in the third and fourth spaces, even to the nipple line or beyond it. In right-sided effusions, the displacement may be very obvious, the left margin of the dullness extending as far out as the left mid-axillary line. The auscultatory signs are very variable, and much less characteristic than those obtained by palpation and percussion. In some cases, the breath-sounds over the dull area are distant and weak or even absent, in others they are loud and bronchial or tubular. This inconstancy probably depends upon the extent of pulmonary collapse and the degree of patency of the bronchi. With marked collapse and patent bronchi, bronchial breathing is heard; with partial collapse and obstructed bronchi, the breath-sounds are almost or quite abolished. As a rule, no

adventitious sounds are heard, but râles may be audible in the lung above the effusion. Conduction of spoken voice is diminished or abolished, but towards the upper part of the effusion and just above it, the sound produced is heard distantly and with a peculiar nasal or bleating twang, a condition known as egophony. Baccelli stated that the whispered voice is conducted through a serous but not through a purulent effusion, and called this sign "pectoriloque aphonique," but no reliance can be placed upon this as a diagnostic sign. The breath-sounds heard under the clavicle over the relaxed lung above the effusion are frequently harsh or puerile. In the contralateral lung the breath-sounds may be vesicular or exaggerated, and in cases of large effusions, where there is marked circulatory obstruction, there are frequently signs of congestion or œdema at the base. Similarly pressure on the descending thoracic aorta may cause lowering of the blood-pressure in the leg as compared with that in the arm (O. K. Williamson). There may be a systolic murmur over the cardiac region (displacement murmur). The abdomen should be examined to determine any downward displacement of the liver or spleen. The blood count in sero-fibrinous pleurisy rarely shows any leucocytosis, apart from complications.

Complications and Sequelæ.—Acute œdema with albuminous expectoration is not uncommon, and is a dangerous condition unless treatment is prompt. Permanent collapse and carnification of the lung may remain after absorption in prolonged cases, and may progress to diffuse interstitial fibrosis. More commonly some degree of pleural thickening and adhesion persists, and expansion of the lower lobe may never be completely restored. Sero-fibrinous effusion due to tuberculosis rarely becomes purulent, but this sequence is common in other forms. Tracking of the fluid externally through the chest-wall and rupture through the lung occur but rarely. An infrequent complication is hemiplegia, probably due to an embolus derived from a thrombus originating in a pulmonary vein. Miliary tuberculosis occasionally follows rapidly on an effusion; more commonly active tuberculosis of the lung occurs after a lapse of some years.

Course.—In effusions of moderate size the temperature usually subsides in from 7 to 10 days, and spontaneous absorption is complete in 2, 3 or 4 weeks. In large effusions reaching up to the second rib or higher, the course may be less favourable. The fever may persist even for weeks, and absorption of the fluid may be slow or wanting entirely. Aspiration may accelerate the resolution, and usually only one tapping is necessary, the fluid left behind being absorbed rapidly. In rare cases fluid reaccumulates quickly after repeated tapplings, and a so-called inexhaustible effusion occurs. In some such patients fluid may remain in the pleura for the rest of life.

Diagnosis.—The recognition of the presence of fluid in the pleural cavity is generally easy, but with small or localised effusions it may be difficult. The most valuable signs are the displacement of the heart, the absence of vocal fremitus, and the stony resistant dullness. The auscultatory signs are of less value, and may even be misleading. The chief conditions which may simulate effusion are fibroid lung with thickened pleura and bronchiectasis, pneumonia, particularly the massive form, malignant disease of the lung, pleura or mediastinum, massive collapse, a large pericardial effusion, and an aneurysm pressing on one or other main bronchus. Subphrenic abscess may also give rise to difficulty (see Empyema). Fibroid disease can usually be

recognised, since there is generally flattening and sinking-in of the affected side instead of bulging. The heart, if displaced, is drawn towards instead of away from the affected side, vocal fremitus is present although possibly diminished, and the dullness is rarely of the stony character obtained over fluid. The breath-sounds are generally weak, and if bronchiectasis is also present, the characteristically variable signs of that condition should be helpful in diagnosis. In massive pneumonia the differentiation may be difficult, since breath-sounds and voice-sounds are sometimes completely absent, but the position of the cardiac impulse is generally of decisive importance. In malignant disease and aneurysm, careful observation should afford diagnostic indications, such as glandular enlargement or abnormal pulsation, and in both instances the X-rays may establish the diagnosis. Malignant disease of the pleura may first show itself as a pleural effusion; the tendency to recur after tapping and the onset of emaciation may help to suggest the cause. In massive collapse there is, as a rule, but little difficulty, owing to the displacement of the cardiac impulse to the affected side. In pericardial effusion the shape of the cardiac dullness may be suggestive, and the dislocation of the impulse may indicate the real condition; moreover, the dullness over the lung behind is rarely of extreme degree unless pleural effusion co-exists. In any doubtful case, examination by the X-rays is desirable, since it may give valuable aid in diagnosis. The shadow of serous fluid is generally dense, but does not obscure the rib shadows completely. The upper level is curved and shifts to some extent with the position of the patient. It merges into the shadow of the collapsed lung above. The diaphragm is immobile on the affected side. A further aid to diagnosis consists in exploratory puncture, which has the advantage of establishing the nature of the fluid as well as its presence. The technique of puncture is similar to that of paracentesis described on pages 1147, 1148, save that a 5 or 10 c.c. syringe with a needle long enough to enter the pleura is used instead of an aspirator. The preliminary local anaesthesia by novocain is often dispensed with, but it is wiser to employ it to obviate the risk, remote though it be, of pleural shock. Serous pleural fluid of inflammatory origin varies in colour from pale greenish yellow to brown. The specific gravity is usually 1018 or over. Protein is present as serum albumin, serum globulin and fibrinogen, the total quantity being, as a rule, over 4 per cent. The fluid generally clots spontaneously after withdrawal. The cytology of the fluid is varied, showing lymphocytes, polymorpho-nuclears, erythrocytes and altered endothelial cells in varying proportions. A marked preponderance of lymphocytes is very suggestive of a tuberculous origin, while the presence of large numbers of polymorpho-nuclears is usually an indication of some other infection, generally by a pyogenic organism. In rare cases large numbers of eosinophils have been found. The origin of these cases of so-called "eosinophil pleurisy" is at present doubtful. Cultural examination of tuberculous fluid usually proves sterile, but in fluid from other causes the infecting organism can often be grown. To establish the tuberculous nature of a pleural fluid, inoculation of 15 c.c. of the fluid into a guinea-pig may be tried. Other methods formerly employed were examination of the centrifugate from the fluid, and Jousset's "inoscopy," which consists in examination of the clots derived from the fluid after they have been submitted to artificial gastric digestion. These two methods, however, fail in many cases. The methods

of differentiation of an inflammatory exudate from a passive transudate are given on page 1153.

Prognosis.—The immediate prognosis is good, although with large effusions of 4 pints or more, sudden death sometimes occurs from acute œdema of the lungs, cardiac failure or embolism. The ultimate result depends on the cause. In non-tuberculous effusions, recovery may be complete, save for pleural adhesion, or they may progress to empyema. In tuberculous effusions arrest may remain complete, but, as already stated, a considerable proportion of the cases develop active pulmonary disease in after years.

Treatment.—The patient should be kept in bed in an airy and well-ventilated room until the temperature is normal. Fluid should be restricted, and the diet may be salt-free with advantage. The administration of diuretics, diaphoretics and saline or mercurial aperients may assist in the disappearance of the exudate. The use of iodide of potassium has been recommended, but it is of doubtful value in these cases. The application of counter-irritants to the chest-wall in the form of iodine or of fly blisters is often helpful. A sedative lozenge or linctus may be given for the irritating cough present in the early stage. Exploratory puncture is generally advisable to permit the examination of the fluid, but in young children special care is necessary, owing to the risk of shock. Opinions differ somewhat as to the indications for paracentesis, which, however, is nowadays performed earlier and more frequently than was formerly the case. It is unnecessary in cases in which absorption of the fluid is apparent within 10 days. The following conditions may be considered to suggest its employment: (1) if the effusion is large and causing positive pressure, as shown by dullness up to the clavicle, marked dyspnoea, downward displacement of the liver or spleen, and collateral hyperæmia of the sound lung; (2) if absorption is slow, the fluid remaining at the same level for a fortnight or more; (3) if acute œdema with albuminous expectoration occurs; (4) in cases of bilateral effusion with increasing dyspnoea, the side with the larger effusion may be aspirated. Paracentesis can be performed in various ways. The simplest method is that of siphonage; a long rubber tube filled with sterile saline solution is attached to a trocar and cannula, which are passed into the pleural cavity and the fluid is siphoned into a receptacle at a lower level. This method has the great advantages that the degree of suction employed is under control, and the lung expands gradually as the fluid is withdrawn. It is often difficult to remove a large quantity of fluid by this means, and it fails in loculated effusion. Aspiration is more generally effective, and may be carried out either by Dieulafoy's pump and two-way tap, or by Potain's apparatus. With these methods it is impossible to withdraw all the fluid, and removal with oxygen, nitrogen or air replacement is now often practised with advantage. For this purpose a Potain's aspirator and an apparatus like that used in the induction of artificial pneumothorax is required. This method lessens the tendency to recurrence of the effusion and promotes expansion of the lung. In performing aspiration the patient should sit up in bed, or lie slightly turned on the unaffected side, and the area for operation should be painted with iodine. The skin and muscles should be anaesthetised with novocain and a small incision made through the skin, though this is not essential in the case of a small instrument. The trocar and cannula are then pushed quickly into the pleural cavity just above a rib to avoid puncturing the intercostal artery.

The sites chosen depend on the situation of the fluid, but the most convenient are in the sixth space in the mid-axilla, the seventh space in the posterior axillary line, or the eighth space just below the angle of the scapula. Aspiration should be stopped if cough becomes troublesome, if pain is severe, or if albuminous expectoration with signs of œdema supervenes. In rare cases sudden death from pleural shock has occurred. The risk of this may be obviated by careful local anaesthesia with successive injections of novocain down to the pleural level. Other risks are due to faulty technique, and comprise entrance of air into the pleural cavity from wrong connection of the apparatus or from wounding the lung, and infection of the pleural cavity from failure in the aseptic preparations causing empyema. It has been recommended to inject 3 to 6 c.c. of adrenalin solution (1 in 1000) after paracentesis to check reaccumulation, but oxygen replacement seems preferable.

After absorption or removal of the fluid, re-expansion of the lung may be promoted by the use of Wolf's bottles, or by appropriate breathing exercises. With the former, fluid is forced from one bottle to another by blowing. In the latter, the patient takes deep inspirations while seated in a chair with the sound side partly fixed. In all cases in which a tuberculous origin is proved or suspected, prolonged convalescent treatment on sanatorium principles is advisable.

ANOMALOUS PLEURAL EFFUSIONS

Two unusual forms of pleural effusion require brief mention—they are encysted interlobar and encysted diaphragmatic sero-fibrinous pleurisy. The former of these can only be recognised by X-ray examination followed by exploratory puncture. Encysted diaphragmatic sero-fibrinous pleurisy is rare, but a case has been erroneously recorded as acute serous mediastinitis. This condition is simply one of pleural effusion localised to the space between the mediastinal pleura, the diaphragm and the lung. Both of these conditions, if diagnosed, should be treated on general principles. The effusion may absorb spontaneously, but if not, aspiration may be necessary.

PURULENT PLEURISY (EMPHYEMA)

In this condition the pleural exudate becomes purulent. The fluid may be turbid and the presence of pus be apparent only on microscopical examination, or it may consist of typical pus.

Ætiology.—**PREDISPOSING CAUSES.**—Empyema is common in children under 10 years of age, and the younger the child the greater the probability that any effusion will be purulent. In adults it is commonest between the ages of 20 and 40 years, probably owing to the heavy incidence of pneumonia in this age period. Debility, exposure and alcoholism may promote its occurrence. Purulent pleurisy is but rarely primary, except in the form due to the pneumococcus. It is most commonly due to extension from the lungs, especially from lobar pneumonia and from bronchopneumonia. Other pulmonary causes are tuberculosis, bronchiectasis, abscess, gangrene, new-growth, or septic infarcts in infective endocarditis. It may develop in association with mediastinal lesions, such as suppurating glands, ulcerating carcinoma of the œsophagus, or from suppuration in the neck track-

ing downwards. Infection of the pleura may occur through the chest-wall as a result of gunshot wounds, stabs, fractured ribs, and faulty technique in aspiration of a serous effusion. The primary source of pleural infection may be in the abdomen, the organisms passing through the diaphragm from a subphrenic or hepatic abscess, or from localised or generalised peritonitis consequent on rupture of a gastric or duodenal ulcer. The involvement of the pleura may take place through the blood in septicæmia, suppurating gunshot wounds, compound fracture of the femur, and in otitis media with lateral sinus thrombosis.

Empyema may develop during the course of many of the acute specific fevers, such as scarlet fever, variola, measles and the enteric group; but since in these conditions it is usually secondary to broncho-pneumonia, it belongs strictly to the pulmonary group.

Exciting Causes.—The organisms most frequently found in purulent effusions are the pneumococcus and the streptococcus, the former accounting for more than half of the cases. Occasionally the pus proves to be sterile on culture; such cases are generally the result of the tubercle bacillus or of a pneumococcus which has died out. Other organisms less commonly found are staphylococci, Pfeiffer's *Bacillus influenzae*, the *B. typhosus*, and Friedländer's pneumo-bacillus. Streptothrix organisms are occasionally found (see Actinomycosis), also various saprophytes and anaerobic organisms, especially in foetid empyema.

Pathology.—The initial stages are similar to those of dry and sero-fibrinous pleurisy, but when the effusion occurs, it proves to be rich in leucocytes undergoing disintegration and to contain the infecting organism. It varies from a slightly turbid semi-translucent fluid to typical thick, opaque, creamy pus. Its colour ranges from pale amber to green or greenish grey. It may be odourless or extremely offensive. In cases secondary to gangrene, it may be thin and horribly foetid, while in pneumococcal cases it may be curdy and of slightly sweetish odour. The pleura is covered with a more or less thick layer of sodden fibrinous exudate. In cases due to the pneumococcus this false membrane may be very thick. Adhesions form quickly, leading to encystment or loculation of the pus. Such adhesions also prevent the lung from expanding after evacuation of the pus, with the result that the lung becomes carnified and interstitial fibrosis results. There is usually some enlargement of the bronchial glands. In long-standing cases there may be lardaceous disease of the liver, spleen, kidneys and intestines.

Symptoms.—Since empyema usually develops in the course of, or as a sequel of, some other disease, its symptoms are often masked by those of the primary disease and may easily be overlooked. In primary cases due to the pneumococcus the onset may be like that of pneumonia; in the more common secondary cases a rise of temperature and increase of signs develop after the crisis. In general it may be stated that the symptoms are similar to those of sero-fibrinous pleurisy, but more severe. There is more malaise, and the patient may appear profoundly ill, with rigors, sweats and dyspnoea. The temperature ranges higher, up to 103° F. or more, and may be of septic type with marked daily remissions, but some cases are almost if not completely apyrexial. The signs are usually exactly similar to those of sero-fibrinous effusion, but in some instances special features may be noticed. In neglected or prolonged cases, wasting, pallor and cachexia become marked. The

intercostal spaces may be found to bulge, and oedema of the chest-wall is sometimes apparent. The pus may track through an intercostal space, generally the fifth near the nipple, producing a fluctuating swelling known as a pointing empyema or empyema necessitatis. This may infiltrate the skin and simulate a superficial abscess. The swelling so induced may pulsate, especially if it be on the left side—a condition known as pulsating empyema. Pulsation communicated to the chest-wall may also be observed in some large left-sided purulent effusions without local swelling. The displacement of the liver or spleen may be greater than with serous effusions, probably owing to the higher specific gravity of the pus, which is usually 1030 or more, and to the associated inflammation of the diaphragm. In foetid empyema, the breath and sputum may be offensive, even before rupture into a bronchus occurs. Clubbing of the fingers and toes occurs in empyema of long standing. Blood examination reveals a moderate leucocytosis in the majority of cases. Counts of 15,000 leucocytes per cubic millimetre are usual, and in some instances figures up to 100,000 per cubic millimetre are obtained.

Complications and Sequelæ.—In neglected or untreated empyema the pus may track and become discharged in various directions. The commonest is rupture through the visceral pleura into the lung and discharge through a bronchus. This may lead to sudden death from suffocation; on the other hand, in small empyemata spontaneous cure may follow this evacuation of the pus. In other instances pyo-pneumothorax results, and occasionally gangrene of the lung. A second method of discharge is through the chest-wall, as an empyema necessitatis. Perforation may occur into the pericardium, or into the œsophagus with the formation of a pleuro-œsophageal fistula. The diaphragm may be perforated with the production of a subphrenic, lumbar or psoas abscess, while in other cases general peritonitis may ensue.

The pericardium or the mediastinum may become infected without perforation; similarly costal periostitis may be induced. After spontaneous or operative evacuation the cavity may fail to close and a chronic empyema or sinus result. This is generally due to the lung being permanently collapsed and adherent, and therefore failing to expand. It subsequently undergoes fibrosis with development of bronchiectasis. Sometimes the failure to close may be due to the nature of the infection, particularly when it is due to tuberculosis or nocardiasis. In other cases it may be due to a bronchial fistula, or to a foreign body in the pleura. Generalised infection is rare, but cerebral abscess, probably of embolic origin, is not very uncommon, especially in cases due to streptococci. Chronic pulmonary osteo-arthritis is an occasional complication, and lardaceous disease sometimes occurs in cases of long duration. Diphtheritic infection of the wound, with subsequent paralysis, has been recorded after operation, more especially in cases secondary to influenzal broncho-pneumonia.

The sequelæ in untreated cases may be fistulæ, such as pleuro-bronchial, pleuro-œsophageal or external, and various deformities. The sequelæ after operation may be a small amount of pleural thickening, or if operation were delayed and re-expansion incomplete, there is falling-in of the chest, with flattening, dropping of the shoulder and secondary scoliosis. In other cases, as mentioned above, a chronic sinus may result.

Course.—Apart from spontaneous cure of small empyemata by inspissation of the pus, or discharge through a bronchus or through the chest-wall,

death generally occurs in untreated cases within a month or two. As in sero-fibrinous pleurisy, sudden death may occur, but much less commonly. ~~Death may occur after operation from exhaustion or from cerebral abscess.~~

Diagnosis.—The diagnosis of empyema involves two distinct problems—one, the recognition of the presence of fluid in the pleura, which is considered under sero-fibrinous pleurisy; the other, the demonstration of its purulent character. In spite of the more severe symptoms, empyema is frequently overlooked even by physicians of experience. This is partly due to the fact that its development may be insidious, with signs increasing but little from day to day, and partly to its secondary character, its onset being obscured by the clinical features of the primary condition. It is wise, therefore, to suspect its existence in any case of obscure lung signs, especially those with dullness, cardiac displacement and fever, consequent on pneumonia of any variety.

There are a few special difficulties as compared with sero-fibrinous effusion which merit separate mention. The first of these is subphrenic abscess. This may lead to immobilisation of the diaphragm on one side, more commonly the right, and cause collapse of the lung and even pleural effusion. The difficulty is the greater when the subphrenic abscess contains gas as well as pus. The history, the absence of displacement of the heart's impulse, and examination by X-rays may all assist, but the differentiation is often extremely difficult.

Empyema necessitatis may simulate a tuberculous or other abscess about a rib, and empyema should always be suspected in any case of local fluctuating swelling about the chest-wall. Pulsating empyema requires to be distinguished from aortic aneurysm; the pulsation is less forcible and little, if at all, expansile in the former. The cardiac displacement, the X-rays and cautious exploratory puncture, enable the nature of the condition to be recognised.

In any case in which empyema is suspected three examinations may be undertaken—a blood count, radiographic methods, and exploratory puncture. A polymorpho-nuclear leucocytosis of 11,000 per cubic millimetre and over, a dense shadow in the radiogram obscuring the ribs, together with cardiac displacement may be very suggestive, while puncture may prove the presence of pus. Sometimes, however, puncture may fail, although pus is present. This may be due to the pus being too thick to pass through the needle, to loculation of the pus, or to wrong choice of the site for puncture. In this case, if the other signs indicate pus, repeated punctures with a larger needle under anaesthesia are called for, but it is well to be prepared to proceed to operation if pus is found.

Prognosis.—This depends upon the primary cause, the method of treatment adopted, and the duration of the effusion before the operation. The most favourable forms are those due to the pneumococcus, which are recognised and treated at an early stage. In neglected cases, with profound toxæmia, with gangrene of the lung or lardaceous disease, the outlook is extremely grave. Empyemata due to streptococcal infection are serious, unless recognised early; similarly with cases of fetid empyema due to anaerobic infections. Infected hæmothorax consequent on gunshot wounds of the chest is of grave prognosis. The outlook is serious in cases of bilateral empyema, but recovery may follow successive evacuation of the pus on the two sides.

Treatment.—This consists in the evacuation of the pus by operation as

soon as the diagnosis is established in pneumococcal cases. In those of streptococcal origin, operation should not be resorted to while the fluid is of thin sero-purulent character, but should be postponed until it is definitely purulent. A preliminary aspiration is of advantage in large effusions, and may be repeated in streptococcal effusions until they are ready for operation. The operation consists in drainage by removal of a piece of rib subperiosteally and incision of the parietal pleura. For the operation a general anæsthetic may be given, but it is now often carried out under local anæsthesia; but if the patient's condition renders this undesirable, an incision under local anæsthesia may be made through an intercostal space and a drainage tube inserted, a piece of rib being removed later under general or local anæsthesia when improvement has occurred. The wound is dressed at least daily and the drainage tube sterilised, every endeavour being made to prevent secondary infections. To this end the pleural cavity may be irrigated daily by the Carrel-Dakin method, or washed out with some antiseptic such as flavine or brilliant green. By some authorities pneumococcal empyemata, particularly in young children, are treated by repeated aspirations or by siphon drainage. If the pus is thick and difficult to evacuate, incision of the pleura with immediate suture is performed, any reaccumulation being treated by aspiration with or without oxygen replacement. If, however, toxic symptoms persist, drainage should be effectively established at once.

In cases of chronic empyema, or of sinus failing to close, the question of some plastic operation must be considered. This is rarely practicable or advisable in cases due to the tubercle bacillus or to streptothrix organisms. Various forms of operation have been devised, involving removal of portions of many ribs, the most important of which are those suggested by Estlander and Schede, and the decortication operation of Fowler and Delorme. The general condition of the patient must be carefully considered before these operations are advised. In some cases an autogenous vaccine seems to be of value, if drainage is satisfactory.

Special varieties of empyema.—Certain special localisations of purulent pleurisy require separate consideration, notably apical, interlobar and diaphragmatic empyemata.

Apical empyema.—This condition is usually secondary to apical pneumonia, less commonly to pulmonary tuberculosis. It is one variety of encysted empyema, the pus being shut off from the rest of the pleural cavity by adhesions. The symptoms and signs are not characteristic, but may be suggestive. There is very marked dullness below the clavicle, not transgressing the middle line, with weak or absent breath-sounds, and possibly some indications of mediastinal displacement. Diagnosis can, as a rule, be established only by the X-rays and exploratory puncture, the latter being carried out in the second space near the mid-clavicular line. The treatment consists in drainage by incision as near the lower limit of the effusion as possible.

Interlobar empyema.—Pus collecting between two of the lobes may be difficult to differentiate from pulmonary abscess, gangrene and bronchiectasis. It is often not diagnosed until rupture into a bronchus draws attention to it. The signs are generally most marked in the axilla or near the angle of the scapula. They are often slight until rupture occurs, and even then there may be only a small area of dullness in the line of an interlobar fissure, with distant or weak bronchial breathing and a few râles. The pus expecto-

rated may be foetid, and the patient's breath may be offensive a few days before rupture occurs. The condition simulates abscess of the lung, and may be almost impossible to differentiate from that affection. Examination by the X-rays gives the greatest help in the diagnosis. Recent observations suggest that interlobar empyema is much less common than abscess. The treatment is identical with that for pulmonary abscess.

Diaphragmatic empyema.—The pus is usually encysted, and may be so deeply situated as to give but few signs. The initial symptoms are generally severe, being those of diaphragmatic pleurisy, but hiccough is often a troublesome feature. When pus forms, there may be marked constitutional symptoms, and obscure signs may develop, such as dullness, at a point just above the base behind, with weak or distant bronchial breathing. With such a history and obscure basic signs, especially when they occur after an attack of pneumonia, the use of the X-rays and of the exploring needle should not be neglected. In cases not recognised and treated, rupture into a bronchus or through the diaphragm may occur. The treatment is similar to that for ordinary empyema.

HYDROTHORAX (DROPSY OR HYDROPS OF THE PLEURA)

Hydrothorax is the name applied to a collection of clear fluid in the pleural cavity, the result of passive transudation from the capillaries.

Ætiology.—The commonest cause of hydrothorax is cardiac failure from chronic valvular disease, or from myocardial weakness or degeneration. It occurs in acute and chronic renal disease, under conditions similar to those leading to dropsy in these affections. It is sometimes found in severe anemias, especially pernicious anæmia. Obstruction to the azygos veins may lead to transudation into one or other pleural cavity or into both. This obstruction may be induced by pressure from without by a mediastinal or pulmonary new-growth, or by internal causes such as thrombosis.

Pathology.—The pathology of hydrothorax is that of dropsy elsewhere. It is produced by mechanical or chemical conditions affecting the blood flow through the capillaries, and it must be distinguished carefully from inflammatory effusion. There is a difference in the composition as well as in the origin of the two kinds of pleural fluid. The characters of inflammatory effusions have been described under pleurisy with effusion. The fluid in hydrothorax is pale yellow in colour, and the specific gravity is 1015 to 1010 or less. It is clear and does not clot after removal. There is little protein, often not more than 1 per cent., but transudates due to local obstruction may contain as much as 3 per cent. The cellular elements are scanty, although some endothelial cells may be present, often united together in plaques. The fluid may be definitely bloodstained, when it is described as hæmo-hydrothorax.

Hydrothorax is usually bilateral in cases due to cardiac or renal disease, but in the former there is often more fluid on the right side, or the fluid may be confined to that side. The explanation of this is somewhat obscure. It has been suggested that it is due to pressure or traction on the vena azygos major by the enlarged right heart, but according to Fetterolf and Landis, a more likely explanation is pressure of the distended right auricle upon the

pulmonary veins. Fluid may also collect in greater quantity on the side upon which the patient lies most constantly. In cases with unilateral pleural adhesion, œdema of the lung may occur on that side, while hydrothorax occurs upon the other.

Symptoms.—The symptoms of hydrothorax are generally overshadowed by those of the condition causing it, but the occurrence of dyspnœa and cyanosis in any case of cardiac or renal disease should suggest careful examination of the bases of the lungs. In the absence of inflammatory complications the condition is afebrile. The signs are identical with those of sero-fibrinous pleurisy, save that no friction sounds are audible at any stage. It is, however, more difficult to assess the significance of displacement of the cardiac impulse, owing to the increased size of the heart in the cases of cardiac origin.

Diagnosis.—This depends upon the presence of signs of fluid in the pleura in association with cardiac or renal disease, with absence of fever, and also upon the characters of the fluid withdrawn by puncture or aspiration.

Treatment.—Removal of the fluid, with or without oxygen replacement, may give great relief. It may be necessary to repeat the operation, since the fluid often reaccumulates. The treatment of the primary condition should also be carried out.

HÆMORRHAGIC PLEURAL EFFUSIONS

All fluids poured out into the pleura contain a certain number of red blood corpuscles. It is only when a number sufficient to give a definite red colour are present, that the fluid is regarded as hæmorrhagic.

For convenience of description three forms may be differentiated—(1) Hæmorrhagic pleurisy or hæmo-serothorax; (2) hæmo-hydrothorax; and (3) hæmothorax.

1. **HÆMORRHAGIC PLEURISY.**—This is simply a pleurisy with effusion, in which the exudate is blood-stained.

Ætiology.—The commonest causes are tuberculosis of the lung and pleura, and malignant disease of the lungs, pleura or mediastinum. Hæmorrhagic pleurisy may occur in association with hepatic cirrhosis, but in this case it is often the result of a terminal tuberculosis. It occurs less frequently in association with blood diseases, such as purpura, and with the malignant or hæmorrhagic varieties of acute infectious fevers such as scarlet fever and small-pox, and occasionally with lobar pneumonia. Sometimes in tapping a sero-fibrinous effusion for the second time, it is found that the fluid, which was originally clear, is now bloodstained. This is not necessarily an indication of increase in the severity of the process, but may be due to injury of a blood vessel at the first operation.

Symptoms.—The symptoms and signs are identical with those of serous effusion, and the hæmorrhagic character can only be recognised by withdrawal of the fluid. An interesting point is the frequency of excess of eosinophils in these effusions. Diagnosis and treatment are the same as for sero-fibrinous pleurisy.

2. **HÆMO-HYDROTHORAX.**—This condition has been referred to under hydrothorax. It consists simply in blood-staining of a passive transudate into the pleura.

3. **HÆMOTHORAX.**—Hæmorrhage into the pleural cavity is the result of injury or disease of the vessels of the lung, mediastinum or chest-wall.

Ætiology.—The chief causes are injury, such as penetrating chest wounds or fracture of the ribs, rupture of an aneurysm, and erosion by new-growth. Experience of the traumatic group has been largely increased during the Great War. Hæmothorax was noted in about 70 per cent. of chest wounds.

Pathology.—The effused blood generally comes from the lung vessels, less commonly from the intercostals. It is "whipped" by the movements of the heart and lungs, with the result that fibrin is deposited in layers upon the diaphragmatic pleura, and the parts of the visceral and parietal pleura in contact with the blood. The fluid remaining in the pleura or withdrawn by aspiration is largely defibrinated and therefore does not clot, unless a secondary pleurisy develops.

The lower lobe of the lung on the affected side becomes collapsed and eventually carnified, unless absorption occurs or unless the blood is aspirated. The upper lobe may show some compensatory emphysema, and adhesions may form in the pleura, separating it from the hæmothorax below. When secondary infections of the bronchi or lungs occur, such as bronchitis or broncho-pneumonia, the collapsed lower lobe is not affected.

Symptoms.—The symptoms of hæmorrhage into the pleura from medical causes, such as rupture of an aneurysm or erosion of a large vessel, are collapse and rapid death. When due to disease or injury of an intercostal vessel, they may be insidious and slowly ingravescent until dyspnoea, restlessness and the other indications of internal hæmorrhage develop. When due to injury, similar symptoms occur, but may be masked or overshadowed by the shock, hæmoptysis and cough, induced by the wound of the lung or chest-wall. The signs are those of pleural effusion, but in traumatic cases certain special features may be mentioned. There is a great tendency to retraction of the chest-wall on the affected side, and the cupola of the diaphragm on this side is displaced upwards. This is thought to be due to an active lobar collapse of the lung, the lung contracting, not as the result of the pressure of the effusion, but in consequence of a nervous protective reflex initiated by the trauma. Vocal fremitus is usually diminished or absent. The breath-sounds over the effusion are frequently bronchial, and well-marked bronchophony and pectoriloquy may be present.

Complications and Sequelæ.—The most serious complication is infection of the effusion. This is generally due to organisms introduced at the time of the wound, either by the missile or by portions of the clothing or skin carried in with it. Aerobic organisms, such as a streptococcus, or anaerobic ones, as the *B. aerogenes encapsulatus* or the *B. sporogenes*, may be present. A hæmo-pneumothorax may develop, the gas entering the pleural cavity from the wound in the lung or through the chest-wall. Gas may also be formed by gas-producing infecting organisms in the effusion. Massive collapse may occur in the contralateral lung, or other complications may arise, such as bronchitis, broncho-pneumonia, lobar pneumonia or œdema of the lungs. If the effusion is small and not infected, there are usually no permanent after-effects. In severe cases sequelæ, similar to those of sero-fibrinous pleurisy and empyema, may result.

Course.—This depends upon the cause and size of the hæmothorax, and upon the mode of treatment adopted. It is profoundly and gravely

influenced by infection of the effused blood. A small sterile hæmothorax is generally absorbed spontaneously. Medium-sized and large effusions may not disappear unless aspirated. An infected hæmothorax will inevitably prove fatal, if untreated.

Diagnosis.—Hæmothorax should be suspected when basic dullness develops shortly after a gunshot wound of the chest. The mistake that is most likely to be made in such cases is to confuse hæmothorax with **lobar pneumonia**. The cardiac displacement and the diminution of vocal fremitus over the dull area are the most valuable diagnostic signs. An active lobar collapse is distinguished by the fact that the heart is displaced towards the affected side. The X-rays afford valuable confirmatory evidence in most cases. When air and blood are present, the upper border of the dark area in the radiogram has a sharply defined edge, while the pleural cavity above is very translucent. The use of the exploring syringe generally settles the diagnosis, except in certain cases in which, although a considerable quantity of blood may be present, none is removed by aspiration owing to the needle entering the clot.

Prognosis.—In a sterile hæmothorax due to a chest wound the prognosis is good. If infection occurs, the prognosis depends upon the promptitude with which this condition is recognised and radically treated, although in very acute infections death may occur in 2 or 3 days despite immediate operation.

Treatment.—A small sterile hæmothorax may be left untouched. In medium and large-sized effusions, recovery is accelerated by aspiration. The possible danger of renewal of the hæmorrhage, as the result of lowering the pleural tension by this operation, is very slight, and negligible if it is delayed until 2 or 3 days after the wound. If the temperature in a case of hæmothorax rises suddenly to 102° or 103° F. in the evening, it is criminal to wait until the next morning to see what will happen. A specimen of fluid should be withdrawn and examined microscopically. Direct films may occasionally reveal the presence of organisms, but the important point to determine is the number of polymorphonuclear leucocytes present. When these are numerous, operation should be performed without awaiting the findings of aerobic and anaerobic cultures. A rib should be resected as in empyema, and the blood and clots should be removed from the pleural cavity and drainage established.

CHYLOUS AND OTHER MILKY EFFUSIONS

A milky fluid is occasionally obtained on exploratory puncture or aspiration of a pleural effusion. It is usual to classify such fluids into three groups—(1) Chylothorax; (2) chyloform fluid; (3) pseudo-chyloous fluid.

1. **Chylothorax.**—There is an effusion of pure chyle or of serous fluid mixed with chyle.

Ætiology.—Chylothorax is usually the result of injury to, or disease of, the thoracic duct. The traumatic form is, as a rule, secondary to crushing of the chest-wall with fracture of the ribs. In disease, the thoracic duct may be pressed on by a malignant growth or enlarged mediastinal glands, or the flow may be obstructed by a thrombosis of the left subclavian vein. Invasion of the thoracic duct by the *Filaria sanguinis hominis* may also be a cause.

Pathology.—The fluid in true chylothorax is a milky emulsion which remains so on standing, although a cream-like layer may form at the top. With the microscope fat globules can be seen, which stain with the usual fat stains and can be dissolved by ether.

2. *Chyliform effusion.*—In this condition fat is present, but it is not derived from the thoracic duct.

Ætiology.—Chyliform effusions occur in association with tuberculosis and carcinoma of the pleura or lung.

Pathology.—The fluid is milky and contains fat in emulsion, although in smaller quantities than in true chylothorax. On microscopical examination large fat droplets are seen, and numbers of cells, chiefly leucocytes undergoing fatty degeneration. It is, no doubt, from this process that the fat is derived.

3. *Pseudo-chylous effusion.*—In this condition the milky appearance is not due to fat, but to other particles causing opalescence.

Ætiology.—Pseudo-chylous fluid has been observed in chronic effusions due to heart disease, nephritis, tuberculosis and malignant disease.

Pathology.—The milky appearance is due in some cases to a lecithin globulin complex (Wallis and Schölberg). Other rare causes of milky, opalescent or turbid effusions are the presence of particles of calcium phosphate, cholesterol or filarial embryos. These fluids are distinguished from the above by showing a deposit on standing.

Diagnosis.—This can only be established by microscopical and chemical investigation of the fluid withdrawn.

Prognosis.—The prognosis in most cases of milky effusions is serious, owing to the gravity of the primary condition. Some traumatic cases of true chylothorax recover.

Treatment.—The treatment is for the most part symptomatic and dependent upon the primary condition. In true chylothorax, removal of the fluid is inadvisable, unless it is causing dyspnoea or other symptoms of pressure. The drain of fat caused by it is a serious loss, especially if the tapping has to be repeated frequently. In chyliform effusions there is a marked tendency to recur after removal of the fluid.

PNEUMOTHORAX

In pneumothorax, gas, usually air, collects between the layers of the pleura, which now becomes a real instead of a potential space. When serous fluid is present as well as the gas it is called a hydro-pneumothorax, when pus forms the condition is described as pyo-pneumothorax, and when blood and gas collect the term hæmo-pneumothorax is applied.

Ætiology.—Pneumothorax is more common in men, and the maximum incidence is between the ages of 20 and 40 years, but it may occur at any age. The air may gain access to the pleural cavity in the following ways: (1) Through the visceral pleura from the air in the lungs and bronchi. This accounts for 95 per cent. or more of the cases. The commonest cause is rupture of a subpleural tuberculous focus, which is said to be responsible for 90 per cent. of all cases. Rupture of an empyema into the lung is the next most frequent antecedent condition. Other pulmonary causes are gangrene,

abscess, septic infarct, bronchiectasis and rupture of an emphysematous bulla or vesicle. Puncture of the lung during paracentesis, or rupture of the pleura over a diseased focus, owing to rapid expansion of the lung during the same operation, may lead to pneumothorax. A broken rib perforating the lung can also induce it. (2) Through the chest-wall, as a result of penetrating wounds, although pneumothorax is not a common result. An abscess in the chest-wall opening externally and through the pleura, or a discharging empyema necessitatis, may be a cause. (3) Through the mediastinum, by ulceration of an œsophageal growth, or of a diseased bronchial gland, into the pleura, or from accidental perforation of the œsophagus during the passage of an œsophageal bougie or œsophagoscope. (4) Through the diaphragm, from some hollow abdominal viscus, *e.g.* an ulcer of the stomach or duodenum may perforate, leading to the formation of a subphrenic abscess, which in turn may break through the diaphragm into the pleura. (5) Gas may accumulate in the pleura owing to infection of a pleural effusion by gas-producing organisms. This is generally the result of wounds. In a few cases pneumothorax occurs in apparently healthy persons; this is probably due to rupture of an emphysematous vesicle or bulla, or of a small latent tuberculous focus.

The exciting cause of pneumothorax may be physical strain or violent cough, but many cases occur while the patient is at rest or even during sleep.

Pathology.—The entrance of air between the layers of the pleura disturbs the pressure relations in the thorax in a similar way to the effusion of fluid; but whereas with the latter the process is gradual, in pneumothorax it is rapid, and the pressure within the pleura changes from the normal negative figure to that of the atmosphere, often in a few minutes or less. Mediastinal and cardiac displacements like those in pleural effusion, and due to the unopposed traction of the sound side, are also rapidly produced. The subsequent pressure relations depend upon the source of the air. If the opening is in the chest wall, the intrapleural pressure will remain equal to the atmospheric, until the opening becomes closed. If the opening is in the lung, three varieties occur: (1) the opening may remain patent, when the pressure keeps at atmospheric level; (2) the opening may be valvular, permitting the entry of air into the pleura during inspiration, but preventing its escape during expiration. In this case the pressure in the pleura rises above that of the atmosphere, and the air within it is at a positive pressure, causing further cardiac and mediastinal dislocation with downward displacement of the diaphragm; (3) the opening becomes sealed, and there is a condition of closed pneumothorax in which the pressure may be equal to, greater or less than, that of the atmosphere.

To demonstrate pneumothorax post mortem, the autopsy may be performed under water, or a flap being made of the skin and muscles at the side of the thorax, this may be filled with water before puncturing the intercostal spaces. A third method is to dissect carefully through an intercostal space down to the pleura, when the lung will be found to be retracted. On opening the thorax the appearances vary. If the air entering the pleura is sterile, no inflammatory reaction occurs, the pleura remains shiny and no fluid is formed, the condition being one of simple pneumothorax. More

commonly, bacteria gain access to the pleura with the ingoing air, or subsequently through the opening when this remains patent, with the result that either serous fluid or pus collects. In the former case the condition is described as hydro-pneumothorax, in the latter as pyo-pneumothorax. The appearances of the pleural membrane are similar to those found in sero-fibrinous pleurisy and empyema respectively. The lung is collapsed in every case of pneumothorax, and lies retracted towards the hilum and the spine. In tuberculous disease, a caseous focus or small cavity just under the pleura is the most frequent cause. The perforation may be a large circular rent or a small pin-hole, but multiple apertures may occasionally be present. The opening can usually be found, even if small, by submerging the lung under water while pumping air down the trachea. When extensive adhesions are present, the collapse of the lung is largely prevented and the pneumothorax is only partial. In such cases the perforation is frequently near the adhesions. In cases where fluid is present the diaphragm may be seen to be depressed on the affected side and its curvature lessened or reversed.

Symptoms.—In a considerable proportion of cases the onset is sudden and the condition of the patient becomes alarming at once. On the other hand, pneumothorax may develop insidiously, with surprisingly little pain and dyspnoea, so that its occurrence may only be discovered on routine physical examination. This is more likely to be the case when perforation occurs in a lung extensively diseased or when the aperture is small, and the leak of air is slow. In the acute form of onset the patient is seized with severe pain while coughing or engaged in some extra exertion. There is often a feeling of “something having given way,” and at once great dyspnoea, with signs of collapse and severe mental anguish develops. The patient may appear blue, cold and clammy, breathing is rapid and shallow, the temperature falls to subnormal, the heart beats quickly and the pulse becomes small and weak. The patient is often restless, very alarmed and unable or afraid to speak. Occasionally death occurs in a few minutes. As a rule, the more acute symptoms subside in a few hours, but the temperature rises and the rapid breathing usually persists for some time. On examination the patient will usually be found sitting up, with *alae nasi* working and with rapid shallow breathing. The affected side is almost or entirely immobile and is usually “bulged.” The displacement of the cardiac impulse towards the unaffected side is generally obvious, and is almost immediate. Palpation confirms the absence of movement, and vocal fremitus is found to be absent, except where the collapsed lung remains in contact with the chest wall, over which area it may be increased. The exact position of the cardiac impulse should also be determined: in right-sided cases it will be found in the left axillary region; in left-sided cases it may be under or beyond the right nipple. The liver may be felt much depressed in right-sided cases. The note over a pneumothorax is characteristically tympanic or drum-like, as a rule, but in cases with positive pressure the tympany may be flat and muffled. The tympanic area should be carefully mapped out; it may be found to extend across the middle line, or to encroach on the liver dullness in right-sided cases. On the other hand, in partial pneumothorax, the area may be small and easily escape recognition. In left-sided cases, the cardiac dullness may be completely wanting on that side, and a dull area found to

the right of the sternum. This may give a useful hint as to the diagnosis. On auscultation, the breath-sounds are often absent, but they may be present at the apex, although weak. In other instances distant tubular breathing may be audible from the collapsed lung; in cases with a large patent opening hollow cavernous breathing may be heard. The voice sounds have an amphoric or metallic quality, and an amphoric echo may occur with any sound produced near the pneumothorax. Metallic tinkling is an example of this, being the quality conveyed to râles or other adventitious sounds produced in breathing. The bell sound or *bruit d'airain* is a valuable sign, but is not invariably present. It is elicited by listening over the chest, near where a coin is placed flat and tapped with another. A similar sound may be heard with the stethoscope on flicking over a pneumothorax with the thumb and finger. The displacement of the heart can be confirmed by auscultation, and the heart sounds may be found to have a metallic character. When air and fluid are present in the pleura the signs are somewhat modified. There is dullness at the base, which shifts its level with the patient's movements, the upper limit being straight, in contrast with the curved line of ordinary effusions. A marked succussion splash may be heard and felt on shaking the patient, or the patient may demonstrate the sign by a sudden shake or jerk.

Complications and Sequelæ.—Cardiac failure and rapid death occur occasionally. The chief complications are due to the entry of infective organisms into the pleura, leading to pleurisy and the effusion of sero-fibrinous fluid or pus. The sequelæ may be pleural adhesions in cases that recover, especially if effusion occurs. There may be also permanent collapse of the lung in long-standing cases, and in pyo-pneumothorax a fistula, either pleuro-pulmonary or external, may remain in spite of treatment.

Diagnosis.—The recognition of a large or of a complete pneumothorax is easy as a rule, the signs being characteristic. When a large quantity of fluid is present in an open pneumothorax, the presence of air may not be recognised until after paracentesis or X-ray examination. The latter gives information of the greatest value and sometimes demonstrates the presence of local pneumothorax where it has not been suspected. The air space between the lung and pleura shows most clearly in radiograms, and if fluid is present as well, the dead level of the upper border of the shadow, varying with position, is most characteristic. Diagnosis is more difficult in cases where pleural adhesions exist, or where the pneumothorax is small and localised, especially if X-ray examination is impracticable. The following conditions may give rise to difficulty and should be considered in doubtful cases. (1) Total excavation of a lung, or a large pulmonary cavity, in either of which the note may be boxy or even tympanic, the breath sounds amphoric and the râles metallic or tinkling, while the coin sound may be obtained. These conditions can usually be distinguished by the flattening and retraction of the chest-wall over them, and the absence of cardiac displacement, or if it exists, the traction of the heart towards the affected side by fibrosis. (2) Advanced emphysema, with complete obliteration of the cardiac dullness, may be confused with pneumothorax. (3) Massive collapse of one lung, with compensatory emphysema of the opposite side, may also be mistaken for it. In both these conditions careful examination will establish the real nature. (4) A subphrenic abscess containing gas (subphrenic pyo-pneumo-

thorax), in this condition the diaphragm may be displaced upwards, and the note over the lower ribs may be markedly tympanitic. These signs are more suggestive when right-sided. Succussion splash and bell sound may be elicited. The heart, if displaced, is pushed upwards. The history of previous abdominal disease may be helpful, and a radiogram may give conclusive evidence of the subphrenic origin of the condition. (5) A hernia of the stomach or bowel through the diaphragm, or eventration of the diaphragm, all rare conditions, may simulate pneumothorax but in all there is generally abdominal flattening and little if any cardiac displacement. Examination by X-rays after an opaque meal will, as a rule, establish the nature of the condition.

Course and Prognosis.—The course and prognosis of pneumothorax are profoundly influenced by the cause. In cases due to rupture of an emphysematous vesicle, or of a small localised tuberculous focus, where the pleura remains sterile and the aperture of entry closes, the air is usually completely absorbed in a few weeks and recovery is often complete. In tuberculous cases with moderate disease, in which the pleura remains sterile, pneumothorax may exert a favourable influence. In tuberculous cases with extensive disease, the pleura becomes infected and death usually results in a few weeks or months, although with judicious treatment life may be prolonged for years in some cases. In pneumothorax secondary to some grave disease, such as carcinoma or gangrene, the course is brief and the prognosis is grave in the extreme. In cases secondary to empyema, surgical treatment may be followed by complete recovery, unless a bronchial fistula is present.

Treatment.—The indications in cases of acute onset are to relieve the patient's pain, distress and anxiety, and to lessen the intrapleural pressure, if this is positive. A hypodermic injection of morphine, gr. $\frac{1}{4}$ for an adult, with oxygen inhalations if necessary, may achieve the first of these. If dyspnoea is extreme and the cardiac displacement marked, a trocar or large hypodermic needle should be inserted through an intercostal space to allow air to escape. A Southey's trocar with a long rubber tube, the end of which is placed under water, is the safest. This simple manoeuvre may be the means of saving the patient's life in valvular pneumothorax, as well as of relieving distress. In simple cases no other treatment may be required, although the puncture may need to be repeated. If serous fluid or pus collect in the pleura, they may be withdrawn, preferably by siphonage, and in this case, as also with removal of air, too much should not be withdrawn in the early stages, as a slight positive pressure may assist in closure of the aperture in the lung, whereas a negative pressure may open it, after it has begun to close.

The question of operation in pneumothorax may be difficult to decide. In cases secondary to empyema, resection of a part of a rib and drainage often lead to satisfactory results. In cases of moderately severe or advanced tuberculosis with pyo-pneumothorax operation is generally contra-indicated, and if performed is liable to result in a permanently open pneumothorax. It is preferable to remove fluid from time to time by aspiration, with or without oxygen replacement. The latter method of aspiration sometimes seems to assist the lung to re-expand.

HYDATID DISEASE OF THE PLEURA

Hydatid cysts may be primary in the pleura, or may encroach on the pleura, although originating in adjacent structures such as the lung, liver, spleen or mediastinum (parapleural hydatid).

Ætiology and Pathology.—Primary pleural hydatid is rare, but secondary invasion of the pleura is more common. In this situation the cyst may reach a large size, even 5 or 6 inches in diameter, before rupture occurs. As in other situations, a fibrous capsule is developed around the cyst from the irritative changes set up in the adjacent tissue. Contrary to what might be expected, extensive pleurisy is uncommon until rupture or suppuration of the cyst occurs. The pressure of the cyst may lead to collapse of the contiguous areas of lung and to displacement of the heart and mediastinum.

Symptoms.—These may be absent until the cyst is large enough to produce pressure symptoms, such as dyspnoea, pain and cough. There is little or no expectoration, unless rupture into a bronchus occurs, when cyst wall, daughter cysts and hooklets may be found in it. There is no fever until suppuration occurs. The signs are practically identical with those of encysted pleural effusion.

Complications and Sequelæ.—Rupture and suppuration are the two most important complications. Rupture may take place into the lung, into the pleural cavity, rarely through the chest-wall or through the diaphragm. At the time of rupture an urticarial rash may develop. This is probably an anaphylactic phenomenon associated with the liberation of toxin present in the fluid of the cyst.

Course.—The cyst may be latent for some time, but it usually enlarges and produces increasing symptoms, culminating in rupture or suppuration. Very rarely death of the cyst occurs and its contents become inspissated.

Diagnosis.—The symptoms and signs generally suggest either pleural effusion or new growth, and hydatid disease may not be suspected. Obscure basic signs, in patients coming from countries where hydatid disease is common, should suggest special methods of investigation as to the possibility of its presence. Should it be suspected, aspiration is to be deprecated, unless all preparations for immediate operation are complete, if the diagnosis is confirmed. These methods comprise X-ray examination, an eosinophil blood count, the complement fixation test and the precipitin reaction.

Prognosis.—If untreated until rupture occurs, a fatal result is most probable. If diagnosed and treated before rupture, the prognosis is not unfavourable.

Treatment.—The former practice of aspiration and injection with formalin or iodine, although sometimes successful, is dangerous and should be discarded. Exposure of the cyst by thoracotomy, and its removal entire, should be the treatment if practicable, or if too large, it may be aspirated and then dissected out.

ACTINOMYCOSIS (NOCARDIASIS, STREPTOTRICHOSIS) OF THE PLEURA

The general characters of infection by the nocardia or streptothrix group of organisms, and the special features of the pulmonary localisations have been described. It is possible, although improbable, that the infection may be primarily pleural, more commonly clinical manifestations may point to a predominating involvement of the pleura, although the primary lesions may be in adjacent structures, such as the lungs, mediastinum or liver.

Symptoms.—The symptoms and signs in such cases are those of empyema, but the following points are noteworthy. The empyema is rarely large, and it commonly extends through the chest wall, producing a local swelling which soon discharges through the skin if untreated, causing a suggestive infiltration and puckering around. Exploratory puncture of a nocardial empyema often fails, since the grumous caseous material it contains may be too thick to pass through the needle.

Diagnosis.—The characteristic “sulphur granules” in the pus may draw attention to the real nature of the condition, but they are not always present. Direct films should always be made from the pus obtained from empyemata. The streptothrix may be found in this way, when culture fails. If the lung is involved as well as the pleura, the organism may be found in the expectoration, and the nature of the pleural condition may thus be established before operation.

Prognosis.—Some cases respond to treatment, but prognosis is in general unfavourable, death resulting from exhaustion or toxæmia due to dissemination of the disease.

Treatment.—The pultaceous pleural contents should be removed as far as possible by operation, and large doses of potassium iodide given by the mouth, increasing the quantity until 60 to 90 grains, three times a day, are given. An autogenous vaccine may be tried if the organism can be grown.

SIMPLE TUMOURS OF THE PLEURA

These are very rare and are, as a rule, only discovered after death. They are almost invariably of extrapleural origin and their presence in the pleura is due to the direction taken by the growth. Lipoma of the subpleural or of the mediastinal fat may occur as small pedunculated tumours or very rarely as a large mass.

MALIGNANT TUMOURS OF THE PLEURA

Primary malignant disease of the pleura is rare, and may take the form of endothelioma, carcinoma or sarcoma. Secondary carcinoma and sarcoma are more common.

Ætiology.—Primary endothelioma of the pleura is more common in late adult life and in the male sex. Sarcoma is more likely to occur in children and in young adults. Secondary growths may occur at any age, but more commonly in later life.

Pathology.—Endothelioma of the pleura is a growth of obscure origin. It has not been conclusively established that it is derived from the pleural endothelial cells, and by some writers it is classed as a carcinoma. It is generally unilateral, but it involves the affected pleura over a wide area, sometimes universally. The membrane appears to be overlaid with an irregular, rough hard covering, sometimes nodular. In other cases there is more thickening and the condition may be localised. There is nearly always a large amount of blood-stained serous effusion. The condition may spread to the bronchial or supraclavicular glands, the lung, the diaphragm and the peritoneum.

Primary carcinoma of the pleura has also been described, but is very rare. Primary sarcoma is also extremely uncommon, but the round-celled and spindle-celled varieties may occur, and angio-sarcoma, fibro-sarcoma, myxo-sarcoma and chondro-sarcoma have all been recorded.

Secondary carcinoma and sarcoma of the pleura are relatively common, and may occur from direct *extension* in growths of the lung, bronchi and mediastinum, by *metastases* of growths in almost any distant part, or by *lymphatic permeation* in mammary carcinoma. In the last-named condition pleural and pulmonary growths are a not infrequent form of recurrence, sometimes occurring months or years after removal of the primary growth.

Symptoms.—These are not characteristic, and increasing dyspnoea due to an accumulation of fluid may be the first indication. More commonly pain and cough, similar to those of pleurisy, may occur acutely or develop more gradually. Although afebrile as a rule, the occurrence of fever does not exclude malignant disease. Cachexia and wasting are often not marked until the condition is advanced. The signs are generally indistinguishable from those of ordinary pleural effusion, unless secondary growths become manifest in the cervical or axillary glands. Sometimes coarse dry friction may be heard, or there may be signs of pleural thickening without fluid. There is often local pain and tenderness over the chest. Exploratory puncture may demonstrate the hæmorrhagic character of the effusion. The specific gravity is generally 1018 or over, and the cytology of the fluid may be suggestive, especially if excess of endothelial cells, often aggregated into plaques, is found.

Complications.—The growth may spread to the lung and cause cough and expectoration, often blood-stained, or it may involve the chest-wall. Metastases sometimes develop along the course of the needle track after aspiration of the fluid. The secondary growths, especially those in the glands, may exert pressure, e.g. the axillary glands may cause œdema and swelling of the arm.

Course.—This is almost invariably progressive, the duration being rarely more than 2 years, and occasionally much less.

Diagnosis.—A chronic pleural effusion in a middle-aged man, not associated with fever, and not due to tuberculosis, should arouse suspicion of malignant disease of the lung and pleura. Evidence of fluid in one pleura, at an interval after excision of the breast for malignant disease, is very suggestive of secondary pleural growth. A hæmorrhagic effusion, not due to tuberculosis or renal disease, should also arouse suspicion of malignancy, especially if reaccumulation after tapping is rapid, and if the subsequent tapplings show increasingly hæmorrhagic characters. When aspiration of a considerable quantity of

fluid gives little relief to symptoms, or when irregular dull areas remain where resonance might be expected, the probability of growth must be borne in mind. Involvement of the chest-wall, or the presence of cervical or axillary glandular metastases render it certain.

Prognosis.—Malignant growth of the pleura is invariably fatal.

Treatment.—From the nature of the condition this can only be palliative. Analgesic drugs may be given freely for the relief of pain, morphine being reserved for the severe forms and later stages, as far as possible. Repeated tapplings may be almost compulsory, if there is much distress from the reaccumulation of the fluid, but it must be remembered that in hæmorrhagic effusions the loss of blood by this means is considerable. Oxygen or nitrogen replacement may sometimes give relief for a longer period than simple aspiration.

INJURY

Injury to the pleura may occur in fracture of the ribs, the fragments piercing or tearing it. Similarly in penetrating wounds of the chest, the pleura may be extensively lacerated. It may also be torn by direct violence without breaking of the ribs, and in rare cases a hernial protrusion of lung may occur, forming a small swelling in an intercostal space, protruding with inspiration and emptying with expiration.

DISEASES OF THE DIAPHRAGM

SPASM OF THE DIAPHRAGM

Diaphragmatic spasm may be either clonic or tonic, the former being termed *hiccough*.

Clonic spasm.—This may be due to a variety of causes, namely: (A) Alimentary: From irritation of the œsophagus or stomach by pungent or irritant substances, such as pepper, pickles, or tobacco. It occurs also as a symptom in gastritis, dilatation of the stomach, enteritis, intestinal obstruction, tympanitis and peritonitis. (B) Nervous: as in hysteria, cerebral tumour, meningitis, hydrocephalus, epilepsy and alcoholism. It may also result from peripheral nerve irritation, in such conditions as mediastinal tumour, mediastinitis, enlarged thoracic glands, diaphragmatic pleurisy, or pericardial effusion. *Epidemic hiccough* has been regarded as a form of encephalitis lethargica. There is usually some slight pyrexia, and the condition may persist without intermission for several days. (C) Renal: As in chronic nephritis and uræmia.

Tonic spasm.—This may be met with in tetanus, strychnine poisoning, laryngismus stridulus, eclampsia, epilepsy and hydrophobia. If there is associated intercostal or laryngeal spasm, there is grave risk of death from asphyxia.

Treatment.—Simple hiccough may often be relieved by holding the breath, pressure on the chest, or by simple inhalations, such as of ammonia,

1166 DISEASES OF THE RESPIRATORY SYSTEM

ether, or spirits of chloroform. Hiccough due to organic disease or to peripheral irritation may only be relieved by removal of the cause. In epidemic hiccough, in obstinate cases of hiccough due to other causes and in the tonic form of spasm, various antispasmodic measures may be tried, such as trinitrin, bromides, musk, or luminal, by the mouth, adrenalin, or adrenalin and pituitrin, hypodermically, or the inhalation of chloroform.

DIAPHRAGMATIC PLEURISY

This condition is described on page 1141 under the heading of Pleurisy.

PARALYSIS OF THE DIAPHRAGM

Definition.—Paralysis and inactivity of either leaf of the diaphragm, or of both.

Ætiology.—Paralysis of the diaphragm may be caused by disease damaging the centre in the spinal cord, by conditions affecting the phrenic nerve in its course, or by reflex inhibition of the centre. Causes involving the centre include poliomyelitis, hæmorrhage into the spinal cord, and tumours of the spinal cord or its membranes, or of the spine itself. The phrenic nerves may be affected by diphtheritic neuritis. Either or both of the nerves may be compressed by mediastinal tumours, or by inflammatory exudates. They may be severed or injured by wounds in the neck. Exsaisis or evulsion of the phrenic nerve is now frequently employed therapeutically, in order to promote collapse of the base of one lung in cases of tuberculosis and in bronchiectasis.

Symptoms.—Diaphragmatic paralysis results in the affected leaf of the diaphragm becoming immobile and remaining at a higher level in the thorax than normal. This can easily be seen on X-ray examination. Sometimes there is a reversal of the ordinary abdominal movements during respiration, with the result that there is epigastric recession during inspiration. Massive collapse of the lung, described on page 1068, has been regarded as due to reflex inhibition of the diaphragm on one side, though this explanation is not now generally accepted.

Treatment.—This is, in general, that of the condition causing the paralysis.

HERNIA OF THE DIAPHRAGM

Definition.—Protrusion of some part of the abdominal viscera through an opening in the diaphragm into the thoracic cavity.

Ætiology.—Diaphragmatic hernia may be congenital or acquired. The congenital form is due to an error in development. Acquired hernia generally results from gunshot wounds or stabs involving the diaphragm. More rarely, it may be caused by severe and prolonged vomiting. As might be expected from anatomical considerations, diaphragmatic hernia is much commoner on the left side.

Symptoms.—These are more definite and characteristic when the hernia is on the left side. In the congenital variety the symptoms may be slight,

and the condition may only be discovered accidentally on X-ray examination. More often there is dyspnœa and discomfort, particularly after meals. In acquired cases, if the onset is sudden, there may be great shock and dyspnœa. More often the condition develops gradually, and the symptoms are those of discomfort or dyspnœa and distress after eating. In left-sided cases, vomiting is not infrequent. Hiccough and cough are common symptoms. The disturbance of digestion may cause considerable loss of weight. There may be some flattening of the upper part of the abdomen and some displacement of the heart. There is often diminished vocal fremitus at the base behind, and palpation may confirm the dislocation of the heart to a higher level than normal, or to the right. The percussion note may be tympanitic and breath sounds may be absent or weak.

Diagnosis.—This has to be made from pneumothorax and from eventration of the diaphragm, and in regard to these the X-ray findings are generally crucial. The physical signs of left-sided hernia may be strikingly similar to those of pneumothorax, and it is only by X-ray examination that the real nature of the affection may be recognised.

Treatment.—The treatment of the condition is surgical.

EVENTRATION OF THE DIAPHRAGM

Definition.—This name has been applied to a condition in which, owing to congenital or acquired thinness of half of the diaphragm, the pressure of the intra-abdominal contents causes the affected leaf of the diaphragm to bulge upwards. It is a rare condition. Symptoms are often entirely lacking, and the diagnosis may only be made by X-ray examination. When symptoms are present, they may be somewhat similar to those of hernia of the diaphragm.

DISEASES OF THE MEDIASTINUM

The mediastinum is the interpleural space, and occupies the median part of the thorax, from the superior aperture above to the diaphragm below. Strictly speaking, any affection of any of the important structures occupying this space, such as the pericardium, heart, great vessels, air passages and the thymus, might be included under this heading. They are, however, more conveniently grouped under the various systems to which they belong, and diseases of the mediastinum are commonly restricted to conditions arising in, or affecting the connective tissue and glands found in this space.

MEDIASTINITIS

Mediastinitis, or inflammation in the mediastinal connective tissue, may be acute or chronic. In the acute forms there may be an inflammatory serous exudate causing œdema, or the inflammation may progress to abscess formation. The chronic forms are indurative or fibroid in character, although chronic abscess may occur.

ACUTE SIMPLE MEDIASTITIS

Ætiology.—Acute mediastinitis without suppuration may result from injuries to the chest-wall or sternum, and from lacerating wounds of the œsophagus or trachea. It is sometimes secondary to inflammatory processes in the lungs, pleuræ, pericardium or peritoneum, and to periostitis of the sternum or vertebræ. Pneumonia is a not uncommon cause.

Pathology.—There is hyperæmia of the mediastinal connective tissue with inflammatory œdema. Mediastinal serous effusions have been described, but these are, without doubt, encysted pleural effusions encroaching on the mediastinum.

Symptoms.—The clinical manifestations of acute mediastinitis are vague and not characteristic. There is a mild pyrexia, the temperature reaching 99° or 100° F. Pain under the sternum may be complained of, and on auscultation over it a few fine crepitations may be heard on deep breathing, or they may occur synchronously with the heart beats.

Course.—The affection may subside or proceed to abscess formation. It may result in fibroid thickening or adhesions.

Diagnosis.—Mediastinitis is often not recognised or suspected, since it is masked or overshadowed by the clinical manifestations of the primary condition.

Treatment.—No special treatment is required, apart from that appropriate to the condition inducing it.

ACUTE SUPPURATIVE MEDIASTITIS

Ætiology.—Acute suppurative mediastinitis or mediastinal abscess is more common in males, and may occur at any age, although it is more frequently seen in early adult life than at other periods. Some cases are of traumatic origin, and follow perforating wounds or blows on the sternum, not necessarily causing fracture. Perforation or injury of the œsophagus is a comparatively frequent mode of access of pyogenic organisms to the mediastinum. This may occur from ulceration of an œsophageal new-growth, from injury due to a swallowed body such as a tooth plate, or from the passage of an œsophagoscope or bougie. Perforation of the trachea or main bronchi by an inhaled foreign body is sometimes the cause of mediastinal suppuration. Various pulmonary conditions may lead to pyogenic infection of the mediastinum, such as pulmonary abscess or gangrene, pneumonia and bronchiectasis. Periostitis or osteomyelitis of the sternum, vertebræ or ribs, suppuration in the mediastinal glands, or tracking down of deep cervical abscesses may all lead to mediastinal abscess. Extensions of pyogenic processes from the pericardium, pleura or peritoneum may also be causes. A suppurating hydatid or dermoid cyst may rupture into the mediastinum, and, lastly, the infection is blood-borne in some cases from infective endocarditis, pyæmia, erysipelas or enteric fever. Dieulafoy pointed out that certain cases of empyema, originating near the mediastinum, may, by encroaching on this region, induce predominating mediastinal symptoms, which he described as the “mediastinal syndrome.” Such cases,

although abscesses in the mediastinum, are not mediastinal abscesses, but are in reality special instances of encysted empyema.

Pathology.—The suppuration may be limited to any part of the anatomical subdivisions of the mediastinum, or may spread from one compartment to another. The pus sometimes tracks in various directions, *e.g.* upwards to the neck, downwards to the abdomen, or it may point in the chest-wall. The abscess may rupture into the œsophagus, trachea, aorta, pleura or pericardium.

Symptoms.—The onset may be insidious or acute. In the latter case it may be ushered in by severe pain under the sternum, radiating to the back and shoulders. The symptoms may be divided into those due to the inflammatory process, and those resulting from the pressure exerted by the collection of pus. The former comprise malaise, fever and sometimes rigors, while blood examination may demonstrate a leucocytosis of 10,000 per c.mm. or over. The pressure symptoms vary according to the amount of pus produced and its situation. They include dyspnœa and paroxysmal or brassy cough, from compression of the vagus nerve or direct pressure on the trachea. There may also be dysphagia from obstruction of the œsophagus, and hoarseness from pressure on the left recurrent laryngeal nerve. Pressure on the spinal nerve roots, intercostal nerves, or brachial plexus may lead to severe neuralgic pains. Partial or complete obstruction of the great veins may be apparent from distension of the superficial thoracic veins or of those in the neck. (Edema of the chest-wall is sometimes seen from this cause, or it may result from the inflammatory process extending to the chest-wall. The signs in severe cases will be those caused by the pressure effects just described. The patient looks ill, distressed, dyspnoic and more or less cyanosed. The respirations may be noisy, as there is sometimes inspiratory dyspnœa with stridor, this being known as the *bruit de coraque*. The dilated veins may be apparent and the direction of the current may help to localise the seat of the obstruction. There is sometimes local redness and œdema from pointing of the abscess, near the sternum, in the neck, or in the interscapular region on either side. Palpation may reveal local tenderness and even fluctuation in any of these areas. There is often dullness over the sternum, sometimes extending to one or other side, or the dullness may be found in the interscapular region. It is said that the dullness may shift with the position of the patient in some cases. Breath sounds are distant, and weak or bronchial over the dull area, except when it is behind the sternum, when they are harsh.

Complications and Sequelæ.—The important complications are those due to rupture of the abscess. If this occurs into the lung or the œsophagus, pus is expectorated, or passes into the stomach. Gangrene of the mediastinum may follow, or death may occur from suffocation or hæmorrhage. Extension of the abscess may lead to purulent pleurisy, pericarditis or peritonitis, or to suppuration in the neck. In cases that recover, chronic mediastinitis with matting together of the mediastinal contents may be a sequel.

Course.—The disease is acute and rapidly progressive, unless relieved by operation or by spontaneous external drainage in a few fortunate cases.

Diagnosis.—The “mediastinal syndrome” of dyspnœa, stridor, paroxysmal cough, hoarseness and dysphagia with signs of pressure on arteries, veins and nerves is common to many conditions causing mediastinal pressure,

notably mediastinal new-growth, enlarged mediastinal glands, aneurysm and pericardial effusion. The differential diagnosis of these is more fully considered under mediastinal new-growth. The occurrence of fevers and rigors, the presence of a pointing swelling, and the demonstration of a leucocytosis may give strong suggestion as to the inflammatory origin of these symptoms and signs. The X-rays may reveal a localised mediastinal shadow, often non-pulsating, although it must be remembered that in rare cases a mediastinal abscess may pulsate.

Prognosis.—This is very grave, and the majority of cases die unless recognised and treated early. If gangrene develops, a fatal result is inevitable. The outlook is more hopeful when the anterior mediastinum alone is involved.

Treatment.—*Prophylactic.*—Foreign bodies in the œsophagus and trachea should be removed as rapidly and as gently as possible. The utmost care should be exercised in the passage of a bougie or the œsophagoscope in cases of œsophageal stricture.

Remedial.—As soon as mediastinal suppuration has been diagnosed and localised, surgical measures should be adopted. The mediastinum can be reached by resection of pieces of costal cartilage or by trephining the sternum.

CHRONIC MEDIASTITIS

This also occurs in two forms, chronic indurative mediastinitis and chronic abscess.

CHRONIC INDURATIVE MEDIASTITIS.—This may occur as a sequel of any form of acute mediastinitis. The best known is that associated with chronic adhesive pericarditis, and usually known as chronic indurative mediastino-pericarditis. This condition is dealt with in the section of diseases of the pericardium. Other forms include the chronic inflammation and thickening which occur around enlarged, sclerotic and pigmented mediastinal glands, and around the same glands when affected by caseous or calcareous tuberculous lesions.

CHRONIC MEDIASTINAL ABSCESS is generally of tuberculous origin, arising from breaking down caseous bronchial or mediastinal glands, or from tuberculous disease of the spine or ribs. A chronic abscess may, however, be caused by a foreign body, such as a bullet.

Symptoms.—Simple indurative mediastinitis may give rise to practically no symptoms or signs. Chronic abscess may cause symptoms of ill-health and of mediastinal pressure, or may only become apparent when it points superficially.

Treatment.—The treatment of chronic mediastinal abscess is practically the same as that for other "cold" abscesses due to tuberculosis, incision and drainage being avoided if possible in favour of aspiration and injection of anti-tuberculous substances. Other cases may require operation.

EMPHYSEMA OF THE MEDIASTINUM

In performing tracheotomy, the pretracheal layer of deep cervical fascia is of necessity incised. If difficulty arises in inserting the tube into the

tracheal incision, air may be drawn deep to this fascia by the vigorous attempts at respiration and thus pass into the superior mediastinum, or superficial to it into the anterior mediastinum. Rupture of the trachea, bronchi or œsophagus, or rupture of air vesicles or pulmonary lesions where the pleura is adherent, may also cause it. In acute interstitial emphysema of the lungs, the escaped air may track along to the root and reach the mediastinum.

Symptoms.—Emphysema of the mediastinum may give rise to very indefinite indications. A few fine crackling sounds may be heard on listening over the sternum, sometimes varying with respiration or with the heart movements. The percussion note over the præcordium may be hyper-resonant, and the heart sounds may be distant and muffled. Small quantities of air escaped into the mediastinum can be rapidly absorbed and may not be of serious import.

Diagnosis.—This is often a matter of speculation, unless the air spreads upwards to the neck and causes superficial surgical emphysema.

Prognosis.—This depends entirely on that of the underlying cause, which is often of serious nature.

Treatment.—No special treatment is required, as a rule, apart from that of the primary condition, except that pain may necessitate the use of analgesic drugs at the onset.

ENLARGED MEDIASTINAL GLANDS

The mediastinal lymphatic glands are arranged in three groups. A few small ones are found in the anterior compartment, another group is situated in the posterior mediastinum. The third and most important is the tracheo-bronchial group, situated around the bifurcation of the trachea and extending along the bronchi. It is enlargement of this group that most often gives clinical manifestations.

Ætiology and Pathology.—A simple inflammatory enlargement of these glands may occur in many acute affections of the bronchi and lungs, and in certain acute specific fevers, notably influenza, pertussis and measles. A more chronic enlargement, associated with indurative changes, results from chronic respiratory diseases, such as chronic bronchitis and the pneumokonioses. In the latter case, considerable pigmentary changes may be found, from deposition of the particles derived from the dusty inspired air. In town-dwellers, these glands are often grey or black in colour from deposited carbon. Tuberculosis is the commonest cause of enlargement of the mediastinal glands, particularly of the tracheo-bronchial group, those about the right bronchus being most affected, as a rule. This is a frequent early localisation of tuberculous disease in children. The infection spreads from the lungs in the majority of cases (Ghon), but in some instances the path of infection is from the tonsils through the cervical lymphatics and glands, while in others the mode of entrance is from the intestines through the mesenteric glands. The lesions may be miliary tubercles, or small caseous nodules which calcify subsequently, or which may soften and lead to local spread or generalisation. In other cases a fibroid hyperplasia of the glands results.

In syphilis, mediastinal adenitis may occur in the secondary or tertiary

stages. In Hodgkin's disease and in lymphatic leukæmia, the mediastinal glands may share in the general adenopathy, and in the former the condition may be primary in these glands. Enlargement due to malignant disease is of great importance and receives separate consideration.

Symptoms.—These may be slight and escape notice, unless the enlargement is sufficient to produce pressure or irritation. Cough is the commonest symptom; it is usually dry, irritative, noisy and ineffective. It may occur in paroxysms, somewhat suggestive of those of whooping-cough. Dyspnœa and dysphagia occur only when the enlargement is considerable. Vomiting sometimes develops, probably reflexly from vagal stimulation. Pain behind the sternum or in the upper thoracic region posteriorly may be complained of. In children with tuberculous disease in these glands, there is often languor, anorexia, anæmia and wasting, sometimes with slight irregular fever and night sweats. Such symptoms in a child of 5 to 12 years of age are very suggestive. The signs are also variable and frequently inconclusive. In tuberculous cases, the appearance of the child, pale, delicate looking or sallow, with long eyelashes and fine hairy growth over the back, may also be suggestive. In glandular enlargement from any cause there may be dilated veins over the front or back of the chest, especially in the upper part, and a "hilum dimple" has been described as appearing in the second intercostal space beside the sternum, on holding the breath at the end of inspiration. One pupil may be larger than the other, owing to sympathetic stimulation. Small areas of dullness may be found at the back, near the upper thoracic spines, or in front close to the manubrium. Breath sounds over these areas may be bronchial or harsh. Occasionally the enlarged glands impede the air entry to a lower lobe, generally the right, in which case breath sounds are notably weakened over this area, while the percussion note may be impaired. Normally, whispering pectoriloquy ceases at the seventh cervical spine; with enlarged mediastinal glands it may be heard along the middle line or close beside it, in the upper thoracic region from the first to the fifth thoracic spines. This is known as d'Espine's sign or tracheophony. It is a valuable confirmatory sign, when other indications are present. Eustace Smith's sign is of little value. It consists in a venous hum, audible over the manubrium sterni, when the child's head is thrown back as far as possible. Occasionally pressure on the recurrent laryngeal nerve may lead to an abductor paralysis of one vocal cord. In cases of tuberculosis, syphilis, Hodgkin's disease or leukæmia, enlarged glands may be present in other parts of the body, and may thus assist in diagnosis.

Complications.—A caseous gland may ulcerate into a bronchus or into the trachea, and death has resulted from glottic impaction of a portion of the gland. Ulceration into the œsophagus has been described. Rupture into the mediastinum may lead to mediastinal abscess. Invasion of the pleura, lung or pericardium may occur, or generalisation causing widespread miliary tuberculosis.

Diagnosis.—Whenever the condition of mediastinal glandular enlargement is suspected, an X-ray examination should be made if possible. It may help to distinguish between other conditions causing mediastinal pressure, such as aneurysm, abscess and malignant growth. Unfortunately in regard to tuberculous disease, it shows best the condition of least importance, namely, the old healed calcified glands. "Soft" or "woolly" shadows are regarded

as indicative of active disease, but in doubtful cases it is wise to act upon the clinical indications.

Prognosis.—This varies with the cause, being serious in Hodgkin's disease and leukæmia. In tuberculous cases, the prognosis is as a rule good, apart from complications, provided treatment is prompt and adequate.

Treatment.—In tuberculous adenitis, the general condition should be improved by every possible means. The child should be taken from school, rest and exercise are to be carefully graduated, and a liberal diet supplied, with extra milk, cream and butter. In England, the Isle of Thanet seems especially valuable in the climatic treatment of glandular tuberculosis. Cod-liver oil, malt extracts and the syrup of the iodide or phosphate of iron are useful. In afebrile cases, tuberculin cautiously given may be of value in children of 8 years or over, but it is not necessary, as a rule. If given, the initial dose should be small, $\frac{1}{500,000}$ mgrm. B.E., and the dosage gradually increased. In glandular enlargements due to syphilis, Hodgkin's disease and leukæmia, the treatment appropriate to these diseases should be employed, and symptoms due to pressure relieved as far as possible.

MEDIASTINAL NEW-GROWTHS

The mediastinum may be the seat of either simple or malignant new-growths, the latter being much more common.

SIMPLE TUMOURS OF THE MEDIASTINUM.—A bare enumeration is sufficient for their dismissal, since they rarely give rise to symptoms, and the recorded cases have, as a rule, only been discovered in the course of a routine post-mortem examination. The chief varieties found are lipoma, chondroma, osteo-chondroma and myoma.

MALIGNANT TUMOURS OF THE MEDIASTINUM.—Although it is certain that some malignant growths arise primarily in the mediastinal tissues, while others invade the mediastinum secondarily by extension or metastasis, it is often impossible, even at autopsy, to determine whether a mediastinal growth originated in the mediastinal tissues or in one of the adjacent organs, particularly the lungs. The differentiation between primary and secondary growths is therefore less sharp than in other situations.

SARCOMA OF THE MEDIASTINUM.—Recent research has proved that the majority of mediastinal growths are sarcomatous. A primary sarcoma may arise in the lymphatic glands, connective tissue, periosteum of the sternum or vertebrae, or in the remains of the thymus gland. The commonest variety is the lympho-sarcoma, but spindle-celled and chondro-sarcomata may occur. Mediastinal sarcoma is commoner in males than females; it may occur in early life, and the majority of cases occur before the age of 40 years.

CARCINOMA OF THE MEDIASTINUM.—This is rare as a primary tumour. It occurs in older people. It may originate from the trachea, bronchi or œsophagus, in the remains of the thymus or in a retro-sternal goitre.

SECONDARY MALIGNANT GROWTHS OF THE MEDIASTINUM.—These usually result from direct extension of primary growths of the lung, bronchi, trachea, œsophagus, chest-wall or breast, but true metastases may occur from mammary growths or from more distant primary tumours. Endothelioma has been described in the mediastinum, but is probably generally secondary to endothelioma of the pleura.

Pathology.—The morbid appearances depend upon the situation of origin, the directions of growth, and the nature of the tumour. Sarcomata are generally soft, pinkish in colour and vascular, while carcinomata are paler and firmer. There may be one large mass weighing several pounds, or there may be multiple growths. When the tumour reaches a considerable size it may infiltrate, surround, compress or displace contiguous structures. This is particularly the case in the lympho-sarcomata. The trachea, œsophagus, and large vessels may be surrounded, the pericardium and heart may be extensively infiltrated, and the nerve trunks may be enclosed and compressed. Secondary deposits are common in other glands, but not infrequently the pigmented bronchial glands may be seen entirely enclosed in growth without being infiltrated.

Symptoms.—The onset is often insidious, and the condition may not be suspected until the cachexia and pressure signs develop. Malaise, weakness, shortness of breath, cough and pain are often early symptoms, which become more pronounced as the case progresses. The pressure symptoms and signs constituting the “mediastinal syndrome” comprise—

1. *Pressure on the air passages.* giving rise to dyspnoea, cough and expectoration. The dyspnoea may be inspiratory and associated with stridor, or expiratory and paroxysmal. The cough is harsh and may be “brassy”; it is often associated with mucoid, blood-stained, or even “prune juice” sputum. Bronchiectasis may result in some cases.

2. *Pressure on or infiltration of the lung,* leading to collapse and sometimes breaking down of lung tissue. If the pleura is reached or invaded, pleural effusion, often blood-stained, may result.

3. *Pressure on arteries.*—Compression of branches of the pulmonary artery may lead to local gangrene, or in other cases the growth may ulcerate into a larger vessel and cause fatal hæmorrhage. Pressure on the subclavian artery may cause inequality of the radial pulses, and according to Ekgren this may only be present when the patient is lying and not when he is standing.

4. *Pressure on veins.*—Dilated tortuous veins may be seen over the front of the chest and abdomen, or in the neck. The flow of blood in these superficial veins may be reversed, owing to the obstruction of the superior vena cava or its main radicles. The current then runs from above downwards, instead of from below upwards, as normally. There may be œdema of the chest-wall or of the face and neck from the same cause.

5. *Pressure on nerves.*—The vagus may be compressed, causing paroxysmal dyspnoea and cough. Laryngeal paralysis or spasm may result from involvement of the recurrent laryngeal nerve. Dilatation of the pupil, followed later by constriction, drooping of the upper lid and enophthalmos, occurs when the sympathetic is involved. Paralysis of the diaphragm on one side from compression of the phrenic nerve, and pain from involvement of the intercostal nerves, may be present.

6. *Pressure on the œsophagus* may lead to dysphagia of increasing degree.

In addition to the signs afforded by these various conditions, there may be glandular enlargements in the neck, the suprasternal notch, or in the axillæ. The growth may invade the chest-wall at any spot, and in rare cases it may pulsate. The pulmonary physical signs are dyspnoea, sometimes orthopnoea and cyanosis. In some instances the patient prefers to lean forward; this is said to be due to the fact that in this position the antero-posterior diameter

of the mediastinum is increased, and the tension caused by the growth is thereby lessened. There may be dullness over the sternum or over the upper thoracic spines, and over any part of the lung invaded or compressed by the growth. The breath-sounds heard over the dull area may be harsh, bronchial, tubular, weak or absent. The signs due to any secondary condition, such as bronchitis, bronchiectasis or a pleural effusion may be found in addition.

Complications.—These include the secondary conditions just mentioned. Others are due to ulceration of the growth through the chest-wall, into the trachea, bronchi, œsophagus or aorta. Pericarditis may occur if the growth invades the pericardium, and hæmopericardium may result from ulceration of a vessel.

Course.—The growth enlarges progressively and the course is often rapid, particularly in lympho-sarcoma. Fulminating cases lasting only a few weeks occur, more commonly the patients live from 6 months to 2 years from the onset, rarely more.

Diagnosis.—When signs of mediastinal pressure become apparent, new-growth should be suspected, in common with aneurysm, mediastinal abscess or cyst, enlarged mediastinal glands and pericardial effusion. The history, the general condition of the patient, the physical signs, blood examination, and the X-rays may all help in distinguishing between these conditions. The evidence afforded by the X-ray may be of the utmost value. The pulsating shadow of an aneurysm, the large area of a pericardial effusion, the indefinite edge of an infiltrating growth extending into the lung, may be shown clearly, but the appearances should always be interpreted in the light of the other clinical features, and a diagnosis should not be made on X-ray findings alone, since a growth may pulsate, or may give rise to an effusion, while a mediastinal abscess or cyst may give a sharp shadow. An œsophageal new growth can sometimes be differentiated by the œsophagoscope, but this should only be employed when aneurysm can be excluded. Diagnosis from pulmonary new growth may be almost impossible. Before the onset of pressure symptoms, growth may be suspected from the cough and emaciation, and here again the X-rays may give valuable indications. Chronic tuberculous disease should always be excluded by repeated sputum examinations. The diagnosis of mediastinal growth may sometimes be obscured by some of the complications it induces, notably pleural effusion and bronchiectasis. The rapid onset and progress of these conditions and the bloodstained character of an effusion may all suggest the possibility of a malignant cause. The presence of enlarged glands in the neck or axilla, or of nodular growth in the chest-wall or episternal notch, may afford almost conclusive evidence of malignancy.

Prognosis.—This is practically hopeless and death occurs from exhaustion, starvation, toxæmia, asphyxia or hæmorrhage.

Treatment.—The treatment is that of inoperable malignant disease elsewhere. X-ray applications, or radium treatment in some form may be tried. Otherwise treatment is symptomatic and palliative. Pain may be relieved by aspirin, pyramidon, codeine or morphine. Sleep may be induced, if there is insomnia, by chloral hydrate, omnopon or other hypnotics. If effusion is causing dyspnœa it may be tapped, but the fluid usually collects again rapidly.

CYSTS OF THE MEDIASTINUM

SIMPLE CYSTS.—These are usually small and of no clinical importance.

DERMOID CYSTS AND TERATOMATA.—These are very rare and become apparent generally in young adult life. They may enlarge, giving rise to symptoms and signs similar to those of a mediastinal tumour, or they may lead to empyema. They usually contain pultaceous material, and sometimes hairs, muscle, cartilage, bone and teeth. Such cases are almost certainly teratomatous in nature and derived from included embryos. This condition may sometimes be diagnosed during life by the expectoration of hair, teeth, bone or cartilage. The prognosis is, as a rule, serious, but some cases recover under appropriate surgical treatment.

HYDATID CYSTS.—A hydatid cyst may be primary in the mediastinum and may give rise to signs of mediastinal pressure, but the condition is extremely rare. Its presence may be shown by X-rays and its nature demonstrated by the blood reactions or by paracentesis. Such cysts have been successfully treated surgically.

Other rare mediastinal conditions are hernia of the stomach or colon through the diaphragm into the mediastinum. A retro-sternal goitre may also form a mediastinal swelling.

SECTION XV

DISEASES OF THE KIDNEYS

THE CHARACTERS OF NORMAL URINE

THE amount of urine normally secreted in 24 hours is 50 ounces or 1500 c.c. The specific gravity of the total should lie between 1015 and 1025, though individual specimens will vary considerably more, according to the amount of fluid imbibed or the quantity excreted by the skin and bowels. The reaction should be acid, due to the presence of acid sodium phosphate, NaH_2PO_4 . The total acidity should be such that about 650 c.c. of decinormal caustic soda will neutralise the daily output. This is equivalent to 82 grains of NaHCO_3 , but it requires a rather larger quantity (120 grains according to Spriggs) of bicarbonate of soda by the mouth to effect this neutralisation. The total acidity of the urine rises very considerably in acidæmia, and may be more than doubled despite large doses of alkalis. Normally, urine is more acid during fasting than during absorption of food, the acid and alkaline tides being thus produced. The alkaline tide is often explained as due to the gastric juice withdrawing hydrogen ions from the blood, but this must be balanced by the pancreatic secretion of hydroxyl ions. More probably the alkaline tide is due to the absorption of alkaline vegetable salts, as it is more marked in herbivora. On decomposition, either in the bladder or after excretion, the urine becomes alkaline, from the conversion of urea into ammonium carbonate.

The constituents of urine are partly derived from the food (exogenous) and partly from the katabolism of the tissues (endogenous). We may briefly consider the source and significance of the principal constituents.

Nitrogenous constituents.—The total nitrogen excreted each day on an ordinary mixed diet is about 18 grammes or 270 grains. Of the various nitrogenous constituents urea is by far the most abundant, its output being 33 grammes, which contains 15·4 grammes of nitrogen, or 85 per cent. of the total. As so much of the urea comes directly from the food, the amount of urea falls both absolutely and relatively in starvation; the total nitrogen drops to 5 grammes or even less, of which urea nitrogen forms about 60 per cent. On a diet rich in carbohydrates and fat, but containing hardly any nitrogen, these figures may fall still lower, as the assimilation of other food-stuffs reduces the waste of tissue nitrogen to a minimum. This is often forgotten, and in nephritis undue importance is attached to a drop in the output of urea, which is simply due to the diet prescribed being poor in nitrogen, whereas the urea excreted depends mainly on the quantity of protein ingested.

Next in importance come the purin bodies. Purins contain the group C_5N_4 , and the best known is tri-oxy-purin or uric acid $\text{C}_5\text{N}_4\text{H}_4\text{O}_3$. A small quantity of the less oxidised purins, xanthin and hypoxanthin is also excreted. Exogenous purins come mainly from meat juices, from the nuclei of cellular organs (such as liver and sweetbread), and from tea, coffee or cocoa. Only from one-tenth to one-half of the ingested purins are excreted as such, the remainder being destroyed by the liver, ultimately appearing as urea. The alkaloids of tea, coffee and cocoa give rise chiefly to xanthin and hypoxanthin, the rest to uric acid. On a diet rich in meat the daily output of purins amounts to 0.34 gramme of nitrogen, and on a purin-free diet to 0.202 gramme. This endogenous purin, which forms the larger part, comes mainly from the leucocytes and muscles. Anything increasing the leucocytes in the circulation increases the output of endogenous purins, and in leukaemia the excretion of uric acid may rise to 5 grammes a day. Unaccustomed exercise diminishes the output of uric acid, while increasing that of the less oxidised xanthin and hypoxanthin, the total purin excretion remaining the same. Uric acid is only excreted as such when the urine is highly acid: normally it appears as acid sodium urate. (See also Urinary Deposits.)

Creatinin is, according to Folin, the most constant of the nitrogenous constituents on a meat-free diet, and serves as a measure of endogenous nitrogenous metabolism. In a healthy young man on a diet consisting entirely of bread, about 0.9 gramme is excreted daily, while on a diet containing meat extracts more than 2 grammes may be passed. During muscular wasting its output is increased, while in a subject already wasted it is diminished. All this suggests that it is derived from the creatin of muscle—both of the body and of the food. It may be recognised in urine by Weyl's test; with sodium nitroprusside and caustic soda it gives a ruby-red colour, which, unlike that given by acetone, is at once destroyed by glacial acetic acid. Jaffe's test depends upon the deep orange colour, given by even dilute solutions of creatinin on the addition of a saturated solution of picric acid and some 10 per cent. solution of caustic soda: this has been utilised for the colorimetric estimation of creatinin by Folin.

Creatinin can be obtained from creatin by dilute boiling mineral acids. Creatin, which is abundantly present in muscles, is not normally present in the urine. It has been claimed that it appears in urine during starvation, but Graham and Poulton have shown that the presence of diacetic acid, which is invariable in starvation, vitiates the methods ordinarily employed to show it. It is said that its presence in the urine is of value in the diagnosis of carcinoma of the liver; but this is doubtful. It is recognised by the increase in the creatinin which follows treatment of the urine with hydrochloric acid.

Ammonia is normally excreted to the extent of about 1 gramme a day. An increase in this amount is not, as was formerly thought, a sign of incapacity on the part of the liver to form urea, but a sign of acidæmia. The body protects itself against acids in the circulation by forming ammonia from the proteins of the tissues. The increased excretion of ammonia is, therefore, a measure of the degree of acidæmia, and it is estimated by the amount of acid set free from the urine on the addition of formalin, which combines with the ammonia to form hexamine. In the acidæmia of diabetes, the output of ammonia may rise to 4 grammes a day, or even more.

* Hippuric acid is not an important nitrogenous constituent of urine, but it is of interest as being made by the kidney itself by the combination of benzoic acid with glyccoll. It is, therefore, increased by a diet of green vegetables, and is diminished when there is conspicuous degeneration of the renal tubules.

7 The pigments of urine are nitrogenous. The principal one, urochrome, to which urine normally owes its colour, though closely related to urobilin, has an independent origin from hæmoglobin. Even when all the bile escapes from the body through a biliary fistula the excretion of urochrome is unaltered. Urobilin, on the other hand, is a reduction product of bile pigment. The reduction is effected by bacterial action in the bowel, whence it is re-absorbed by the blood and excreted by the kidney. Normally it is not excreted as such, but as a colourless chromogen. The appearance of pre-formed urobilin is evidence either of increased hæmolysis, or of increased intestinal putrefaction, or of increased time for reabsorption, as in intestinal obstruction. It can be recognised with the spectroscope by the absorption band it gives in the blue, or by the green fluorescence it shows on the addition of zinc chloride and ammonia. Very little is known of uroerythrin; it is an unstable body and is readily carried down by urates, to which it imparts the characteristic pink colour. A trace of hæmatoporphyrin is also normally present in the urine; but an obvious amount is an abnormality, which will be considered later.

Non-nitrogenous constituents.—These are principally salts. Chlorides are the most abundant, averaging about 10 to 13 grammes of sodium chloride a day. During the exudative stage of pneumonia this is much reduced, and it may be also considerably diminished in nephritis. The phosphates are partly excreted as acid phosphates of sodium and potassium, partly as earthy phosphates of calcium and magnesium. The former are not precipitated on neutralisation, while the latter are. A phosphatic deposit, as stellar crystals of calcium phosphate or tables of magnesium phosphate, is no proof of a real increase in the output of phosphates, but is usually merely an indication of diminished acidity. Ammonio-magnesium phosphate, on the other hand, is evidence of ammoniacal decomposition. It forms a deposit of "coffin-lid" or "knife-rest" crystals. The amount of phosphoric acid excreted daily amounts to about 2·5 to 3·5 grammes, of which the earthy phosphates form half. Sulphates are present in the urine to the extent of 1·5 to 3 grammes of SO_3 a day. Very little sulphate is taken in the food, and most of that which is taken either as food or medicine is excreted by the bowel, so that the urinary sulphates come almost entirely from the oxidation of the sulphur in the protein molecule. About nine-tenths are excreted as sulphates of the alkalis, and the remaining one-tenth as ethereal sulphates, formed by conjugation with putrefactive products from the tyrosin and tryptophan of the protein molecule. Of these, the most striking is indican, or indoxyl-sulphate of potash. It is best detected by adding an equal quantity of strong hydrochloric acid to some urine, then a few drops of hydrogen peroxide, and shaking up the mixture with some chloroform. The indican is oxidised to indigo, which imparts a blue colour to the chloroform. It should not be found in the urine of children, but is normally present during middle or later life in those living a sedentary life, if meat be taken freely. Herter described those from whose urine it is absent as "candidates for old age." Its presence in excessive

amount is some evidence of excessive intestinal putrefaction or of intestinal stasis; but Mackenzie Wallis believed it was sometimes synthetically produced. It is important that it should be looked for when the urine is fresh, as it tends to disappear on standing. It is not, however, an accurate guide to the total amount of ethereal sulphates, which may be definitely increased even though the amount of indican is small. A rise in the proportion of the total sulphates which are excreted in ethereal combination is better evidence of intestinal intoxication than a well-marked indican reaction. The cherry-red colour sometimes given by this test is due to indol-acetic acid; its presence is usually associated with definite symptoms of intestinal intoxication. All the sulphur in the urine is not excreted as sulphates; some 6 per cent. appears as neutral sulphur, derived from the sulphocyanide of the saliva, the taurine of the bile salts and substances allied to cystin. The neutral sulphur is diminished in insanity.

Many other substances are normally present in traces in the urine, but except diastase, they are of little clinical importance. Ten to 30 units of diastase are normally present, but less will be found in some forms of impaired renal capacity and a great deal more in most pancreatic diseases. The presence of 50 units suggest a pancreatic lesion, while 100 or more make this certain. In severe pancreatitis 300 to 500 may be found.

THE ESTIMATION OF RENAL FUNCTION

It may be necessary to determine (1) the total renal capacity, or (2) the adequacy of either kidney separately. Generally speaking, the first is more the concern of the physician, and the second that of the surgeon. Estimation of the latter is of vital importance before nephrectomy is considered, lest the remaining kidney should prove inadequate to maintain life. Estimation of the former is an assistance both to diagnosis and prognosis. Some of the tests under the first heading have for their object the determination of the part of the kidney involved. These will be considered first.

A.—ESTIMATION OF CAPACITY OF BOTH KIDNEYS

1. *Examination of the blood.*—The damaged kidney will fail to excrete substances which it should, and examination of the blood may reveal their presence in undue amount. The quantity of urea in the blood throws important light on renal capacity; normally this ranges from 0.02 to 0.05 gramme per cent., but is raised in various kidney diseases. According to Widal, patients with more than 0.2 per cent. of urea in the blood cannot live more than a few months. As pointed out under *Uræmia*, a rise in the percentage of urea in the cerebro-spinal fluid above 0.1 is of ill omen, and if it rises above 0.3 the case will almost certainly be fatal. The amount of sodium chloride in the blood may be raised from the normal 0.45 to 0.5 gramme per cent. to 0.6 or higher. When there is extreme renal failure there may be an increase in the H-ion concentration, the uric acid and the indican of the blood, while the calcium content may fall from the normal 10 mgm. per cent. to 6.

2. *The urea concentration test.*—MacLean has recently introduced this

simple and helpful method. Although ordinary estimation of the percentage of urea in urine gives no information of value, the response of the kidney to a given dose of urea does. Fifteen grammes of urea dissolved in a 100 c.c. of water, and flavoured with a little tincture of orange, are given to a patient just after he has emptied his bladder. The urea in the urine passed 1 and 2 hours afterwards is estimated by the hypobromite method. If this amounts to 2 per cent. or more in the first specimen the kidney is efficient, and the second specimen need not be examined. But sometimes the diuretic action of the urea leads to dilution of the urine. This will have passed off by the end of the first hour, so the second specimen will act as a control. Some observers prefer to rely upon the specimen passed at the end of the third hour, and regard a figure below 2.5 per cent. as an unfavourable indication when operation on the urinary tract is under consideration. A moderately efficient kidney may show a concentration of 1.5 per cent., while a very bad one may excrete a urine with 1 per cent., or even less urea. This is one of the best means of estimating renal efficiency.

3. Various tests have been elaborated to try and differentiate between tubular and glomerular damage, but they have not proved very satisfactory. Schlayer has attempted to do this by studying the reaction of the kidneys to the excretion of chlorides, iodides and lactose. He claims that a healthy kidney can get rid of 5 grammes of salt by merely increasing the concentration of the urine, but that if the tubules are damaged it cannot excrete urine of the requisite concentration. A delay in the excretion of iodide is also taken to indicate tubular damage. On the other hand, lactose injected intravenously is believed to be excreted by the glomeruli. But these last two tests are not free from risk.

4. *The specific gravity test.*—This is a simplification of Schlayer's concentration test. After an ordinary breakfast, the patient drinks no fluid and eats no juicy fruit for 24 hours. The sp. gr. of all the urine passed during the second half of this period is determined. A reading of 1020 or less indicates some failure of concentration.

5. *The phenol-sulphone-phthalein (phenol-red) test.*—One c.c. of sterile salt solution containing 0.006 gramme of the drug is injected hypodermically. The urine is collected 1 hour and 10 minutes afterwards, and again an hour later. On the addition of some 25 per cent. caustic potash to the urine, it should turn pink when the drug has percolated. Normally 40 to 60 per cent. should appear in the first hour, and 60 to 85 per cent. in the first 2 hours. According to Rowntree and Fitz this is the best test to distinguish functional incapacity due to nephritis from that due to chronic passive congestion, the failure to excrete the drug being prominent in the former, and only occurring in the latter when the congestion is very severe. Some other observers have not been so favourably impressed by this test.

B.—ESTIMATION OF CAPACITY OF EACH KIDNEY

It is generally agreed that the introduction of a separator into the bladder and the collection of urine from either side is fallacious as a guide to the activity of the two kidneys. Catheterisation of each ureter under the direct view of the cystoscope is the only reliable method. Several of the tests

previously described may be adopted for this purpose, such as the injection of phenol-red. The urine should be collected for 2 to 2½ hours. It is usual to encourage secretion during examination by giving some tea or simple diuretic. Afterwards, hexamine should be given as a precautionary measure, and the patient kept in bed for 36 hours. The amount of sugar with the first test or of colouring matter with the second is compared on the two sides. Another drug frequently used for this purpose is methylene-blue; 15 minims of a 5 per cent. aqueous sterilised solution are injected into the buttock. It is first excreted as a colourless chromogen and, later, as methylene-blue itself. The chromogen turns blue when boiled with acetic acid, and should appear in the urine in from 15 to 20 minutes, after which the excretion of unaltered methylene-blue should begin. It should reach its maximum in from 4 to 5 hours, and should have disappeared in from 40 to 50 hours. Obviously, catheterisation of the ureters cannot be continued all this time, so that observation is directed towards a marked delay in the appearance of blue on one side as compared with the other. As in acute or subacute nephritis the rate of methylene-blue excretion is entirely unaffected, the utility of this test is confined to unilateral chronic disease.

Indigo-carmin may be used for a similar purpose; 0.16 gramme of the drug is dissolved in sterilised water and injected hypodermically. The urine should be coloured in about 10 minutes, first appearing green and then blue. Excretion reaches its maximum in about an hour, so that this test has advantages over the methylene-blue method. Delay in the appearance of the dye and a feeble staining of the urine may be taken as evidence of disease. For fuller details of these methods the writings of Thomson-Walker should be consulted.

Pyelography is a valuable method of detecting hydronephrosis, pyonephrosis, etc. Four to 10 c.c. of 15 per cent. solution of sodium bromide are injected very slowly through a fine needle into either ureteric catheter and an X-ray photograph taken. In this way, the bromide being opaque to the rays, a beautiful picture of the ureter and pelvis of the kidney may be obtained.

ABNORMALITIES OF THE URINARY SECRETION

POLYURIA

Polyuria may be due to—

1. Increase in the quantity of fluid imbibed.
2. Increase in the molecular concentration of the urine as in diabetes mellitus, or after saline diuretics. More water is thereby attracted into the blood stream by osmotic pressure.
3. Incapacity of the kidney to excrete a concentrated urine, as in chronic interstitial nephritis.
4. High blood-pressure, which tends to force more blood through the renal vessels.
5. Dilatation of the kidney vessels, as produced by stimulating diuretics of the caffeine group.

“Diabetes insipidus” is frequently due to disease of the pituitary gland

or of the overlying hypothalamus, or to damage in this neighbourhood by specific meningitis of the base of the brain. It is also probable that hysterical polyuria is due to a temporary effect on the pituitary through the sympathetic (Cushing). This alteration of the pituitary secretion appears to affect the renal vessels directly, since pituitrin will check diuresis, even in the denervated kidney.

ANURIA

Suppression, as opposed to retention of urine, may be due to—

1. Acute nephritis with intense congestion and nephrosis, whether the result of an infection or of drugs, such as turpentine, cantharides or carbolic acid.
2. Bilateral obstruction to the ureters.
3. Reflex causes, such as operations on the kidney or trigone of the bladder.
4. Vasomotor conditions, as collapse, shock or irritation of the vasomotor centre. Probably the anuria in diphtheria is due to the last of these (Garratt). In cholera there is not only collapse, but depletion of water by other channels.
5. Hysterical. This condition has been described by Charcot. It is, however, rare, and the element of fraud must be eliminated. Thus in one case I found urea abundantly present in the contents of the washing bowl, and this explained how the urine was disposed of.

ALBUMINURIA

Albuminuria should be more correctly termed proteinuria—since blood serum contains two proteins—albumin and globulin—and either may appear in the urine, though search is seldom made for the latter. The ordinary tests of heat coagulation, nitric acid or salicyl-sulphonic acid give positive results with either. Mackenzie Wallis recommended the following tests for globulin in the urine. If dilute acetic acid (33 per cent.) be added to a urine containing it, a white precipitate is produced without the aid of heat. This may be confirmed by filling a tall cylinder with distilled water and adding urine drop by drop from a pipette. As the drops descend in the water, white rings form when globulin is present in large amounts. The globulin can be precipitated for quantitative examination by making the urine alkaline with ammonia, and then half saturating it with ammonium sulphate.

Proteinuria may be classified thus—

(A) WITHOUT ORGANIC DISEASES OF THE KIDNEYS, as in—

1. *Functional or orthostatic proteinuria*.—This is common in males between puberty and adolescence; it is much less common in females of the same age. Dukes found it in 16 per cent. of all boys entering Rugby School. Protein appears only in the urine secreted in the upright posture, and is absent from the urine passed on first rising. There is no evidence that the amount of protein in the food influences it, though some constituent of raw eggs may excite a transient albuminuria by a toxic action on the kidneys. Severe physical exercise will excite proteinuria in most healthy young adults. Collier

found it present in every one of the Oxford crew of 1906 after rowing a course ; to such a condition the term "physiological" proteinuria may fairly be applied. When the protein appears apart from exertion, the subject is often an anæmic weedy youth with a dull heavy aspect and a tendency to fainting. The heart is irritable, and the blood-pressure unstable, and fluctuates with change of posture. There may also be a few hyaline casts, and frequently calcium oxalate crystals. In any case of proteinuria in a boy or young man the diagnosis of a kidney lesion should not be made unless casts other than hyaline are discovered, unless the tension of the pulse is definitely and permanently raised, and unless there are signs of cardiac hypertrophy. In the absence of such evidence, the urine passed on first rising should be examined. If this is free from protein, the condition is almost certainly functional. Then 15 grains of calcium lactate should be given three times a day for 3 days, after which the urine should be examined again. If this checks the proteinuria no further anxiety need be felt. Some milder forms of toxæmic kidney may simulate functional proteinuria, so that a search should be made for toxic foci, such as septic tonsils, tuberculous glands, or chronic appendix trouble, in all cases. A holiday is advisable if the patient has been doing hard mental work, as the condition is apt to appear under the strain of competitive examinations. A tepid bath, with cold sponging down the spine, and followed by vigorous towelling, is advantageous, and a general tonic such as strychnine, with iron if there is anæmia, should be prescribed. The condition soon rectifies itself when adolescence is past, and any case of proteinuria in a patient approaching thirty probably does not fall into this category.

2. *Febrile*.—Any acute specific fever may be accompanied by proteinuria due to cloudy swelling of the kidney. It should subside soon after the temperature falls to normal.

3. *Congestive*.—In failing heart there is usually proteinuria from venous congestion of the kidneys. Hyaline casts may also be found. Unlike the urine of nephritis the urine is loaded with urates. After an epileptic fit there is often a transitory proteinuria, probably due to the congested condition of the veins during the fit. For a similar reason protein is apt to be present in the urine of any unconscious person.

4. *Toxic*.—This forms an intermediate group between those with and those without organic disease of the kidney, for if the action of the toxin be prolonged a definite nephritis may be established. Thus the proteinuria of pregnancy is generally regarded as toxæmic in origin, and may clear up completely. The proteinuria sometimes seen in jaundice is also toxic in character.

(B) WITH ORGANIC DISEASES OF THE KIDNEYS.—

1. *Nephritis, acute and chronic*.

2. *Leaky kidney*, by which is meant a condition in which the kidney leaks, allowing some of the blood proteins to escape ; but is not the subject of a progressive lesion, as in nephritis. This is considered further under the diagnosis of Bright's disease.

3. *Amyloid disease of the kidneys*.

4. *Tumours and infarcts in the kidney* may cause proteinuria, but more usually simple hæmaturia.

ALBUMOSURIA

Albumose, or more correctly proteose, is the name applied to the disintegration product of protein, which on further breakdown yields peptone. Proteose is found in urine during autolysis of the tissues, such as occurs during reabsorption of a pneumonic exudate, in involution of the uterus or in acute yellow atrophy of the liver. It is not of great clinical importance. Proteose can be recognised by the fact that although it is precipitated by saturation with ammonium sulphate it is not coagulated by heat. Proteose precipitates disappear on heating and reappear on cooling. It can be separated from albumin by saturating the urine with crystals of ammonium sulphate, boiling and filtering. The precipitate on the filter paper is washed with water, when any proteose will be redissolved and carried through the filter paper. It can then be detected by the pink colour it gives on the addition of strong caustic soda and a drop of dilute solution of copper sulphate. With these reagents native proteins give a violet colour. The Bence-Jones protein, which is found in considerable amounts in the urine of sufferers from multiple myelomata, is not a true proteose though possessing similar solubilities. On treatment as above it yields a violet colour, showing that it has affinities with native proteins. It begins to be precipitated at 50° C., but on approaching boiling-point most of the precipitate is redissolved. This is probably due to the influence of certain salts in the urine, and is not a property of the isolated protein. As Bradshaw showed, it also gives a ring of coagulum on contact with strong hydrochloric acid. Its recognition is of great diagnostic value, as it is pathognomonic of multiple tumours of the bone marrow, and enables them to be detected before there is any external sign, but only pain and tenderness in the bones. At a later stage the tumours may break through the investing bone and give rise to palpable swellings. Sometimes the Bence-Jones protein is spontaneously precipitated, causing the urine to appear milky. In one such case I found considerable excess of phosphates in this milky precipitate, probably derived from the autolysis of the surrounding bone.

True peptone is exceptionally found in the urine in pneumonia and phthisis, but is of no clinical importance.

HÆMATURIA

When blood is intimately mixed with the urine it is held to be in favour of its renal origin. Bleeding from the bladder is more apt to occur into the last part of the urine voided, while urethral bleeding is said to occur chiefly into the first part. When the quantity of renal bleeding is not great, it imparts a smoky appearance to the urine, owing to the conversion of some of the hæmoglobin into methæmoglobin, which gives an absorption band in the red on spectroscopic examination. The chief causes of hæmaturia may be classified, more conveniently than scientifically, as follows:

1. *Prerenal*.—The altered condition of the blood which occurs, for instance, in scurvy, purpura hæmorrhagica and certain hæmorrhagic fevers, leads to the escape of some of the blood through the kidney without any evidence of a definite kidney lesion.

2. *Inflammations of the kidney*, due to (a) Bright's disease, both acute

and chronic. Hæmaturia is a constant feature of acute nephritis and of exacerbations of chronic nephritis. It may also occur in the course of chronic interstitial nephritis, without any acute symptoms. "Renal epistaxis" is usually an early sign of an interstitial change, which is sometimes, as shown by Hurry Fenwick, confined to a single papilla where the vessels are dilated.

(b) Tuberculosis or a *Bacillus coli* infection. The latter more usually affects only the pelvis of the kidney.

(c) Certain drugs, such as turpentine, cantharides and carbolic acid, or occasionally hexamine.

3. *Irritation of the kidney by foreign bodies*, such as

(a) New-growth.

(b) Infarcts.

(c) Crystals, such as oxalates or uric acid, and calculi.

(d) Parasites, such as Bilharzia.

Traumatic, vesical and prostatic causes are not considered here.

HÆMOGLOBINURIA

This is due to some hæmolytic agent. It may be

1. *Paroxysmal*, as in Raynaud's disease and in syphilis. In many cases the cause is obscure, but Wassermann's reaction will probably show that most of these are syphilitic. It would appear that in such persons there is always present a hæmolysin which is set free in the serum on exposure to cold, and which is absorbed by the red corpuscles. On return to warmth this hæmolysin is activated by a complement present in normal serum and leads to destruction of red corpuscles (Donath and Landsteiner). Thus, if the patient's finger with a string tied firmly round it be immersed in ice-cold water for a few minutes, some of the red corpuscles will be found to have hæmolyzed.

2. *Continuous*, or, rather, for as long as the hæmolytic agent is at work. The real distinction is that in this second group the agent can produce the hæmoglobinuria without an additional factor. Sometimes the agent is a drug like potassium chlorate or arseniuretted hydrogen, sometimes it is an organism like the malarial parasite, and sometimes it is an unidentified toxin, such as is developed by extensive burns. In this connection it may be observed that potassium chlorate appears to be less frequently the cause than formerly (perhaps because it is given in smaller doses or is prepared in a purer state), and that some observers believe black-water fever, a variety of malaria in which hæmoglobinuria is a leading symptom, is due to the large doses of quinine. The chemical tests for hæmoglobinuria are the same as for hæmaturia, but the microscope will fail to reveal red corpuscles. Some of the pigment may be excreted as methæmoglobin, especially after drugs of the aniline group, nitrites, or potassium chlorate.

HÆMATOPORPHYRINURIA

Sometimes the hæmoglobin molecule is broken down in the blood stream and the pigmentary portion is excreted apart from the protein and iron. This is usually due to poisoning by sulphonal or trional, particularly when

the drug has been taken regularly for a long time. It is then of grave prognosis; large doses of alkalis should be given. It is commoner in females than in males. Occasionally hæmatoporphyrinuria occurs apart from these drugs, when it is not of grave import. It has been met with in cirrhosis of the liver, gastric ulcer and as a congenital abnormality of metabolism, when it may be associated with hydrops æstivale. Exceptionally toxic symptoms occur even when it is not associated with sulphonal or trional, as in two cases recorded by Ranking and Pardington, and by one of us. In these, some intestinal toxin with a reducing action appeared to be at work. Hæmatoporphyrin sometimes imparts a port-wine colour to the urine, but sometimes it is excreted in combination with a metal. In the latter case the urine is brown, from the admixture of some unknown pigment, and the spectroscope shows two bands closely resembling those of oxyhæmoglobin. On the addition of an acid, however, the characteristic bands of acid hæmatoporphyrin appear.

CHOLURIA

Another derivative of hæmoglobin, bile pigment, appears in all forms of jaundice due to obstruction of the main or intrahepatic ducts. In a true hæmolytic jaundice, such as acholuric family jaundice, as the name implies, bile does not appear in the urine. Bile pigment can often be recognised by noting the tinging of the froth caused by shaking the urine, but is best detected by the addition of a drop of fuming nitric acid to filter paper dipped in the urine, when rings of colour appear, green being the essential one. The green colour given on addition of a solution of iodine to the urine is a less delicate test. Bile-salts are often absent from the urine when bile pigment is present. Matthew Hay's test is the only reliable one for their presence there. On putting flowers of sulphur on the surface of the urine, they sink to the bottom, owing to the lowering of surface tension by the bile-salts.

MELANURIA

Melanin only appears in the urine in melanotic sarcoma. Garrod has shown that in all other diseases in which melanuria has been recorded the test employed has been unsatisfactory. The melanin is excreted as melanogen which darkens on standing, and gives a black precipitate on addition of ferric chloride, which is soluble in excess of the reagent, yielding a black solution. A more delicate test is made by the addition of sodium nitroprusside and sufficient caustic soda to render the urine alkaline. The ordinary ruby-red colour, due to creatinin, is developed. The urine is now made acid with acetic acid, and if melanin is present a prussian-blue colour appears.

ALKAPTONURIA

This is not the manifestation of a disease, but is rather of the nature of an alternative course of metabolism, harmless and usually congenital and lifelong (Garrod). The individual is incapable of completely breaking down the tyrosin in the protein molecule, so that the intermediate product, homo-

gentisic acid, appears in the urine. The urine reduces Fehling solution on boiling, but it does not ferment, and it darkens on standing, or at once on the addition of alkalis. It may stain the linen brown. When a dilute solution of ferric chloride is allowed to fall drop by drop into the urine, each drop produces a transitory deep blue colour. The urine reduces ammoniacal silver nitrate in the cold, giving a silver mirror on the sides of the test tube. Ochronosis—a blackening of the cartilages and ligaments, and sometimes of the conjunctivæ—may occur, and usually there is also a chronic arthritis, which may lead to a curious “goose-gait.”

[For other reducing substances in the urine, including sugar, see article on Diabetes.]

KETONURIA

Ketonuria is a term used loosely to include the appearance in the urine of diacetic acid and its derivatives, acetone and β -oxybutyric acid. The former is merely a decomposition product of diacetic acid, and, being only present in traces in the urine, is unimportant. The latter, formerly regarded as the source of diacetic acid, is a more saturated and less toxic fatty acid, which has been shown by Hurlley to be formed out of diacetic acid by the liver, as an attempt at detoxication. Diacetic acid is derived from the incomplete oxidation of fats or of the fatty acid groups in protein. It is probably always made in small quantities, but when there is an abundant consumption of carbohydrate, it is completely oxidised. One molecule of carbohydrate must be metabolised for every two molecules of fat if oxidation of the latter is to be complete. In starvation the store of glycogen is quickly exhausted and the body chiefly lives on its fats; hence acetonuria. Persistent vomiting, advanced carcinoma of the digestive tract and rectal “feeding” also are equivalent to starvation and will excite ketonuria, though without such a degree of acidæmia as to cause toxic symptoms. In conditions where the liver is thrown out of gear, such as post-anæsthetic poisoning, ketonuria may occur with toxic symptoms, because of the severe disturbance of all metabolic processes. But there are other agents at work besides diacetic acid which may be responsible for those symptoms. Only in advanced diabetes do we find toxic symptoms directly due to diacetic acid. Here there may be complete inability to utilise carbohydrates, so that the body, perforce, lives on protein and fats. If these are freely given in the food the amount of diacetic acid produced may be very large. But if a diabetic be fasted there is a great drop in ketonuria, showing that most of this is exogenous in origin (see Diabetes). The test formerly used for diacetic acid was the mahogany red colour given on the addition of ferric chloride. This has the disadvantage of being masked if the patient is taking any salicyl body. The nitro-prusside test was formerly regarded as showing the presence of acetone, but Hurlley has demonstrated that it is really a much more sensitive test than ferric chloride for diacetic acid. A crystal of nitroprusside of soda is dissolved in the urine, and then a strong solution of ammonia is poured on the top. A ring, the colour of Condyl's fluid, speedily develops at the junction of the liquids and spreads upwards. The intensity of colour is a rough measure of the degree of ketonuria. The reaction is made still more sensitive by previous addition of crystals of ammonium sulphate to saturation.

DRUGS WHICH ALTER THE COLOUR OF URINE

Methylene-blue is used as a colouring matter of sweets and also as an ingredient of certain proprietary pills. It is also given sometimes for gonorrhœa and bilharzia, or less commonly as an analgesic in rheumatism, sciatica and migraine. In small quantities it imparts a green colour to the urine, when it may be precipitated with the mucin. In larger doses it turns the urine blue. It can be recognised by its presence in suspension, so that it can be removed by simple filtration. It can be dissolved from the filter paper by chloroform, and is turned pink by the addition of alkalis. Eosin may be used in sweets and turns the urine a fluorescent pink. Pyramidon may give rise to a reddish orange colour in the urine. Rhubarb and senna may turn the urine ~~reddish~~ brown from the chrysophanic acid they contain. The urine turns pink on the addition of an alkali. Santonin turns the urine a vivid yellow, which becomes rose pink with alkalis. Carbohc acid may turn the urine greenish-black on standing, from the formation of hydroquinone. In one case of carbohc acid poisoning under my care the urine withdrawn by a catheter was olive-green without exposure to the air. Other drugs which may have this effect are salol, creosote, naphthalene and uva ursi. In chronic carbouluria, ochronosis may occur as in alkaptonuria.

Certain drugs can readily be recognised in the urine by some colour reaction. Thus, salicylates are excreted as salicyluric acid, which gives a violet colour on the addition of ferric chloride. Copaiba, which is precipitated by nitric acid, can be distinguished from albumin by the solubility of the precipitate in alcohol. On the addition of hydrochloric acid a urine containing copaiba turns cloudy, the cloud soon becoming rose pink. Iodides in urine give a blue colour with guaiacum, and on the addition of hydrochloric acid impart a violet colour to chloroform shaken up with the urine.

PYURIA

Pus may come from the urethra, prostate, bladder or kidney. The diagnosis of the source is discussed under septic diseases of the kidney. The best test for pus in the urine is the microscope. If the amount of pus be considerable it will yield a ropy mass on the addition of liquor potassæ. If ozonic ether be shaken with the urine, bubbles of oxygen are evolved. With tincture of guaiacum a blue colour may be given even without the addition of ozonic ether.

CHYLURIA

True chyluria is due to blocking of the thoracic duct by the *Filaria sanguinis hominis*, with consequent rupture of lymphatics of the bladder through back pressure. Fat may be found in the urine in the lipæmia of diabetes, in growths of the kidney, and after fracture of long bones, when fat may be liberated into the circulation. Accidental contamination by an oily lubricant for a catheter and fraudulent addition of milk to the urine must be excluded. Pseudo-chyluria is due to a lecithin compound of globulin, and is sometimes found in non-nephritic proteinuria. Unlike true fat, this substance is not extracted by shaking up with ether.

PNEUMATURIA

Osler gives the following causes for gas in the urine: (1) Mechanical introduction of air in vesical irrigation or cystoscopic examination in the knee elbow position. (2) Infection of the urine as by the *Bacillus aerogenes capsulatus*. (3) Vesico-enteric fistula.

CRYSTALLINE DEPOSITS IN URINE

These may be:

1. *Uric acid*, which is characterised by multiplicity of forms and the yellow colour due to the urinary pigment they absorb. The chief varieties found are derived from the barrel and the whetstone types. Thus with a small whetstone stuck at either end of a barrel we get the lemon-shaped crystal. If the whetstones at the end of the barrel are larger, we obtain the "bicycle-handle" crystal. A very characteristic form is that derived from two whetstones with their broader ends apposed. The rosette crystal is a group of whetstones joined by their bases. The factors in the excretion of uric acid are considered under renal calculi; the chief factors in the deposit of uric acid crystals as such are, according to Sir Wm. Roberts, high acidity, high percentage of uric acid, poverty in mineral salts, and low pigmentation. The first two are the most important, especially the first. Poverty in salts or pigments is not considered important to-day. Deposits of urates are usually amorphous, but ammonium biurate may crystallise out as spheres with projecting spines.

2. *Oxalate of lime* is found in the urine, usually as small regular tetrahedra, which under the microscope appear as "envelope" crystals. They may arise from (a) ingested oxalates. Rhubarb, spinach, strawberries, and sorrel are the only things likely to produce oxaluria sufficient to excite symptoms, though many other articles of diet contain some oxalates. (b) In achlorhydria, from gastric fermentation of the carbohydrates. (c) In chronic pancreatitis, according to Mayo Robson and Cammidge. Here there is more usually hyperchlorhydria, and the fermentation of the carbohydrates must be intestinal. (d) In crises in neurasthenics, with irritability, lassitude and neuralgic pains, without discoverable cause.

Oxaluria may cause smarting on micturition and may excite both albuminuria and hæmaturia. Its importance as a starting-point for renal calculi is considered later.

3. *Phosphates*. See Characters of Normal Urine (p. 1177).

4. *Cystin* is an amino-acid containing sulphur, and is contained in many proteins, being especially abundant in hair. Its presence in more than minute traces in the urine appears to be due to an inborn error of metabolism, affecting only the endogenous protein, since it is not increased by the administration of cystin by the mouth (Garrod). It is deposited as hexagonal plates, and is often accompanied by a variable amount of diamines, such as putrescin and cadaverin, pointing again to an incomplete breakdown of the tissue proteins. If the urine becomes infected, these cystin crystals may aggregate to form a calculus.

5. *Tyrosin* rarely appears in the urine as sheaves of fine glistening crystals. It is then generally accompanied by *Leucin*, which does not appear until the urine is concentrated by evaporation, when it forms spheres with

concentric rings. The presence of these substances is sometimes regarded as pathognomonic of acute yellow atrophy of the liver, but they are occasionally seen in other severe disintegrations of the liver, such as cirrhosis.

ORGANISED DEPOSITS

of red blood corpuscles, pus, epithelium, casts and spermatozoa do not call for detailed description here. The first two have already been referred to. For Epithelium and Casts see sections on Inflammatory Diseases of the Kidney.

W. LANGDON BROWN.
GEOFFREY EVANS.

CIRCULATORY DISTURBANCES

1. *Active congestion.*—There is no distinction to be drawn between active congestion of the kidney and the early stage of acute nephritis.

2. *Passive congestion.*—Anything which raises the pressure in the renal vein must produce a passive congestion of the kidney. Failing compensation in valvular disease of the heart is the commonest cause of this; but it may also be brought about by respiratory diseases or by pressure on the renal vein by abdominal tumours or ascites. A transient congestion may result from an epileptic fit.

The cardiac kidney, as it is called, is the most typical example of passive congestion. The organ is firm and dark in colour, especially the pyramids. The capsule strips normally. The stellate veins are engorged. The kidney may drip with blood, and if placed in a dish after section soon exudes oedematous fluid.

The urine is scanty, high-coloured and of high specific gravity. Unlike the urine of chronic nephritis it is loaded with urates. It contains a variable amount of albumin and hyaline casts, with a few red blood corpuscles, if the congestion is at all considerable. With increasing grades of congestion, glomerular secretion is first impaired, as shown by the lactose test, and then tubular secretion, as shown by delay in excreting chlorides and iodides. But renal inadequacy never reaches the high grade seen in true nephritis, nor is death from uræmia likely. The prognosis and treatment are those of the cardiac condition causing it. Stimulating diuretics are of much more service than in nephritis, since there is no primary disease of the secreting structures.

3. *Infarction.*—This, which is a common complication of infective endocarditis, may take two forms—(a) Multiple small hæmorrhagic infarcts, producing the “flea-bitten” kidney, which may lead to foci of embolic nephritis with fibrinous exudate and much leucocytic infiltration. (b) Larger anæmic infarcts, “map-like” areas of coagulation necrosis, roughly wedge-shaped, but with irregular edges and with the base reaching the surface of the organ. Their formation may cause a sudden pain in the loins, if they are large. Either of these conditions will cause both albuminuria and hæmaturia.

4. *Thrombosis of the renal vein.*—This is rare, and is usually significant of a terminal infection, as in a marasmic infant. In thrombosis of the

inferior vena cava the process may reach as high as and spread into the renal vein. This would produce the same effects as the cardiac kidney, but in a much more intense form.

NEPHRITIS

Bright described an acute inflammation of the kidney accompanied by dropsy and albuminuria, and a chronic form in which dropsy is absent. There has been much controversy as to what should be included in the category of "Bright's disease." Some forms of nephritis are degenerative rather than inflammatory in origin, and these are included under the description of toxæmic kidney. It may be said that all nephritis tends to be diffuse in its distribution, though the different elements in the kidney may be involved in very varying degree. Thus the occasional occurrence of an *acute interstitial nephritis* is described in the earlier stages of scarlet fever and other infections, especially syphilis; it is characterised by much infiltration with plasma cells and lymphocytes in the boundary zone of the pyramids, around the glomeruli and beneath the capsule. But here, too, there may sometimes be degenerative changes in the tubular epithelium and glomeruli. Again, in the changes induced by corrosive sublimate poisoning the tubules alone may be involved. Diphtheria toxin, cantharides and phosphorus may have a similar effect. The toxæmia of pregnancy may affect the kidney in the same way. Williamson says of this: "The histological picture is essentially that of a necrosis, as though a virulent toxin in the process of its excretion had killed the cells of the convoluted tubules, affected to a less extent those of the loop of Henle, and spared altogether the glomerular epithelium." Similar changes may occur in acute yellow atrophy of the liver.

Febrile albuminuria is a mild degree of the same thing. If the poisoning is recovered from, a complete regeneration of the tubular epithelium may take place, and the recovery of function be complete. This tubular degeneration can be distinguished from the typical glomerulo-tubular inflammation during life by certain features described under Toxæmic Kidney. But it is difficult to draw a hard-and-fast line between these different forms, as they shade off into one another. Clearly, whether the actual infecting agent reaches the kidney, or only its toxic products, must often depend upon the severity of the infection. The classification which in our opinion harmonises, as far as possible, the pathological, anatomical and clinical phenomena is as follows:

I. DEGENERATIVE GROUP. *Toxæmic kidney.*

II. INFLAMMATORY GROUP:

(A) *Glomerulo-tubular*.—1. Acute nephritis. 2. Subacute or reparative stage, commonly called chronic parenchymatous nephritis or large white kidney. 3. Chronic or sclerotic, commonly called secondarily contracted kidney or small white kidney.

(B) *Embolic focal nephritis* set up by infective endocarditis.

(C) *Chronic interstitial nephritis*, commonly called granular kidney or small red kidney.

III. VASCULAR GROUP:

(A) *Hyperpietic kidney.*(B) *Senile or atheromatous kidney.*

TOXÆMIC KIDNEY

Definition.—Certain toxic substances may excite degenerative rather than inflammatory lesions in the kidneys, which are nevertheless capable of complete recovery. To such conditions the name of toxæmic kidney has been given.

Ætiology.—The commonest cause is bacterial toxæmia. As fever in itself does not necessarily cause albuminuria, all the so-called “febrile albuminurias” should be referred to this group. Thus the acute specific fevers—pneumonia, typhoid fever, diphtheria, small-pox, tonsillitis and scarlet fever (notwithstanding the fact that the two last often cause a true nephritis)—are common causes of the slighter degrees of toxæmic kidney. More potent are exogenous and endogenous poisons. Mercurial salts, arsenic and cantharides are important causes clinically, while uranium and bichromate salts are frequently used in the experimental production of the condition. Jaundice and diabetes mellitus are not uncommon causes, but the outstanding example of the endogenous group is the toxæmia of pregnancy.

Pathology.—The post-mortem appearances are not distinctive. When œdema is present it may be diffuse, as in nephritis, or limited to the lower extremities. There is no cardiac hypertrophy or gross arterial disease. Hæmorrhages are rare. The organs are pale and swollen. The kidneys are pale and increased in size and weight; the parenchyma tends to bulge through the capsule when the latter is incised. The capsule is not thickened; it strips readily and leaves a smooth polished pale surface, on which engorged stellate veins may be seen. The cut surface of the cortex is pale, in contrast to the congested pyramids; it is increased in thickness and its structure is blurred. On microscopical examination, the parenchyma shows degenerative changes, particularly affecting the convoluted tubules. There is cloudy swelling, vacuolation and desquamation of the secreting cells, there may be fatty degeneration, and in more severe cases focal or diffuse necrosis. These changes result from the action of the poison on the parenchyma in the process of its excretion. Apart from the presence of some swelling of the glomerular tufts and the presence of an albuminous exudate in the intercapsular space, the glomeruli show little damage. The loops of Henle and the collecting tubes are also relatively little affected. The venules are congested and there may be thrombosis with extravasation of blood; unless the degenerative process has gone on to necrosis the arteries and arterioles show little significant change. There is œdema of the interstitial tissue, but there is no small cell infiltration except as a secondary reaction to necrosis. The absence of tissue reaction that is undoubtedly inflammatory and the presence of tissue changes that are certainly degenerative are the distinctive features of the histological picture. Similar changes are to be found in other organs of the body, and especially in the liver, which may show various degrees of damage, namely, cloudy swelling, fatty degeneration and focal or diffuse necrosis.

Symptoms.—When due to bacterial toxæmia the condition does not give

rise to symptoms. It is recognised by the presence of a trace or cloud of albumin in the urine on boiling, and by the presence, in the centrifugalised deposit, of granular, hyaline and epithelial casts. In addition, there may be a few white blood corpuscles; when red blood corpuscles are present, or when there is frank hæmaturia, the differential diagnosis from an acute nephritis cannot be made with certainty. In the severer types with insidious onset, as in mercurial poisoning or in the kidney of pregnancy, the first symptom is often malaise, disturbance of digestion and constipation, accompanied by albuminuria and oliguria. Headache is a prominent symptom, and is often persistent. Œdema is commonly present and may be the initial sign; it is either a general œdema of the renal type, or it appears first in the lower extremities, as in cardiac œdema. Eye symptoms are important; there may be dimness of vision and flashes of light before the eyes, or rarely sudden blindness. On examination of the fundus oculi the disc may appear normal, or there may be œdema of the disc or partial detachment of the retina. The vessels are normal and hæmorrhages are rare. These symptoms may be followed by fits, as in ordinary uræmia, but sometimes the fits occur without previous warning. In general, the symptoms of a fully developed case are clinically indistinguishable from those occurring in the uræmia of true nephritis. The urine contains up to 3 or even 4 per cent. protein. Hyaline, granular and epithelial casts may be present, and may be very numerous; white blood corpuscles may be present, though few in number. In severe cases, the urine contains blood-cell casts, the result of capillary thrombosis and extravasation of blood.

NEPHROSIS.—This term has been used in various ways. We propose to limit it to those cases which, like toxæmic kidney in general, present merely degenerative tubular lesions without inflammatory reaction. The condition is characterised by marked œdema, cholesterolemia and massive albuminuria. On the other hand, there is an absence of cardio-vascular changes, hæmaturia or cylindruria. The urea of the blood remains normal, as does the globulin of the plasma, while its albumin content falls as the disease progresses. Nephrosis is probably part of a general toxæmia, for when experimentally produced, the first protein to appear in the urine may be hepatic in origin. At the necropsy, a large amount of cholesterol may be found in the kidney tubules—the so-called “myelin” kidney.

Diagnosis.—The diagnosis depends on the recognition of the signs and symptoms of kidney disease in a patient affected by one of the known causes of toxæmic kidney, and on certain biochemical tests by which a true nephritis can be reasonably excluded. In milder cases, the possibility of the symptoms being due to heart failure must be excluded. Complete recovery is in favour of the diagnosis of toxæmic kidney. Exacerbation of a chronic nephritis can be recognised by a history of previous nephritis and the presence of definite cardiac hypertrophy and arterial changes. The difficulties are sometimes considerable, however, since a marked rise of blood-pressure may occur in a toxæmic kidney, while advanced degrees of chronic nephritis may occur without cardiac hypertrophy, increased blood-pressure or clinical evidence of arterial disease. The blood urea is normal or only slightly increased in the toxæmic kidney; whereas in chronic nephritis the blood urea tends to rise, and may reach 300 mgm. or even more. In the toxæmia of pregnancy, the appearance of albuminuria in the early months of pregnancy is in favour

of the condition being one of chronic nephritis, whereas the albuminuria due to toxæmia generally makes its first appearance in the later months.

Prognosis.—The importance of recognising the toxæmic kidney is that both the immediate and ultimate outlook are better than in nephritis of apparently equal severity. The prognosis in the single case depends on the nature of the cause, the degree of its severity, and the possibility of its early and complete removal. Recovery, when it occurs, is complete, but in the severe cases and in some cases of nephrosis, chronic nephritis may supervene and there is doubt as to recovery.

Treatment.—If not already in bed on account of the condition responsible for the toxæmic kidney, the patient should be immediately confined to bed. Treatment is directed towards eliminating the toxins and resting the kidneys. Barley water and milk and soda should be given. A free evacuation of the bowels must be secured daily by the use of magnesium sulphate, or by the use of jalap in severe cases. An alkaline diuretic, such as potassium citrate, should be given in $\frac{1}{2}$ drachm doses 4-hourly, to which may be added sufficient sodium bicarbonate to render the urine neutral to litmus paper, for it has been shown that there is an increased acidity of the blood in these cases. The diet should be limited in quantity. At the same time, since there is little or no retention of urea in the blood, it is unnecessary strictly to limit the intake of protein. Indeed, in nephrosis the Epstein diet described under chronic parenchymatous nephritis has been advocated. Soups, meat extracts and condiments are to be withheld. The action of the skin should be stimulated with hot packs or hot baths. The above outline of treatment is for the severer cases; for the febrile albuminurias special treatment for the renal condition is not required.

ACUTE NEPHRITIS

The classical form of acute nephritis is hæmatogenous in origin and essentially glomerulo-tubular in distribution. Such a definition would exclude an ascending infection of the tubules from the pelvis of the kidney, such as occurs in pyelonephritis. It would also exclude the embolic nephritis of infective endocarditis, where inflammatory foci are set up in the kidney as the result of septic emboli reaching it from the heart. These produce marked fibrinous exudation and infiltration with leucocytes; but only some capillaries in some of the glomeruli are affected.

Ætiology. Acute nephritis was formerly not a common disease. Herringham found, at St. Bartholomew's Hospital, where the average number of medical cases is 7000 a year, that there were, in a period of 9 years, only 166 cases, 120 being in males. On the other hand, a large number of cases occurred in the epidemic of acute nephritis in the Great War, 1500 being recorded in Flanders alone during 1915. Since the Great War it would appear to have become more frequent.

The causes usually given for acute nephritis are as follows:

1. **ACUTE SPECIFIC FEVERS.**—Scarlatina is undoubtedly the commonest specific fever to produce it. Goodall found nephritis in 8·4 per cent. of all cases of scarlatina.

Nephritis is an occasional complication of typhus, small-pox, chicken-

pox and mumps. Syphilis, malaria and yellow fever may also cause it. It will be noted that, in most of these, the infecting agent is an animal parasite or of unknown nature. In some of the latter, evidence is accumulating that an ultra-microscopic, filter-passing organism may be responsible, and that filter-passing organisms can produce acute nephritis. Thus acute nephritis occurred in the 1918 epidemic of influenza, and opinion tends to the view that a filter-passer, and not Pfeiffer's bacillus, was responsible for this outbreak.

Many cases of nephritis are preceded by tonsillitis, or otitis media, and it is probable that the throat is often the door of entry for the infection.

2. DISEASES OF THE RESPIRATORY TRACT.—It may also occur as a complication of other acute infections of the respiratory tract. The commonest bacterial agent is the streptococcus.

3. DISEASES OF THE SKIN.—The frequency with which acute nephritis may follow burns or extensive skin diseases is interesting, in view of the physiological connection between the kidney and the skin. Thus, it is a not infrequent complication of erysipelas, impetigo, boils, pemphigus and dermatitis. It must be remembered, also, that children who have been burnt are very liable to develop true scarlatina as well as a mere septic rash, and that streptococcal infection may be the responsible agent.

4. DISEASES OF OTHER SYSTEMS.—Acute nephritis may also be a complication of acute infections of other systems. Purpura, which is probably toxic in origin, may be accompanied by a true nephritis.

5. EPIDEMIC TYPE.—In the American Civil War and in the Great War acute nephritis occurred as a primary disease in an epidemic form, characterised by dyspnoea at the onset, and in general by a benign course. In the fatal cases, inflammatory and thrombotic lesions were found in the lungs and spleen.

It is a very common idea that cold or chill is a cause of acute nephritis. The statistics of the army epidemic go far to disprove this. For, during the first winter, when there was much wet weather, and the men were much exposed, cases were few and far between, and not until the weather was better did the disease assume epidemic proportions. On the other hand, a patient who has nephritis is more susceptible to cold, which may provoke an exacerbation. Where exposure seems to be responsible for acute nephritis, examination will generally reveal some definite evidence of an old-standing lesion of the kidneys. Conformably with that, after the first winter of the war, there was an agreement between the incidence of nephritis in the army and low temperature.

Pathology.—The kidney is swollen, with punctiform hæmorrhages over a pale, reddish-grey surface. The cortex is increased and, on section, the kidney drips with blood or with œdematous fluid. Microscopically, the glomeruli are swollen, becoming pear-shaped and protruding into the first part of the convoluted tubules, with Bowman's capsule tightly stretched over them. In these glomeruli the nuclei are less distinct, and the capillaries show fatty changes in their walls. Blood may be extravasated between the layers of Bowman's capsule. The convoluted tubules have their lumen blocked either by the swelling of their epithelium or by debris, casts and blood. The interstitial tissue is swollen and œdematous, with hæmorrhages here and there, and sometimes lymphocytic infiltration. The arteries of the

kidney show little alteration except that some of the afferent arteries share in the glomerular changes.

Symptoms.—The onset is usually acute, though occasionally it may be rather insidious. In the latter instance the patient may complain of biliousness, nausea, vomiting and abdominal pain, with headache and sometimes diarrhoea before the onset of renal symptoms. In the cases with acute onset, he may have more or less severe pain in the back, and *œdema* soon develops. It usually starts in the face; the legs and scrotum are generally involved next, and the swelling soon spreads all over the body. Occasionally the dropsy is curiously localised and fugitive. Though dyspnoea is not regarded as a common feature of acute nephritis apart from uræmia or cardiac failure, in the army epidemic it was almost invariable at the onset. As a rule, shortness of breath started at the same time as the dropsy, but did not last so long, having ceased at the end of 2 or 3 days. There is usually only slight fever, though occasionally a temperature of 102° or 103° may be reached. Some irregularity of temperature, however, is common in the first week or 10 days. The pulse may be raised in tension and the blood-pressure is generally raised. The blood is hydræmic and contains excess of chlorides. Occasionally the serum is milky, as was pointed out by Bright. The skin may be dry and itching, with occasionally a papular or erythematous eruption. Retinal hæmorrhages and *œdema* of the discs may occasionally occur.

The urine is greatly reduced in volume, and may be entirely suppressed. Eight to 12 ounces would be an ordinary figure. It is dark in colour and usually obviously contains blood. This may render the urine as dark as porter, but it may be bright red or merely smoky. Sometimes the blood forms a flocculent, reddish-brown precipitate. The urine is usually loaded with albumin, and casts will be found on microscopical examination. At first blood casts and epithelial casts will alone be found; but, at a later stage, granular and hyaline casts will appear. Fatty casts are not found in the first attack of acute nephritis. Their presence suggests a recrudescence of a chronic disease. Isolated renal cells, transitional epithelium and squamous cells from the lower urinary tract are also commonly found. Micro-organisms are not usually observed, and their presence in any number would suggest that the case is more probably one of pyelonephritis. A sudden rise in the secretion of water after a few days is usually a sign of definite improvement.

Complications may be due to three main causes.

1. *Renal failure*, i.e. uræmia may develop. Some slight uræmic symptoms are common in acute nephritis, such as headache, dizziness, nausea and vomiting. But any of the forms of uræmia described later may assert themselves. Convulsions are the most common of the severe symptoms, but are not as grave in significance as in chronic nephritis. If treated promptly, recovery may follow.

2. *Extension of the œdema*.—Water-logging of the lungs may occur, producing serious dyspnoea; but this is sometimes chiefly due to cardiac failure. In any case it is serious. A milder degree of bronchial catarrh is quite common. A rare but very dangerous complication is *œdema of the glottis*, which calls for prompt treatment.

3. *Secondary infections*.—The subjects of nephritis are always liable to secondary infection, and these are particularly apt to affect the serous mem-

branes; therefore pleurisy, pericarditis, and peritonitis are not uncommon complications. The last two are very dangerous.

Sequelæ.—If complete resolution does not occur, the patient may be left with a "leaky kidney" or else with a more serious condition of chronic nephritis. These are discussed later.

Diagnosis.—The combination of dropsy, albuminuria, hæmaturia, casts and scanty urine usually makes the diagnosis quite easy. The most difficult point is to distinguish it from an exacerbation of chronic nephritis. Definite evidence of cardiac hypertrophy and arterial changes would be in favour of the latter. The presence of granular casts at the outset, or of fatty casts at any time, is suggestive of chronic disease. An infarct in the kidney which causes a pain in the back and hæmaturia may simulate nephritis, but general dropsy is not likely to occur, nor are casts present in the early stages. Great reduction in the volume of urine is not usual. It must be remembered, however, that infarcts may start foci of nephritis. Signs of infective endocarditis would suggest infarction. In chronic interstitial nephritis there may be a smart hæmorrhage, but the abundant urine of low specific gravity and the cardio-vascular signs would lead to a correct diagnosis. The renal hæmorrhage in the early stage of new-growth of the kidney is so profuse that confusion with acute nephritis is not likely to occur. Moreover, epithelial casts would not be found, though a large blood cast from the pelvis of the kidney is a very characteristic feature. Pyelitis may give rise to some confusion, as there may be small hæmorrhages, especially at the beginning. The presence of micro-organisms in a catheter specimen and abundant blood corpuscles, with only a haze of albumin, in the absence of casts, will generally make the diagnosis clear. Moreover, general dropsy does not occur in pyelitis unless it sets up severe nephritis as a sequel.

Prognosis.—The prognosis naturally depends on the severity of the disease. It is better in those cases where there is a discoverable cause, an acute onset, and where the patient comes under treatment promptly. Recovery is usually slow, requiring two to four months, and the criterion of the cessation of the acute stage is the disappearance of red corpuscles from the urine. The patient may die from uræmia, secondary infections, or extension of the œdema to vital structures. If the urine becomes free from albumin in one month, the chances of complete recovery are good. In the army epidemic a large number of cases cleared up within a few days; of the remainder, the course was very variable. Recovery occurred in anything between 2 and 16 weeks, although some continued to pass albumin, blood and casts at the end of 6 months. The longer the duration of the acute stage, the more probably will there be permanent damage to the kidney.

Treatment.—(a) *Prophylactic.*—The best prophylactic measure is prompt and efficient treatment of any infective process liable to set up nephritis. There is evidence to show that the routine administration of alkalis in scarlet fever diminishes the incidence of acute nephritis.

(b) *Curative.*—The indications are to remove, if possible, the microbic or toxic cause at work and to ensure such physiological rest for the kidney as is practicable; to promote elimination of nitrogenous and saline waste by other channels; to treat complications as they may arise and to correct the resulting anæmia. In this way much may be done to steer the patient towards recovery, although we can do little to control the course of the

inflammatory process. The patient is naturally kept recumbent in bed. To counteract the congestive effects of gravity, it is well to move him from side to side, and occasionally to put him on to his chest. He should be clad in a flannel nightgown, and be placed between blankets to guard against chills and to encourage free action of the skin. The room should be warm and well ventilated. If suppression of urine threatens, dry cups or poultices should be applied over the loins. This measure is sometimes successfully adopted to diminish hæmaturia.

Diet.—In acute nephritis, the danger of overloading the inflamed kidney with nitrogenous substances is hardly sufficiently recognised; whilst in chronic nephritis the dietetic restrictions are apt to be too severe. The dictum that “in acute affections we concentrate our attention on the diseased organ, whilst in chronic cases we keep the general condition of the patient more in view,” applies particularly to the treatment of nephritis. Nitrogen retention is common and a source of danger, so that the free administration of milk usually recommended is open to objection, since cow’s milk contains 4 per cent. of protein, which equals 0.56 per cent. of nitrogen. It will do little harm to deprive the patient of nitrogen for a time, and von Noorden advises restriction of the diet at the outset to fruit juice, water and sugar. Where there is no nausea, toffee is allowed, which, being composed of butter and sugar, throws no work upon the kidney. It is generally appreciated by children and allays hunger. Barley water, with a little milk added, may also be given, and as the patient improves the proportion of milk may be increased. It is quite unnecessary to give anything else for a few days, and the relatives’ fear of starvation may be allayed by explaining the rationale of the treatment. The excretion of nitrogen is reduced to its lowest level by giving a diet of fats and carbohydrates, when it may fall below that of a fasting person, as was shown by Folin; but excess of fat is inadvisable for reasons given under chronic parenchymatous nephritis. It is well to avoid salt in any form as it is often badly excreted, and its retention increases œdema by raising the osmotic pressure of the tissues.

It is usual to try and flush out the kidneys, and to this end the patient is directed to drink a large quantity of water; but often the inflamed kidney is incapable of excreting water readily, so that attempts at flushing it out will fail and only increase the œdema. The total amount of fluid allowed in the day should not exceed 3 pints for an adult or $1\frac{1}{2}$ pints for a child of 12. It is true that there may be a sudden diuresis after some days; this, however, is not the result of treatment, but the first and surest sign of convalescence. It may be termed a “critical diuresis,” and, after its occurrence, the quantity of water and milk taken may be safely increased. A drink prepared by adding 1 pint of boiling water to 1 drachm of acid tartrate of potash, half a lemon, and some sugar, stirred occasionally until cold and then strained, may be allowed throughout in moderate quantities. The citric acid and the tartrate become bicarbonates in the blood and may render the urine less irritating by making it less acid; apparently it is not as easy to render urine alkaline in a severe case of acute nephritis as it is in the normal individual. Beef-tea, broth, and meat juices are all to be condemned as imposing work on the kidney with very little corresponding nutritive advantage.

Elimination by other channels.—Of these, the simplest and best method

is purgation. A drachm of pulv. jalapæ co. followed by 1 drachm each of sulphate of magnesia and sulphate of soda in as concentrated a solution as possible should be given at the outset and repeated as occasion arises. Diaphoresis is not nearly so satisfactory and may depress the heart if carried to excess. Sponging the patient well with hot water, followed by friction with warm dry towels, will do good and is usually sufficient. The warm room, the blankets, and the flannel nightgown also tend to induce perspiration. More drastic measures are seldom called for in acute nephritis unless uræmia is impending, when the hot-air bath may be a distinct service.

All stimulating diuretics, such as the caffeine group of drugs, are to be avoided. When acute symptoms have quite subsided, 2 grains of theocin sodium acetate in 1 ounce of water, twice a day, may increase the permeability of the kidney. The method is not free from risk, as it may cause a return of hæmaturia if given too soon. A simple guide is the occurrence of diuresis. Unless this occurs, the drug is doing no good and may do harm. Saline diuretics, such as potassium citrate, are safer. In so far as they produce diuresis, they do it by raising the osmotic pressure of the blood and thus drawing water from the œdematous tissues. The following prescription is mildly diaphoretic and diuretic :

Pot. cit., grs. xv.

Liq. ammon. acetatis, ʒi.

Sp. æth. nitr., ʒj xv.

Aq. camph. ad ʒi. To be taken every 6 hours.

The addition of 5 minims of tincture of digitalis is advisable if the heart's action becomes weak.

Treatment of complications.—For the treatment of renal failure, see *Uræmia*. Pleurisy, pericarditis, or peritonitis should be treated on ordinary lines. Œdema of the glottis may call for scarification of the larynx or even tracheotomy.

After-treatment.—Bed is imperative until blood has disappeared from the urine and is advisable until albuminuria has ceased altogether. This may be impossible, since acute nephritis may go on to chronic nephritis, but there is a considerable advantage in prolonging the rest as much as possible. Bread, butter, vegetables, puddings, eggs and then fish may be gradually added to the diet, according to the scale given under chronic nephritis, as the hæmaturia and albuminuria diminish, but abstention from meat is advisable for some time, and meat extracts had better be altogether avoided. If anæmia result, 15 minims of the liquor ferri acetatis should be given, with 1 drin. of liquor ammon. acetatis in camphor water three times a day. Chills should be guarded against in every possible way, and the loins may be protected by wearing a well-fitting cholera belt.

CHRONIC PARENCHYMATOUS NEPHRITIS

It is generally agreed that all chronic nephritis involving the parenchyma of the kidney is diffuse from the first, though naturally the interstitial changes take longer to manifest themselves. It is certain that when parenchymatous nephritis has existed for any length of time, there will be interstitial change as well. On the view here adopted, chronic parenchymatous nephritis or

large white kidney is the subacute stage of a glomerulo-tubular inflammation. If the patient lives long enough, the kidney will pass into the sclerotic or secondarily contracted stage, often called small white kidney. Dalton believes that this later stage is more often seen than it was, because improved treatment enables more patients to reach it.

Ætiology.—It is most frequently the sequel of acute nephritis, though the initial attack may have been so mild as to have escaped notice. The kidney of pregnancy may develop chronic parenchymatous change. Alcohol, syphilis and malaria are all credited with being able to cause it.

Pathology.—The kidney is large and swollen; the capsule strips easily, leaving a smooth white surface on which the engorged stellate veins are prominent. On section the cortex is increased and pale, while the pyramids are engorged. Microscopically, the glomeruli are large and irregular, with disorganisation of structure and thickening of the fibrous tissue of the capsule. The tubular epithelium shows swelling, fatty degeneration and desquamation. Casts of different kinds are seen in the lumen of the tubules. The interstitial tissue is diffusely increased by new fibrous tissue. The vessels do not show any alteration except for some fatty changes in or close to the glomeruli. The heart may show some hypertrophy of the left ventricle, though not nearly so much as in the later stages of secondarily contracted kidney.

Pathology of œdema in chronic parenchymatous nephritis.—Dropsy is one of the most characteristic features of the disease. Various explanations have been given of its causation. One of the earliest was that it was due to hydræmia from retention of water which the kidney could not excrete. But marked hydræmia may occur without œdema, and even total anuria need not cause dropsy. The next hypothesis was that the capillary endothelium was damaged by toxins and, therefore, became unduly permeable (Cohnheim). But it has been shown experimentally that such damage actually hinders the passage of fluid from the blood to the tissues. There is more in favour of Widal's view that defective elimination of salt by the kidney leads to accumulation of water by raising the osmotic pressure of the tissues. The chief difficulty in this view is that salt retention does not always cause œdema. McLean and Russell point out that if water is not eliminated its retention would lower salt concentration, which would lead to retention of salt until the balance was restored. It is obvious, therefore, that the same effect will be produced whether the primary defect in the kidney relates to elimination of salt or water. Yet another explanation that has been advanced is Martin Fischer's, that there is an acidæmia which increases the permeability of the tissues; but this has not been confirmed. An important advance was made when Epstein showed that a feature peculiar to nephrosis and to chronic parenchymatous nephritis was a great reduction in the protein content of the blood and exudates, almost entirely affecting the albumin, so that the amount of globulin is always increased relatively and sometimes absolutely. In chronic interstitial nephritis, on the other hand, while the residual nitrogen fluctuates considerably, there is no change in the protein composition of the serum. In chronic parenchymatous nephritis the daily drain on the protein may even amount to 10 per cent. of the total protein in the blood. This causes a fall in the osmotic pressure of the blood, giving the tissues the controlling power to absorb and retain fluid. In support of this view it may be mentioned that the œdema produced in per-

fusion experiments with normal saline or Ringer's solution is prevented by the addition to the perfusing fluid of colloids which are in osmotic equilibrium with the colloids of the lymph and tissues. A weak point in this hypothesis is its failure to explain the dropsy of acute nephritis, which comes on long before any depletion of the proteins of the blood can occur.

The tissue starvation in chronic parenchymatous nephritis is also shown by the high cholesterol content of the blood, comparable to that observed in advanced diabetes. That the blood serum in nephritis may be milky was noted by Bright, and subsequent observers have called attention to pseudo-chylous ascites in this disease. This cholesterol seems further to damage the kidney, while the abstraction of lipoids from tissue cells allows of imbibition of fluid, with consequent swelling of cells.

To sum up, salt retention and protein depletion are probably the most important causes of œdema in this disease. But at the present time the œdema is regarded mainly as a result of damage to the extra-renal tissues by the same agent that damaged the kidneys, rather than as a consequence of the failure of renal function.

Symptoms.—These may be continued from those of acute nephritis. More usually there is an interval of apparently normal health. Then the patient begins to suffer from languor and digestive disturbances, followed by the combination of anæmia and dropsy, which gives rise to a very characteristic aspect. Hence the saying "large white kidney, large white man." The dropsy may extend to the serous sacs. The urine is scanty, probably 20 ounces or less in the day; its specific gravity is high, but urates are not so abundant as in the urine of the cardiac kidney. It contains a large amount of protein, usually about 0.5 per cent., as measured by Esbach's method. Numerous tube casts will be found on sedimenting the urine, epithelial, fatty, granular and hyaline forms all being present. Red blood corpuscles may be found from time to time. Examination of the blood may show a rise in the chlorides, while, on the other hand, there need be no increase in the blood urea.

Vomiting and diarrhœa are common and troublesome. Ulceration of the colon, probably due to the vicarious elimination of toxins by the bowel, is an occasional and dangerous complication. Areas of exudate, known as "cotton-wool" patches, and œdema of the discs—constituting one form of albuminuric retinitis—may be found in severe cases. There may be dyspnœa, due to acidæmia, the result of diminished excretion of acid sodium phosphate. Secondary infections of the lung, pleura, pericardium or peritoneum may occur.

If hypertrophy of the heart and a rise of blood-pressure fail to take place, the outlook is very grave, and death from uræmia or secondary infection is likely to close the scene. If, on the other hand, the blood-pressure rises and the heart hypertrophies, while the amount of urinary secretion may increase considerably over normal, and the dropsy subsides, the stage has been reached of

SECONDARY CONTRACTED KIDNEY

Pathology.—The kidney is small and its capsule is adherent. On stripping it a coarsely granular, mottled surface is exposed. The term

small white kidney is therefore a misnomer. On section the mottled appearance is seen to extend throughout the cortex, some areas being red, the others yellow or white. Microscopically, the affected glomeruli are seen to form rather large homogeneous nodules. Other glomeruli are preserved to a greater or less extent, and regeneration of epithelium has occurred in some places, covering the remains of the capsular space. To a great extent the tubules are destroyed; those which remain are dilated and lined by a flat epithelium. The interstitial increase is chiefly round the destroyed glomeruli and tubules. The whole arterial system of the kidney usually shows hypertrophy of the media and hyperplasia of the intima.

The heart is hypertrophied, especially the left ventricle. The aorta is thickened, and ordinary atheromatous changes may occur at an unusually early age.

Symptoms.—This stage takes at least a year to develop after the onset of chronic parenchymatous nephritis. The urine is increased, probably to 80 ounces or more. The quantity of albumin is very variable, but is always more than that of chronic interstitial nephritis. Epithelial, fatty, granular and hyaline casts are present. Renal permeability to solids is lowered so that the output of water has to remain at a raised level if dropsy is to be avoided. Towards the end the secretion of urine is sure to fail, and uræmia is likely to follow. Signs of cardiac hypertrophy can be detected, and the blood-pressure is generally raised to something between 160 and 220. Albuminuric retinitis, of the form described on p. 1202, is not uncommon. Later, silver-wire arteries, retinal hæmorrhages, which are often flame-shaped, and even glistening white patches (see p. 1208) are sometimes to be noted. Infarction of the lung may occur, causing pain, dyspnoea, hæmoptysis with signs of consolidation, and perhaps a pleural friction. It results from detachment of a clot in the right auricular appendix, and, being generally due to a secondary infection, marks a definite step downwards. There may be other signs of infection, such as pericarditis or peritonitis. But in the absence of complications life may be prolonged for several years. In children contracted kidney may cause a remarkable condition of infantilism and dwarfism. Puberty does not occur at the recognised time. Bone deformities resembling rickets often develop, associated with a low calcium content of the blood.

Diagnosis.—The combination of dropsy, anæmia, albuminuria and cylindruria generally makes the diagnosis of chronic parenchymatous nephritis easy. In the dropsy with albuminuria of failing heart the oedema first occurs in the most dependent parts, while in nephritis the eyelids are first affected. In cardiac dropsy the liver will probably be enlarged and tender, and the urine will only contain hyaline casts; the permeability of the kidney for dyes is not seriously impaired. Amyloid kidney may be accompanied by cachectic dropsy; but the heart will not be hypertrophied and the blood-pressure is not raised. Moreover, a cause for amyloid disease, and the presence of amyloid disease elsewhere, are usually obvious.

If there is no oedema the diagnosis has to be made from functional albuminuria, leaky kidney and chronic interstitial nephritis. Functional albuminuria only occurs between puberty and thirty, albumin is absent from the urine secreted in the recumbent posture, casts are absent, with the possible exception of the hyaline variety, and calcium lactate may clear up the

albuminuria for a time. A "leaky" kidney is the result of some old damage, and is not an indication of a progressive disease. The albuminuria is detected accidentally, there being no symptoms. The blood-pressure may, however, be slightly raised. There are no cells in the centrifuged deposit of urine. In **chronic interstitial nephritis** the specific gravity of the urine is very low, and the albumin does not amount to more than a trace. Unless the heart is failing there will be no œdema. In extreme secondary contracted kidney the picture may approximate closely to chronic interstitial nephritis. Fatty casts are not found in the latter. The estimation of blood urea should be carried out whenever there is a question as to renal efficiency.

Prognosis.—The outlook in chronic parenchymatous nephritis is always very serious. It is essentially a progressive disease, leading to secondary contraction. Death may occur from uræmia, heart failure or secondary infections. If there is secondary contraction of the kidney, the outlook is still serious; but with care life may be prolonged for several years. Death may be brought about in the same ways as in the parenchymatous stage. Retinal changes make the prognosis more serious, and "woolly" exudate with swelling of the optic disc generally foretell death within two years. Retinal hæmorrhages and discrete white patches of degeneration in the retina are, however, of less serious significance.

Treatment.—It is essential, as a prophylactic measure, that the treatment of all cases of acute nephritis should be thorough and prolonged. Septic foci, especially in the tonsils, should be looked for and thoroughly treated, as also should any syphilitic or malarial infection. Confinement to bed is only advisable during exacerbations, when dropsy is extreme, or when uræmia is threatening. The skin should always receive attention, and patients should sleep between blankets and be careful to avoid exposure to cold and wind.

Diet.—There has been a tendency to restrict the protein intake too much, since there is no evidence that the albuminuria is influenced by the amount of protein in the food. Epstein has urged, indeed, that a high protein diet is indicated in order to raise the low protein content of the blood, while fats should be avoided to diminish lipæmia. That such a diet may markedly reduce œdema is true, but not necessarily by raising the protein content of the blood. Probably the diuretic action of the urea formed from the high protein diet is largely responsible. It is, therefore, wise to estimate the blood urea, and if it is not raised to carry out MacLean's urea concentration test (p. 1180), and only to make use of the high protein diet if this test shows at least 2 per cent. of urea. If it is below that figure we can arrive at the appropriate diet in this way. Chittenden has shown that nutrition can be maintained by a normal individual on 50 to 60 grammes of protein a day, which corresponds roughly to 1 gramme of protein per kilogram of body weight. The minimum protein allowance for a chronic nephritic should be this plus the amount of protein which he is losing in the urine, which, in a case of ordinary severity, will be about 6 grammes a day, or about the same as that contained in one egg. It may rise, however, as high as 25 grammes. Von Noorden has shown that nitrogen can be excreted in chronic nephritis satisfactorily, so long as not more than 94 grammes of protein are taken in a day. Above this amount, elimination may become irregular and un-

certain. We may say, therefore, that the theoretical minimum is 56 grammes and the practical maximum 94. There is not a wide difference between these figures, and it may be added that a pint of milk, one egg, a quarter of a pound of fish, and 2 ounces of meat contain altogether 63 grammes of protein. Allowing for the protein in bread and vegetables, it will be seen that the amount of nitrogen in this diet is sufficient, unless the urea concentration test indicates a capacity to excrete more than 2 per cent. of urea, and the blood urea is not raised, when proteins may be given freely. Naturally meat extracts and cellular organs, such as liver, kidney and sweetbread, should be avoided, because they contain a large amount of purin; that has to be excreted by the damaged kidney, which eliminates uric acid with difficulty. This is contrary to the principles of physiological rest but, equally, such restrictions of diet must be avoided as would lead to failure of appetite and consequent wasting, while incapable of diminishing the albuminuria. A much greater variety of diet than is usually allowed might be permitted; cooked eggs and dishes made from eggs may certainly be taken. Raw eggs, however, contain certain indeterminate substances which may irritate the kidney. The distinction drawn between red and white meat is fallacious. Red meat is assumed to be more injurious, presumably because it is supposed to contain more purin, whereas the reddest meat contains far less than sweetbread. Chronic nephritics should not be restricted to milk, which is too dilute a form of food for them, and may increase the dropsy. Salt should be moderately restricted, since it is often badly eliminated, and if it accumulates in the tissues will increase œdema. It can be replaced by lemon juice. In this way we can avoid increasing the miseries of an incurable disease by unnecessary restrictions. If nitrogen retention exists, as shown by estimations of blood urea, a diet poor in protein should be taken on one day in each week. Indeed, a day when the diet is restricted to fruit and sugar is often as useful in chronic nephritis as is the day of vegetable and egg diet in diabetes. But prolonged nitrogen starvation is as bad for the nephritic as for any one else, and in some cases increases the water-logging of the tissues.

Generally speaking, alcohol is inadvisable in any form, and should never be ordered to those unaccustomed to it. In those who have been taking it regularly, deprivation may interfere with appetite, in which case a little well-diluted whisky is probably as innocuous as any form of alcohol can be. But the strictest moderation must be enjoined. Tea and coffee used to be forbidden, because of the methyl-purins they contain, but in our opinion this restriction is unnecessary.

Diuretics.—It is generally considered well to flush out the kidney in chronic nephritis; but, before attempting this, we should consider what method of diuresis is to be used, how far it is desirable in an individual case, and how far it can achieve the end desired.

Diuresis can be produced (a) by *vaso-dilatation of the kidney*, as by caffeine, theobromine, theocin or diuretin. These are direct stimulants to the renal epithelium, the vascular change being secondary. (b) By *vaso-constriction elsewhere*, which raises the blood-pressure and forces more blood through the kidney. (c) *Increase in the quantity of circulating fluid.*—(1) By absorption of water from the intestines, as by giving the patient large quantities of fluid to drink. (2) By increasing the osmotic pressure of the

blood. Urea and the saline diuretics, citrates, acetates, etc., act in this way, drawing water from the tissues into the blood stream.

The first group are usually unsuitable in chronic nephritis, since it is unwise to stimulate a damaged structure. Any of this class may cause an exacerbation with hæmaturia. The same applies to juniper and scopolarium. Theocin sodium acetate in doses of 2 grains twice a day renders the kidney more permeable, and may be followed by an improvement. But, unless it is followed by a prompt diuresis, its use should be discontinued. In general, it may be said that the stimulating group should be reserved for those cases where an increased flow is required and the kidneys are not organically diseased, as in failing heart.

As to the second method of diuresis, since the blood-pressure is generally raised in chronic nephritis, it seems unnecessary to raise it further. Digitalis is the drug usually employed for this purpose; but it is now known not to raise the blood-pressure, its diuretic action being secondary to its effect on the heart. Therefore, it should be used as a diuretic when the heart is failing, as it is liable to do at some stage in the course of this disease. Even here, it may fail if the blood-pressure is already high.

A marked feature of chronic nephritis is the defective adjustment of the kidneys to varying water supply. Von Noorden found that whereas a normal individual, with an average hourly diuresis of 52 c.c., excreted 723 c.c. for 3 hours after drinking 1800 c.c. of Salvatore water, the nephritic hardly showed any response. As in acute nephritis, the drinking of large amounts of fluid may, therefore, merely increase the œdema. The reaction to drinking a pint of water may be determined; unless this definitely increases the quantity of urine it is no use persisting with attempts to flush out the kidney.

As explained under Acute Nephritis, the saline diuretics are the least open to objection; since they draw the extra water from the tissues they cannot increase and may diminish the œdema. Urea as the natural diuretic of the body is often given in doses of 45–60 grains three times a day, when there is no nitrogen retention. Some of the newer diuretics, such as ephyllin and novasurol, appear to act by liberating water from extra-renal tissues. In this way they would come under heading (c), but they do not seem suitable in chronic nephritis. One to 2 drachms of ammonium chloride is given on each of two days before giving $\frac{1}{2}$ –1 c.c. of novasurol, this treatment being repeated at intervals of 3 to 9 days.

Diaphoretics.—The arguments for and against diaphoretic measures will be found under uræmia. Diaphoretic drugs are not suitable for the routine treatment of chronic nephritis, as a moist perspiring skin renders the patient more liable to chills—always a danger in this disease. A course of hot-air baths may sometimes be helpful when there is retention of salt, which increases the œdema. If they are followed by diuresis they are doing good.

Purgation.—Free elimination by the bowel is here, as in other forms of nephritis, a prime requisite. The special liability to mercurialism renders calomel unsuitable for routine treatment.

Paracentesis.—Removal of the œdematous fluid by Southey's tubes is seldom practised now, though occasionally simple incisions are made. But the wounds are likely to suppurate, and the fluid will reaccumulate as

long as conditions remain unfavourable. Ewart prefers to drain the fluid into the legs by adopting the upright posture. In this way the fluid, which is presumably loaded with toxic substances, is removed from the vital organs.

Transfusion.—Epstein has advised transfusion of healthy blood, accompanied by removal of an equal quantity of blood from the patient, with the object of increasing the protein content while removing toxins.

Decapsulation.—This procedure was recommended by Edelbols in 1900; but in many of the recorded cases it was evidently unnecessary, and in some others unsuitable. The operation, therefore, fell into disrepute, and in spite of a recent revival has not stood the test of experience.

Climate is a valuable help. In this country, Ventnor or anywhere on the south coast from Bournemouth westward is the most suitable climate that can be obtained. Egypt generally suits such patients particularly well. Madeira or California is also quite suitable. The wind and the more violent fluctuations of temperature on the Riviera render it much less advisable.

Treatment of complications.—These are uræmia, heart failure and secondary infections, such as pericarditis, pleurisy, colitis and peritonitis. Their treatment is discussed under those headings.

In conclusion, it must be recognised that the kidney, once damaged by chronic nephritis, cannot completely recover, and the main thing is to attune the mode of life to a low key, subjecting the patient to as little strain as possible. He may have a considerable variety of food, provided that the intake of protein is regulated in the way described above, and that he takes very little purin and salt. He can be helped by saline diuretics and un-irritating preparations of iron, such as liquor ferri acetatis. He will do all the better if his medical man realises that many of the methods recommended in the treatment of this disease are impotent, where not actually harmful.

CHRONIC INTERSTITIAL NEPHRITIS

Synonym.—Granular Kidney.

In chronic interstitial nephritis there is an insidious inflammatory condition. It is impossible in the present state of knowledge to give even a general definition of this form of kidney disease, but in the description which follows, the distinction from secondary contracted kidney on the one hand, and from hyperpiesia on the other hand, will be clearly made.

Ætiology.—The disease is commoner in men than in women, and occurs more frequently as the fiftieth year is approached and passed. It is rarely found in young children. Poisons circulating in the blood are the most important cause. Such may occur in alimentary toxæmia, in which case diamines are absorbed, and in focal sepsis. Gout, lead poisoning and alcohol are accredited with special power of damaging the kidneys. Syphilis is not a cause.

Pathology.—The kidney tends to be reduced in size, and is tough. The capsule is adherent, leaving a finely granular surface on stripping. Sometimes the capsule is thickened and splits on attempting to strip it, thus giving an erroneous impression of a smooth surface. Retention cysts may be seen, both on the outside and the inside of the organ. On section the

cortex is reduced; not only is it shrunk from without inwards, making the organ smaller, but the increase of intrapelvic fat shows that it has also shrunk from within outwards. The vessels are unduly prominent. The glomeruli show signs of inflammatory reaction, and the interstitial tissue in their neighbourhood is increased and infiltrated with small cells, generally of the mononuclear type. These areas of disease are patchy, and form wedge-shaped areas, with their base on the cortico-medullary zone. The intervening areas of renal tissue show little or no change. The histological lesions in the arteriæ interlobulares and vasa afferentia, as also the patchy small cell-infiltration in the kidneys and evidence in some glomeruli of proliferation of the cells of Bowman's capsules, provide evidence of inflammatory reaction, and this is a primary event in the pathology of the disease. The distribution of the renal lesion in chronic interstitial nephritis is distinct from that in secondary contracted kidney, for in the latter the lesion is diffuse and every glomerulus is more or less altered in structure. In advanced cases of chronic interstitial nephritis, however, the extent of structural alteration extends and becomes more diffuse, so that it may be as difficult to make the differential diagnosis from secondary contracted kidney histologically as it is clinically.

On account of the toxæmia resulting in chronic inflammatory changes in the kidney, cardio-vascular hypertrophy occurs. The suprarenal glands are often enlarged, and this, like the cardio-vascular hypertrophy, is to be regarded as an expression of physiological response to persistent hypertension.

Symptoms.—The subject of chronic interstitial nephritis often fails to seek medical advice until the condition has become well advanced. The symptoms of which he complains are protean in character. Thus, he may complain of polyuria, but the passage of a larger amount of urine is often a source of pride rather than of anxiety. Nocturnal frequency of micturition may be the initial symptom. If the patient has to pass water more than once during the night there is probably polyuria. On the other hand, the symptoms of hyperpiesia, such as headaches, a sense of fullness in the head, giddiness, and tinnitus aurium, may be first apparent. Thickening, with retraction of the ear-drum, may be found. The patient may complain of migraine or neuralgia. "Dead fingers" and muscular cramps may result from the peripheral vaso-constriction. Failing vision, due to albuminuric retinitis, may lead the patient to seek advice from an ophthalmologist. The so-called "silver-wire" arteries and retinal hæmorrhages, which are often flame-shaped, are often present. Glistening white patches, probably degenerative, and œdema of the discs—constituting another form of albuminuric retinitis (see p. 1202)—are more common and are very characteristic. Sudden amaurosis is evidence of uræmia. Detachment of the retina may occur. Hæmorrhages are quite common, and epistaxis, sub-conjunctival, gastric or renal hæmorrhage, and even apoplexy may be an early event. Instead of the plethora of hyperpiesia, with a well-nourished body and high colour, there is a sallow tinge in the complexion, and loss of weight. Gastric disturbance is more often hypochlorhydria than is the dyspepsia of hyperpiesia; indeed, there may be loss of appetite and even distaste for food and nausea, indicating the presence of a definite, though low-grade, toxæmia. On closer examination, the signs of renal disease are more apparent. The urine is increased in quantity, and its specific gravity is low,

usually lying between 1008 and 1012. It generally contains a trace or cloud of albumin, though this may be lacking in the urine passed on rising. The protein constituents of the blood are not altered, but there are marked fluctuations in its non-protein or residual nitrogen, corresponding to the degree of functional deficiency of the kidneys, and in later stages of the disease non-protein nitrogen may reach the figures reached in secondary contracted kidney. Physical signs of cardio-vascular hypertrophy, described elsewhere, are often present. Oedema of the ankles only occurs when the heart begins to fail. Indications of cardiac dilatation may be met with. Cheyne-Stokes respiration may occur, especially if the heart begins to fail. "Asthma" is cardiac or uræmic in origin. Emphysema is not uncommon in chronic interstitial nephritis, for loss of elasticity is a factor in both. Consequently there may be bronchitis, and intercurrent pulmonary diseases, such as pneumonia, are more frequent and more dangerous. A furred tongue, urinous smell in the breath, anorexia and dyspepsia are common. Vomiting and diarrhoea are suggestive of chronic uræmia.

Complications.—The principal complications are due to failure of the pump, the tubing, or the filter. In other words, the heart may fail, causing venous congestion; the artery may give way, as in cerebral hæmorrhage; or the renal excretion become so inadequate as to lead to uræmia. Glycosuria is sometimes found. This may be due to alcoholic excess, a factor in the causation of the interstitial nephritis; or to the damaged kidney leaking sugar, in which case the blood sugar will be subnormal; or possibly to over-action of the suprarenals.

Diagnosis.—This rests on the combination of urinary and cardio-vascular signs. The differential diagnosis from hyperpiesia is discussed on p. 970, and that from secondary contracted kidney on p. 1204.

Prognosis.—If the condition be recognised early, there may be a satisfactory response to treatment. In so far as there is a structural change in the kidney it is permanent, but when it is not advanced it is compatible with many years of useful life if the patient takes care. The tests for renal permeability afford useful prognostic evidence. Any evidence of cardiac dilatation, or of uræmia, even of the chronic variety, makes the outlook much less satisfactory. Retinal changes are of ill omen. The prognosis is better in hyperpiesia than in chronic interstitial nephritis, and better in chronic interstitial nephritis than in secondary contracted kidney.

Treatment.—*Prophylactic and general.*—The timely discovery of a trace of albumin and casts in the urine should act as a danger signal, enabling the brake to be applied before disaster occurs. If a rise of pressure be discovered before this stage is reached the opportunities for successful treatment are all the greater. Late hours, evening meetings in stuffy rooms, especially when accompanied by heated political discussions, are to be condemned. In few conditions are both the dish of herbs and contentment more essential, and the stalled ox and strife more injurious.

Exercise in the open air, without strain, and not sufficient to affect the pulse or respiration, is a great help in the early cases. Golf seems to be the best form of exercise for those liable to these degenerative changes. Baths may be a valuable aid. A cold bath is inadvisable, but a warm one, either at night or on rising, is beneficial. The advantage of the effervescing Nauheim bath is not so certain, as it lowers blood-pressure by direct vaso-dilatation

and may be followed by faintness. Plombières douches are recommended when there is a suspicion of intestinal intoxication. They should not be given more than three times a week for 3 weeks at a time; the pressure employed should not be more than 18 inches. An annual course of balneological treatment is often helpful; regulation of life, freedom from worry and change of surroundings are of more importance than the chemical ingredients of the water. Climatic treatment should be on the same lines as in chronic diffuse nephritis. The Riviera and high altitudes are specially unsuitable.

Dietetic.—The bulk and the number of the meals should be reduced; roasted meats should be partaken of sparingly, while animal soups, gravies and internal organs should be avoided altogether. On the other hand, fruits, green vegetables, farinaceous and non-nitrogenous foods may be taken freely. The salt added at table should be stopped, and in severe cases a salt-free diet may be advisable for a time. If the pressure show a continued tendency to rise, a few days' rest in bed on a milk diet are advisable. Coffee, tea and tobacco should be limited and in some cases excluded; thus, tobacco should be forbidden if it cause cardiac pain or distress. Alcohol is usually bad, except when the heart is weak or the appetite poor, when a small quantity may be allowed with food. Moderate restriction of fluids does not diminish nitrogenous excretion and spares the heart.

Drug treatment.—The bowels should be kept freely open, to eliminate both toxins from the body and pressor diamines from the bowel. Sodium or magnesium sulphate are specially useful for this purpose, as they combine with the putrefactive substances and render them inactive. A weekly dose of calomel or mercurial pill will help; but, as in other forms of nephritis, there is a risk of mercurialism if they are given more frequently. Indiscriminate attempts to lower arterial tension by vaso-dilator drugs are to be condemned. We do not know what is the correct pressure for a particular degree of interstitial nephritis, but we do know that some elevation of pressure is necessary. Sometimes it may be necessary to lower pressure directly, just as it is compulsory to lower temperature in hyperpyrexia. In that case, those drugs should be selected which have a slow and prolonged action. The fall of pressure produced by amyl nitrite is quite transitory, while nitro-glycerine only acts for 40 minutes. Their usefulness is therefore confined to anginal attacks. Erythrol tetranitrate in half-grain doses, on the other hand, produces a fall lasting 6 hours. It may, however, occasionally produce severe headache. The action of mannitol is also prolonged. A tablet composed of sodium nitrite, gr. $\frac{1}{2}$, erythrol tetranitrate, gr. $\frac{1}{2}$, mannitol nitrite, gr. $\frac{1}{2}$, ammonium hippurate, gr. i, may be given once or twice a day for a time. But the usefulness of vaso-dilator drugs is very limited, and they may be dangerous. Thus, coronary thrombosis is more likely to occur with a falling pressure. Moreover, the inability of the kidney to excrete a concentrated urine demands a rise of pressure to enable it to excrete sufficient dilute urine for adequate elimination. Potassium iodide is more useful, because it does not act by direct vaso-dilatation, but probably aids in the elimination of the toxins concerned, just as it does in the case of mercury, lead and the syphilitic poison. One to 3 drachms of the 1 in 500 solution of collosol iodine may be given in water three times a day if there be intolerance to potassium iodide. The tinct. iodi of the French Codex in doses of 3 to 5 minims is sometimes helpful, as are small doses (gr. $\frac{1}{2}$ to 1) of thyroid extract. It is probably

in hyperpiesia mistaken for chronic interstitial nephritis that iodine is of most value. Venesection is to be looked upon rather as an aid in an emergency arising from high pressure than as a routine treatment. Patients who are nervous about themselves should not be told the reading of the manometer, and they should never be allowed to read the index themselves, as this may easily send up the pressure 10 mm.

Treatment of complications.—Dyspnoea is due to uræmia or failing heart, and should be treated by the measures appropriate to those conditions. Complete rest is indicated if the heart begin to fail, and 2 minims of tincture of strophanthus with 5 grains of potassium iodide should be given every 4 hours. Nitrites given on the plan already described may help to tide over a difficulty, and oxygen will spare the work of the right heart. Venesection may be tried. Although morphine is risky in diseases of the kidney, it may afford great relief in cardiac distress, and may be cautiously tried. Full doses of sodium bicarbonate may help if there be any acidamia. But cardiac symptoms indicate a downward step in granular kidney. Henceforward, we are on the horns of a dilemma; if the pressure be allowed to become too high, there is danger of either cerebral hæmorrhage or cardiac failure, while if it be lowered too much, the urinary excretion becomes inadequate. Epistaxis is a safety-valve and should not be checked too soon, and hæmaturia is similar in character. Digestive disturbances are due to a mild chronic uræmia, and should be treated by free purgation and limitation of the nitrogen intake. Insomnia is due to high tension, and may yield to 20 minims each of sp. æth. nitrosi, sp. æth. co. and sp. ammon. aromat., well diluted. Another remedy is 20 grains each of bromide and chloralamide. It may be occasionally necessary to resort to morphine to break the sequence of restless nights which are exhausting the patient, but, as stated in the article on uræmia, its use is not free from risk.

HYPERPIETIC KIDNEY

In this form of renal disease the vascular changes are of greater importance than the renal, and it will only be necessary to make a brief reference to it here.

Ætiology.—The ætiology is the same as that described under Arterial Hypertrophy (pp. 943, 944) and Supernormal Blood-pressure (p. 970).

Pathology.—The renal changes consist of hypertrophy of the arterioles, which, sooner or later, is followed by fatty degeneration. The latter results in an ischaemic fibrosis of the organs. Thus, the changes are largely degenerative in character, rather than inflammatory changes seen in chronic interstitial nephritis. The kidney is slightly reduced in size, and is somewhat firmer than normal. On section, the fine radial striation in the cortex is preserved, and throughout the organ the small arteries are prominent. Histologically the essential lesion is an increase in the muscular fibres of the media and the musculo-elastic layer of the intima. The hypertrophied tissue becomes fatty, and obliteration of the lumen takes place, and ultimately the renal tissue supplied by the affected arteries undergoes hyaline degeneration due to fibrosis; the fibrous connective tissue in the immediate neighbourhood is thickened, but there is no glomerulitis and little or no small-

celled infiltration, in contrast to the inflammatory reaction found in chronic interstitial nephritis. The condition is one of ischæmic fibrosis. There is cardio-vascular hypertrophy.

Symptoms and Diagnosis.—The patient is generally plethoric, with high colour, and is usually well nourished. His symptoms are described under Supernormal Blood-pressure and Arterial Hypertrophy.

Treatment. This will be found under Supernormal Blood-pressure and Arterial Hypertrophy.

SENILE OR ATHEROMATOUS KIDNEY

In this form of kidney disease also the vascular changes are of greater importance than the renal, and it will only be necessary to deal briefly with the affection.

Pathology.—The kidneys show depressed red areas, which are due to contraction of fibrous tissue along the distribution of particular interlobular arteries, and, therefore, tend to be conical in form, with their base to the surface of the organ. There is an absence of cardiac hypertrophy; the pressure in the diseased arteries falls below that necessary for glomerular excretion. The affected glomeruli accordingly shrink, and the connective tissue around them becomes condensed and thickened. The degenerate glomerulus and its capsule fuse together, and undergo fatty and granular changes. The atheromatous kidney is, therefore, generally due to atrophy following insufficient circulation, with consequent fibrosis.

Symptoms and Diagnosis.—There may be gradual failure of the physical and mental powers—described by Allbutt as “contraction of the spheres of bodily and mental activity”—rather than the more dramatic events of chronic interstitial nephritis. There is a trace of albumin in the urine. The vessel wall is thickened and tortuous. The blood-pressure is not high, and there is an absence of cardiac hypertrophy. Death by cardiac failure or intercurrent affections is the commonest ending, while cerebral hæmorrhage and even uræmia are unlikely.

URÆMIA
